Oxide- or proton-conducting materials (discussed in Sections 3 and 4) can be used as the solid electrolyte or separator in high-temperature fuel cells in a configuration similar to a concentration cell. In SOFC the two compartments contain air or O_2 and a fuel gas, H_2 and/or CO, respectively. The H_2/CO fuel on the anode side could come directly from a hydrogen storage device, or from internal reformation of natural gas (CH_4) as shown in Figure 25. The solid electrolyte is coated with a porous mixed (electron and ion) conductor as the electrodes and the cell reaction produces water as shown in Figure 25. The best component materials currently under development for SOFC are shown in Figure 26. With the YSZ electrolyte, the cathode material is $La_{1-x}Sr_xMnO_3$, the anode is Ni/YSZ cermet, and the interconnect between the individual fuel cells is a conducting oxide, $La_{1-x}Ca_xCrO_3$.

Although SOFCs are in advanced development as promising sources of energy, there are still many problems to be worked out in the materials research and development stage as discussed earlier. Moreover, the operating temperature of the SOFC with YSZ is high, because of the low ionic conductivity of this electrolyte. Lowering the operating temperature of the SOFC is desirable for several reasons; at lower operating temperature, reactions at the interface are less serious, matching of the thermal coefficients of the materials at the interface is less critical and of course the cell is economically more efficient. In addition, problems with the large-scale production of hydrogen and hydrogen-storage materials will have to be solved for a ‘hydrogen economy’ to be realized.

5.4 Lithium Batteries

Rechargeable Li-ion cells are key components of the portable computing and telecommunication equipment required by today’s information-rich, mobile society. A battery is composed of several electrochemical cells that are connected

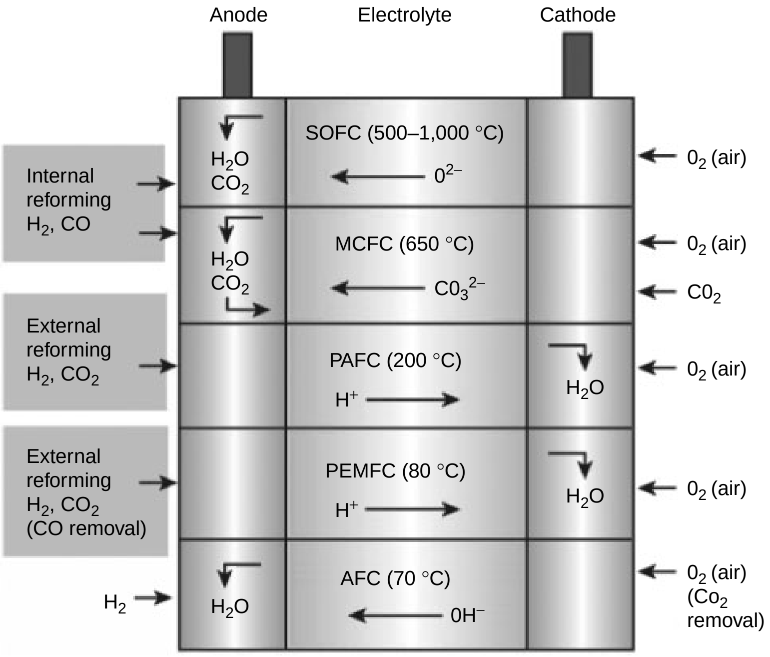

Figure 24 Summary of fuel-cell types. The oxidation reaction takes place at the anode (+) and involves the liberation of electrons (for example, $O^{2-} + H_2 = H_2O + 2e^-$ or $H_2 = 2H^+ + 2e^-$). These electrons travel around the external circuit producing electrical energy by means of the external load, and arrive at the cathode (−) to participate in the reduction reaction (for example, $1/2O_2 + 2e^- = O^{2-}$ or $1/2O_2 + 2H^+ + 2e^- = H_2O$). It should be noted that as well as producing electrical energy and the reaction products (for example, H_2O and CO_2), the fuel-cell reactions also produce heat. The reaction products are formed at the anode for SOFC, MCFC and AFC types, and at the cathode for PAFC and PEMFC types. This difference has implications for the design of the entire fuel-cell system, including pumps and heat exchangers. To maintain the composition of the electrolyte component in the MCFC system, CO_2 has to be re-circulated from the anode exhaust to the cathode input. Additionally, the composition of the polymeric-membrane electrolyte has to be carefully controlled during operation by an appropriate 'water management' technology. (Ref. 197. Reproduced by permission of Nature Publishing Group (www.nature.com))

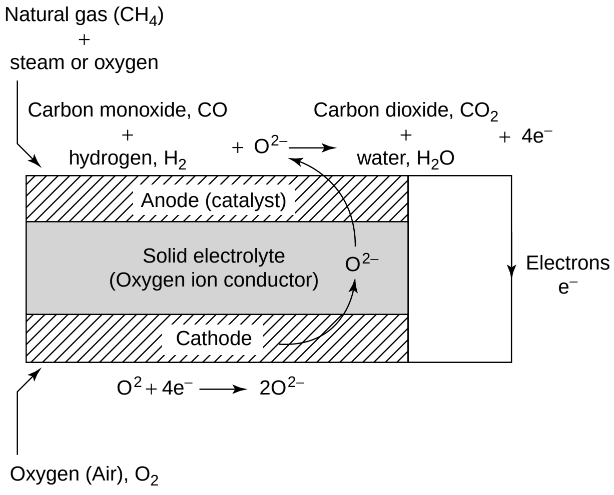

Figure 25 Schematic diagram showing the operating principles of a SOFC running on natural gas (R. Mark Ormerod 'Solid oxide fuel cells' *Chemical Society Reviews* 32: 17–28 (2003). Reprinted with permission of The Royal Society of Chemistry)

in series and/or in parallel to provide the required voltage and capacity, respectively. The amount of electrical energy, expressed either per unit of weight (W h kg^{-1}) or per unit of volume (W h l^{-1}), that a battery is able to deliver is a function of the cell potential (V) and capacity (A h kg^{-1}), both of which are linked directly to the chemistry of the system. Among the various battery technologies (Figure 27), Li-based batteries, because of their high energy density and design flexibility, currently outperform other systems.

The principle of the rechargeable Li-battery is illustrated in Figure 28(a), as it was originally conceived. The preferred anode is Li, the most electropositive (−3.04 V) versus standard hydrogen electrode as well as the lightest metal, which on discharge will donate an electron according to

$$xLi \longrightarrow xLi^+ + xe^- \qquad (13)$$

where Li^+ enters the electrolyte, and the electron exits the anode to the external circuit to power the load. The Li^+ ions move through the electrolyte; because Li is more electropositive than hydrogen, the electrolyte must be nonaqueous and aprotic. A representative nonaqueous liquid electrolyte is a solution (1:1 by volume) of ethylene or propylene carbonate with a lithium salt (at a concentration of ~1M) such as lithium hexafluorophosphate, $LiPF_6$. At

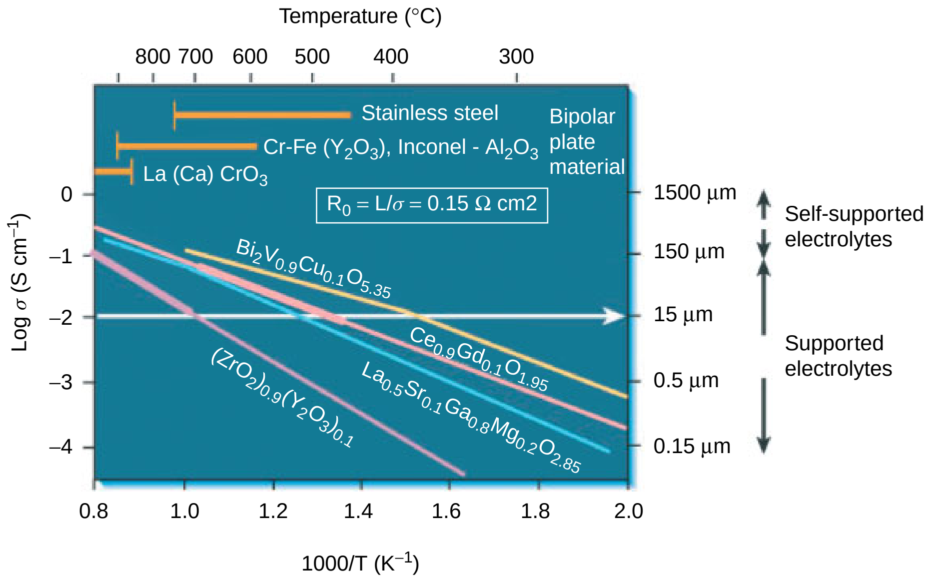

Figure 26 Specific conductivity versus reciprocal temperature for selected solid-oxide electrolytes. To ensure that the total internal resistance (that is, electrolyte + electrodes) of a fuel cell is sufficiently small, the target value for the area specific resistivity (ASR) of the electrolyte is set at 0.15 Ωcm^2. Films of oxide electrolytes can be reliably produced using cheap, conventional ceramic fabrication routes at thicknesses down to ~15 μm. It follows that the specific conductivity of the electrolyte must exceed 10^{-2} S cm^{-1}. This is achieved at 500 °C for the electrolyte $Ce_{0.9}Gd_{0.1}O_{1.95}$, and at 700 °C for the electrolyte $(ZrO_2)_{0.9}(Y_2O_3)_{0.1}$. Although the electrolyte $Bi_2V_{0.9}Cu_{0.1}O_{5.35}$ exhibits higher conductivities, it is not stable in the reducing environment imposed by the fuel in the anode compartment of a fuel cell. (Ref. 197. Reproduced by permission of Nature Publishing Group (www.nature.com))

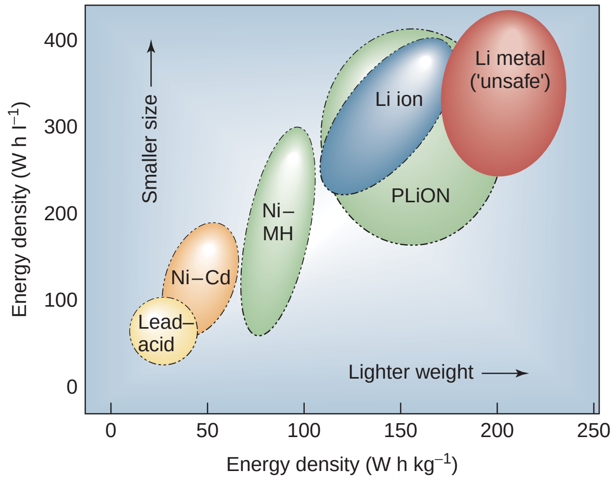

Figure 27 Comparison of the different battery technologies in terms of volumetric and gravimetric energy density. The share of worldwide sales for Ni–Cd, Ni–MeH and Li-ion portable batteries is 23, 14, and 63%, respectively. The use of Pb–acid batteries is restricted mainly in automobiles or standby applications, whereas Ni–Cd batteries remain the most suitable technologies for high-power applications (for example, power tools). (Ref. 47. Reproduced by permission of Nature Publishing Group (www.nature.com))

the cathode, Li^+ ions are inserted topotactically in the open cavities of the host lattice, which calls for compensating electrons, and the cathode also accepts electron via the external circuit and is reduced according to

$$xLi^+ + xe^- + MO_y \longrightarrow Li_xMO_y \qquad (14)$$

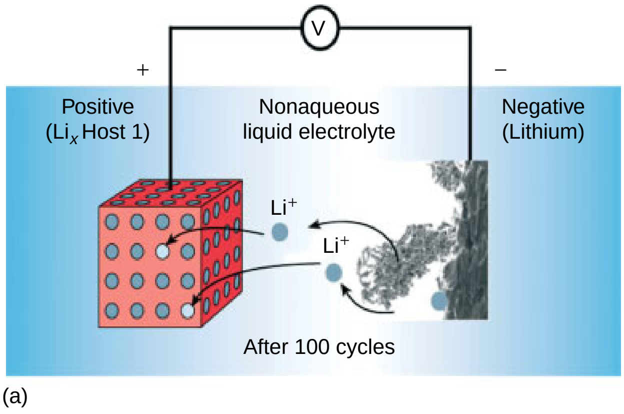
where MO_y is a transition metal oxide with either a layered structure (e.g. $LiMO_2$ M = Co, Ni) or a framework structure (e.g. V_6O_{13}, V_2O_5) as illustrated (Figure 28).

Thus the net reaction is:

$$xLi + MO_y \rightleftharpoons Li_xMO_y \qquad (15)$$

If the battery is to be rechargeable, the reaction must be reversible, and if the load is replaced by a power supply, the reaction in equation (15) is reversed, or the cathode and anode reaction go in the reverse direction. The system depicted in Figure 28(a) was not viable, because of the uneven (dendritic) growth of Li metal upon subsequent discharge-recharge cycles, which lead to explosion hazards.

To circumvent the safety issues related to use of Li metal, anodes that were also Li-insertion materials were introduced[224,225] and led by the early 1990s to the development of so-called rocking–chair technology as illustrated in Figure 27(b). This concept was exploited by Sony Inc. in their first commercialized rechargeable Li-battery with a C/$LiCoO_2$ rocking-chair cell.[226] This cell has a potential exceeding 3.6 V (three times that of alkaline systems), and an energy density of 120–150 Whkg^{-1} (two to three times those of usual Ni-Cd



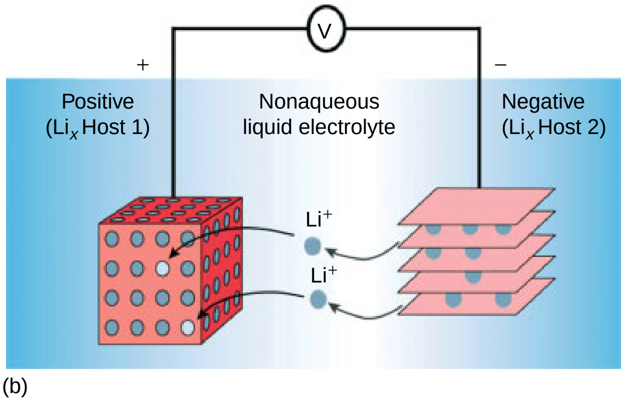


Figure 28 Schematic representation and operating principles of Li batteries. (a) Rechargeable Li-metal battery (the picture of the dendrite growth at the Li surface was obtained directly from in situ scanning electron microscopy measurements), (b) Rechargeable Li-ion battery. (Ref. 47. Reproduced by permission of Nature Publishing Group (www.nature.com))

batteries) found in most of today's high-performance portable electronic devices.

As discussed earlier, the polymer electrolytes were developed primarily to replace the liquid electrolyte by a dry polymer electrolyte in Li-batteries, leading to the so-called Li-solid polymer electrolyte battery. This technology is restricted to stationary power generation, and not portable devices, as it operates only at relatively high temperature ($\sim$80 °C). Subsequently a Li hybrid polymer electrolyte (Li-HPE) battery was developed, where the 'hybrid' electrolyte included three components: a polymer matrix swollen with liquid solvent and a Li-salt. The HPE concept never materialized, as Li-metal dendrites were still a safety issue. Bellcore researchers introduced polymeric electrolytes in a liquid Li-ion system and developed the first practical rechargeable Li-ion HPE battery, called plastic Li-ion (PLiON) in 1996,[227] which allowed the development of thin film technology in addition to usual coin-, cylindrical- and prismatic-type cell configurations (Figure 29).

The 'PliON' thin-film battery technology has been in development since 1999, and has many potential advantages including shape versatility, flexibility, lightness, and miniaturization. Currently commercial Li-ion polymer batteries use a gel-coated, microporous poly-olefin separator bonded to the electrodes (also gel-laden), rather than the P(VDF-HFP)-based membrane (i.e. copolymer of vinylidine difluoride with hexafluorpropylene) used in the plastic Li-ion cells.

Li-based battery technologies continue to be developed. The materials research aspect is particularly intense; new and better electrolyte and electrode materials are designed and investigated (see Li-ion conductors in Section 3) to minimize deleterious reactions occurring at the electrode-electrolyte interface – the critical phase of all electrochemical systems.

Very recently, new reports of inexpensive and nontoxic nanomaterials based on inexpensive and environmentally safe Fe-based compounds promise to revolutionize Li-battery technology.[228–231]

5.5 Electrochromism

A highly important application of solid state ionic materials is in electrochromic devices referred to as 'smart windows'.[232,233] Intelligent glass facades and smart windows are attracting much interest in modern architecture. These windows have the ability to modulate the incoming light and solar energy. Electrochromism[232] is a well-known phenomenon capable of providing the required variation in the optical properties, and presently some full-scale electrochromic smart windows are undergoing practical testing in buildings. An electrochromic material is characterized by its ability to sustain reversible and persistent changes of the optical properties when a voltage is applied to it. The electrochromic phenomenon was discovered in tungsten oxide, WO_3 thin films and this material remains the most promising candidate for electrochromic devices. It is convenient to introduce electrochromism in WO_3 by reference to the simple reaction

$$WO_3 + xM^+ + xe^- \longrightarrow M_xWO_3 \qquad (16)$$

with $M^+ = H^+$, Li^+, Na^+, or K^+ and e^- denoting electrons. Thus when WO_3, which is transparent as a thin film, incorporates electrons and charge-balancing ions it can be reversibly transformed to a material with radically different properties, being absorbing and blue, if the material is heavily disordered and infrared-reflecting if it is sufficiently crystalline.

An electrochromic device embodies a number of superimposed layers on a transparent substrate or between two transparent substrates, and optical transmittance is altered when an electrical potential is applied so that charge is shuttled between layers serving in the same way as anodes and cathodes in an electrical battery. One specific design with a five-layer construction shown in Figure 30 uses cathodically coloring WO_3 and anodically coloring nickel oxide joined by an ion-conducting electrolytic laminate. A potential of a few volts, preferably supplied by solar cells, is applied between

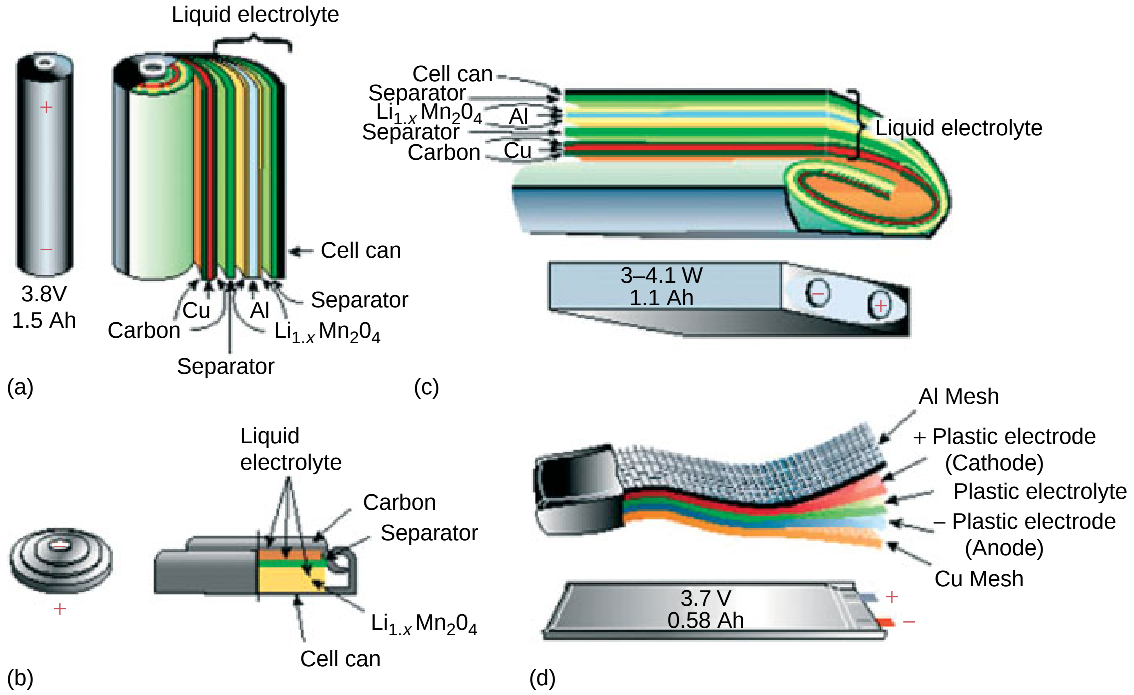

Figure 29 Schematic drawing showing the shape and components of various Li-ion battery configurations: (a) cylindrical, (b) coin, (c) prismatic, and (d) thin and flat. Note the unique flexibility of the thin and flat plastic LiION configuration; in contrast to the other configurations, the 'PLiION' technology does not contain free electrolyte. (Ref. 47. Reproduced by permission of Nature Publishing Group (www.nature.com))

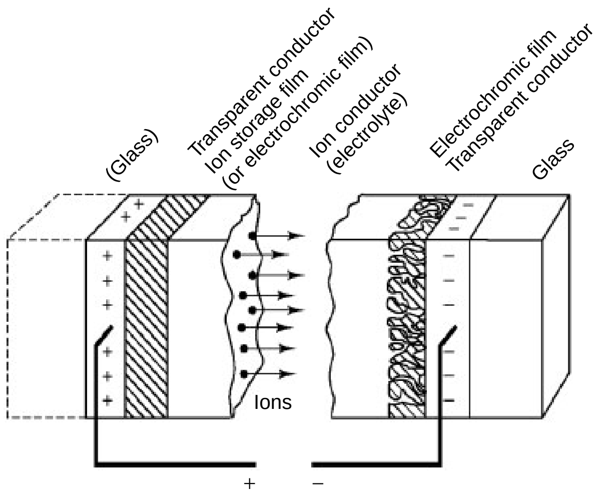

Figure 30 Schematic diagram of an electrochromic device

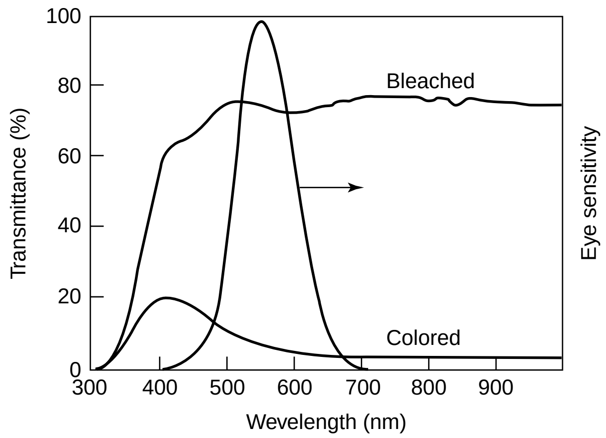

Figure 31 Spectral transmittance of an electrochromic foil in fully darkened and bleached states. Also shown is the sensitivity of the human eye. The visible transmittance is 73.5/7.1% in the bleached colored state. (Ref. 235. Reproduced by permission of Springer Verlag)

transparent and electrically conducting layers of In_2O_3:Sn (known as indium tin oxide ITO) on the glass. The spectral transmittance of this device in fully colored and bleached states is shown in Figure 31; the luminous transmittance – obtained by integration over the eye's sensitivity curve – lies between 74 and 7%. Devices of a similar type, with films of tungsten oxide and nickel oxide operating in concert, have been subject to several recent investigations.[232–241]

When a potential is applied across a smart window, the electrochemical process, indicated in equation (16), changes the window to nearly opaque (Figure 31). The process can be reversed and repeated many times. Smart windows may be used to selectively block sunlight in automobiles, airplanes, and buildings if the environmental stability of the device is made satisfactory. Smart windows may find large-scale

application as architectural glass when the cost of this technology is made economical.

The two active material films, tungsten oxide and nickel oxide (Figure 30), must survive many thousands of cycles of reactions. However, WO_3 is stable in a moderately acidic environment, and rapidly dissolves in a basic electrolyte, while NiO is stable in a basic environment, but unstable in an acidic one. Stability can be accomplished by putting a thin layer of tungsten oxide on top of the nickel oxide counterelectrode;[241] the tungsten oxide film has two different functions: it protects the underlying film in acidic electrolytes, and exhibits electrochromic properties. Figure 32 show highly schematic electron density-of-states (DOS) diagrams: the nickel oxide film may be considered a Mott insulator with a wide band gap due to the large correlation between the Ni 3d electrons.[242] In the bleached state, the Fermi energy, E_F, is expected to lie slightly above the valence band edge.[243] For tungsten oxide, E_F lies in the band gap separating a valence band dominated by O 2p states from a conduction band dominated by W 5d states.[242] When a voltage, U_{col}, is applied between the nickel oxide and tungsten oxide films – as indicated in the right-hand part of Figure 32 – their E_F are separated. Electrons enter the W 5d states, where they may cause strong polaron absorption[232,244] provided that the tungsten oxide film is heavily disordered. A corresponding charge is subtracted from the top of the valence band of the nickel oxide film, thereby rendering this material absorbing by a mechanism that appears to be nonpolaronic but is not known in detail.[245] Hence the initially transparent device turns absorbing (i.e. colored) by a combination of anodic electrochromism in nickel oxide and cathodic electrochromism in tungsten oxide. Thus, if an absorbing device combining nickel oxide and tungsten oxide is electrically shorted it turns transparent, implying that the bottom of the conduction band of tungsten oxide lies at a higher energy than the top of the valence band for nickel oxide. Figure 32 assumes rigid-band behavior for the DOS, which appears well-founded for tungsten oxide,[242] but is less established for nickel oxide. The protective tungsten oxide layer in the device is always transparent and does not contribute to device coloration at any stage, although it may impart chemically desirable surface properties to the anodically coloring electrochromic nickel oxide film.[235]

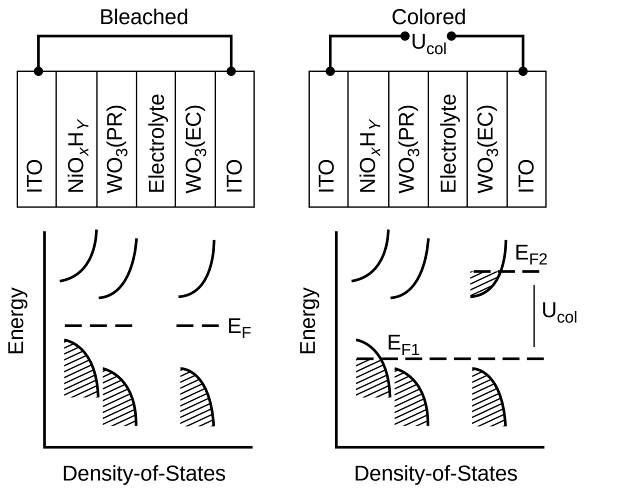

Figure 32 Schematic electron density-of-states diagrams for electrochromic, EC, multilayer design. The materials include In_2O_3:Sn (ITO), nickel oxide (presumably hydrous), tungsten oxide (also presumably hydrous) prepared so that the EC and chemically protective (PR) properties are emphasized, and an electrolyte. The Fermi energy is denoted E_F, with E_{F1} and E_{F2} pertaining to the case of an applied potential, U_{col} filled states are denoted by shadings. (Ref. 235. 1 INTRODUCTION

Iridium is a third-row d-block metal and is the heaviest element in group 9. It is a hard, lustrous, silvery metal, discovered by Tennant in 1803; the name iridium derives from the Latin *iris* (rainbow). The element occurs as a native platinum alloy and in osmiridium (a native alloy of osmium, 15–40%, and iridium, 50–80%). Selected physical and chemical properties of Ir are given in Table 1. It is considered both as a 'platinum metal' and as a precious metal. At room temperature, Ir is particularly resistant to corrosion.

In elemental analysis, the presence of Ir in a compound can be quantified by use of atomic absorption and emission spectroscopies. Both natural isotopes (*see Isotopes & Isotope Labeling*) of Ir possess nuclear spins ($I = 3/2$), but their use in NMR spectroscopy is limited by a large quadrupole moment (^{191}Ir, $Q = 1.5 \times 10^{-28}$ m^2; ^{193}Ir, $Q = 1.4 \times 10^{-28}$ m^2), low sensitivity (^{191}Ir, 0.023; ^{193}Ir, 0.050 with respect to ^{13}C), and low frequencies of observation (^{191}Ir, 6.87 Hz; ^{193}Ir, 7.48 Hz with respect to ^{1}H = 400 Hz). The ^{193}Ir nucleus is suitable for Mössbauer spectroscopy.

Iridium metal has a cubic close-packed structure at 298 K and is stable in air and water. It is inert toward acids but reacts with fused alkalis. In many respects, the chemistry of its compounds resembles that of its group 9 congener Rh (*see **Rhodium: Inorganic & Coordination Chemistry***).

Simple inorganic compounds commonly used as precursors to *Coordination Complexes* and that are commercially available include those listed in Table 2. The dark green hydrate of iridium(III) chloride is usually more reactive than the black anhydrous form.

General sources of reference are as follows: a survey of the chemistry of iridium (pre-1967);[1] compounds of the high oxidation states of Ir;[2] a detailed chemistry of elemental Ir and its alloys, solid-state compounds, and coordination complexes;[3] coordination chemistry of Ir;[4–6] organometallic complexes of Ir including complexes with inorganic ligands;[7,8] general chemistry of Rh and Ir along with that of other precious metals;[9] aspects of the chemistry of the platinum group metals;[10] structural aspects of elemental Ir and its binary compounds;[11] sources of reference for individual inorganic compounds of Ir;[12] chloro and bromo complexes of Ir(III) and Ir(IV);[13,14] halo complexes;[15] and phosphine, arsine, and stibine complexes.[16]

2 OXIDATION STATES AND GEOMETRIES

The ground-state electronic configuration of Ir is 6s^2 5d^7 (Table 1), and oxidation states (*see Oxidation Number*) in its compounds range from −I to +VI (Table 3). Of these, Ir in formal oxidation states −I, 0, and +I is stabilized by π-acceptor ligands (*see **Iridium: Organometallic Chemistry***). This article deals with compounds in which Ir is in formal oxidation state II, III, IV, V, or VI, as well as those complexes of Ir(I) that possess nonorganometallic features of significant interest. Table 3 also lists typical geometrical environments observed for iridium.

3 SOLID-STATE COMPOUNDS EXCLUDING HALIDES

The most stable oxide is the black iridium(IV) oxide, IrO_2; it forms when Ir is heated in oxygen or by controlled hydrolysis of alkaline solutions of $[IrCl_6]^{2-}$, and it crystallizes with a rutile structure. Pure crystalline IrO_2 can be prepared by slow, basic hydrolysis of $IrCl_3{\cdot}2.6H_2O$ at room temperature, followed by calcination at 900 °C.[17] Of practical importance is the fabrication of IrO_x pH electrodes, which have long-term stability; the method involves coating the surface of an Ir metal wire with iridium oxide by oxidizing the wire in a carbonate melt.[18]

High-temperature solid-state reactions[3] lead to mixed metal oxides (metal iridates) such as Na_2IrO_3 (from the reaction of Ir and Na_2CO_3 above 600 °C), $Bi_2Ir_2O_7$ (from IrO_2 and Bi_2O_3), $CaIrO_3$ (from 1:1 $IrO_2 : CaCO_3$), Ca_2IrO_4 (from 1:2 $IrO_2 : CaCO_3$), and the strontium iridates $SrIrO_3$, Sr_2IrO_4, and Sr_4IrO_6 (from $SrCO_3$ and IrO_2). Ca_2IrO_4 possesses a hexagonal structure with rutile-like chains held together by Ca^{2+} ions. In Sr_4IrO_6, each Ir atom is octahedrally sited and

Iridium(IV) oxide	IrO_2
Iridium(IV) chloride hydrate	$IrCl_4 \cdot xH_2O$
Dihydrogen hexachloroiridate(IV) hydrate (chloroiridic acid)	$H_2IrCl_6 \cdot xH_2O$

the IrO_6 units are linked by Sr^{2+} ions. The iridate $KIrO_3$ is prepared from KO_2 and Ir metal. Quaternary oxides include $Ba_6ZnIr_4O_{15}$ and $Ba_6CuIr_4O_{15}$.[19]

At atmospheric pressure, Ir combines with sulfur to yield IrS_2, which has an orthorhombic structure; it is isostructural with $IrSe_2$. If the ratio of S:Ir is raised to ≈3:1, the sulfide formed has a pyrite structure with cation vacancies balancing the charge of the Ir^{3+} ions. At 60 kbar and 1500 °C and with a ratio of S:Ir = 3:1, the product has the stoichiometry $IrS_{2.9}$; with a 2:1 ratio (60 kbar, 1500 °C), a new pyrite phase $IrS_{1.9}$ is formed. Iridium(III) sulfide, Ir_2S_3, possesses a solid-state structure in which pairs of face-sharing octahedra are joined to give an extended structure.

Iridium(VI) selenide, $IrSe_3$, and the corresponding telluride, $IrTe_3$, are made from $IrCl_3$ and Se or Te, respectively. The Ir(IV) compounds $IrSe_2$ and $IrTe_2$ can be prepared from the respective elements or by reducing the corresponding Ir(VI) selenide or telluride with H_2. In $IrSe_2$, each Ir atom is octahedrally sited; half the Se atoms are each surrounded by three Ir atoms at the corners of a distorted tetrahedron, the fourth corner being occupied by a Se atom. The selenide Ir_2Se_3 is prepared from $IrCl_3$ and H_2Se. The mixed chalcogenides IrSSe and $IrSe_{1.5}Te_{0.5}$ are ***Semiconductors***.

The phosphide IrP_2 is isomorphous with RhP_2; Ir_2P and IrP_3 adopt the *anti*-CaF_2 and skutterudite structures, respectively. Crystalline $IrAs_3$ and $IrSb_3$ also possess a skutterudite structure. Ternary phosphides and arsenides include $Ca_2Ir_{12}P_7$ and $Ca_5Ir_{19}P_{12}$.[20]

4 THE HIGHER OXIDATION STATES: IRIDIUM(V) AND IRIDIUM(VI)

The highest oxidation states for Ir are VI and V, stabilized by ligands such as F^-. IrF_6 (a yellow crystalline solid, $\mu_{eff} = 2.9\ \mu_B$ at 300 K) is formed by the direct fluorination of Ir metal. Molecules of IrF_6 are octahedral, and the structure has been studied in the gas phase by electron diffraction[21] and in the solid phase by EXAFS.[22] IrF_6 is hydrolyzed by water, and reactions (1–4) illustrate its general reactivity. Reaction four represents the formation of the first binary, tripositive metal carbonyl complex.[23]

$$IrF_6 \xrightarrow{N_2O_4} [NO]_2[IrF_6] \qquad (1)$$

Table 3 Oxidation states and geometries of iridium in its compounds^a

Oxidation state	Electronic configuration	Coordination number	Characteristic geometry	Example
−I	d^{10}	4	Tetrahedral	$[Ir(CO)_3(PPh_3)]^-$
0	d^9			Cluster compounds, e.g. $Ir_4(CO)_{12}$
I	d^8	4	Square planar	Vaska's compound = *trans*-$IrCl(CO)(PPh_3)_2$
		5	Trigonal bipyramidal	$[Ir(dppe)_2(CNMe)]^+$
II	d^7	4	Square planar	*trans*-$Ir(t\text{-}Bu_2PC_6H_4O)_2$
III	d^6	5	Trigonal bipyramidal	$IrH_3(AsPh_3)_2$
		6	Octahedral	$[IrCl_6]^{3-}$; $[Ir(CN)_6]^{3-}$
IV	d^5	6	Octahedral	$[IrCl_6]^{2-}$; $[Ir(C_2O_4)_3]^{2-}$
V	d^4	6	Octahedral	$[IrF_6]^-$
		5	Pentagonal bipyramidal	$IrH_5(PR_3)_2$
VI	d^3	6	Octahedral	IrF_6

^{a}The boundary between organometallic and inorganic coordination complexes is not a precise one; note the borderline behavior of iridium(I).

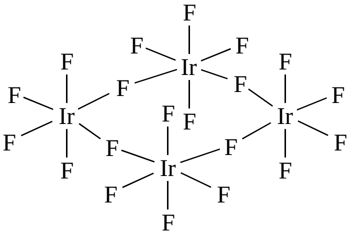
$$IrF_6 \xrightarrow{SO_3} IrF_4{\cdot}3SO_3 \text{ (Blue)} \quad (2)$$

$$IrF_6 \xrightarrow{SO_2} IrF_5{\cdot}SO_2 \text{ (Orange-brown)} \quad (3)$$

$$IrF_6 \xrightarrow{\text{CO in liquid } SbF_5} [Ir(CO)_6][Sb_2F_{11}]_3 \quad (4)$$

Few complexes of iridium(V) are known. Before 1965, literature references to 'IrF_4' actually refer to IrF_5. Reduction of IrF_6 by H_2 at 60 °C gives IrF_5; at 100 °C, further reduction leads to Ir metal. IrF_5 is a yellow crystalline solid ($\mu_{eff} = 1.32\,\mu_B$ at 296 K) with a tetrameric structure (**1**). It is moisture sensitive (equation 5). Other iridium(V) compounds include salts of the type (M)[IrF_6] ($M^+ = NO^+$, K^+, Na^+, Rb^+, Cs^+, Ag^+, XeF^+, $Xe_2F_{11}{}^+$, $ClO_2{}^+$, $Cl_4{}^+$). $KIrF_6$ and $CsIrF_6$ exhibit temperature-independent paramagnetism.

$$IrF_5 \xrightarrow{H_2O} IrO_2{\cdot}xH_2O + 5HF \quad (5)$$



(**1**)

Hydride ligands (*see* ***Hydride Complexes of the Transition Metals***) stabilize iridium(V), for example, in the pentagonal bipyramidal complex $IrH_5(PMe_3)_2$,[24] which is characterized in the IR spectrum by an absorption at 1920 cm^{-1} assigned to ν(Ir–H). The hydride complex $IrH_5(P(^iPr)_3)_2$ is an effective catalyst precursor for transfer hydrogenation reactions, including alkane dehydrogenation. The ligand $[C(Ph_2PO)_3]^-$ also stabilizes Ir(V), as observed in the complex $IrH_2\{C(Ph_2PO)_3\}(SiR_3)_2$.[25]

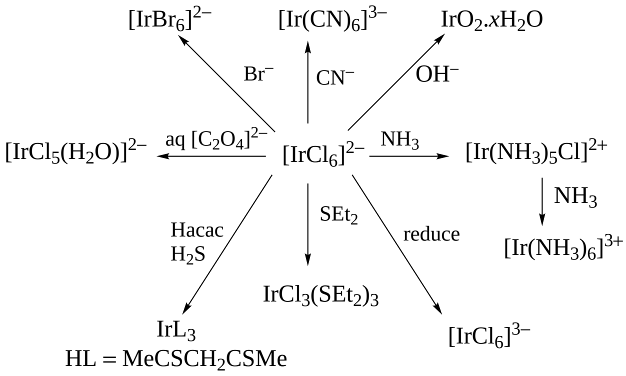
5 MONONUCLEAR COMPLEXES OF IRIDIUM(IV)

Among the halo complexes of iridium, the anions $[IrX_6]^{2-}$ (X = F, Cl, Br) containing Ir(IV) are the most stable. The white salts $M_2[IrF_6]$ ($M^+ = Na^+$, K^+, Rb^+, Cs^+, $NH_4{}^+$, NO^+) can be made by the reduction of M[IrF_6] using water; the Na^+ or $NH_4{}^+$ salts can be prepared by reacting $H_2[IrF_6]{\cdot}xH_2O$ with NaOH or NH_4OH. In neutral or acidic solutions, $[IrF_6]^{2-}$ is stable, but it decomposes in basic media. Electrochemical data for $[IrF_6]^{2-}$ in MeCN show an $[IrF_6]^{-/2-}$ process at +1.29 V and an irreversible $[IrF_6]^{2-/3-}$ process at 1.5 V(vs. SCE).[26]

Chloroiridic acid (Table 2), $H_2[IrCl_6]{\cdot}xH_2O$, is a deliquescent purple–black solid prepared by the dissolution of $K_2[IrCl_6]$ or $(NH_4)_2[IrCl_6]$ in aqua regia. Salts of $[IrCl_6]^{2-}$ can be made by chlorination of an MCl/Ir (M = alkali metal) mixture, or by reacting MCl with IrO_2 in hydrochloric acid. Oxidation of $[IrCl_6]^{3-}$ in acidic solution gives $[IrCl_6]^{2-}$ (equation 6). The ^{35}Cl and ^{37}Cl NQR frequencies and spin-lattice relaxation times in $Cs_2[IrCl_6]$ and $(NH_4)_2[IrCl_6]$ have been measured over the temperature range 4 to 350 K.[27] The ion $[IrCl_6]^{2-}$ is reduced quantitatively by KI or $Na_2C_2O_4$ to $[IrCl_6]^{3-}$, and is used as an oxidizing agent in some organic reactions. $Na_2[IrCl_6]$ is a water-soluble, black crystalline solid. It is an important precursor to a variety of coordination complexes of iridium (Scheme 1); note the predominance of iridium(III) products. Heating $(Et_4N)_2[IrCl_6]$ with CF_3CO_2H leads to the formation of $[Ir_2Cl_{10}]^{2-}$ (D_{2h}).[28]

$$4[IrCl_6]^{3-} + O_2 + 4H^+ \longrightarrow 4[IrCl_6]^{2-} + 2H_2O \quad (6)$$

A series of aquachloro complexes, $[IrCl_x(H_2O)_{6-x}]^{(x-4)-}$ is known; *cis* and *trans* isomers (for $x = 2$) and *mer* and *fac* isomers (for $x = 3$) are prepared by oxidation of the corresponding Ir(III) complexes. In alkaline solutions, red–brown $[IrCl_6]^{2-}$ salts are unstable and the ion is reduced to yellow–green $[IrCl_6]^{3-}$. In the pH range 2.5–6.5, solutions of $[IrCl_6]^{2-}$ contain hydroxy species $[IrCl_x(OH)_{6-x}]^{2-}$; equilibrium constants (*see Equilibrium Constant*) are given in Table 4.



Scheme 1

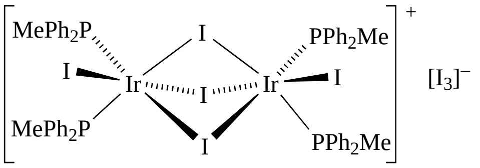
Table 4 Formation of $[IrCl_x(OH)_{6-x}]^{2-}$ and equilibrium constants at 298 K

Equilibrium	Equilibrium constant, *K*
$[IrCl_6]^{2-} + OH^- [IrCl_5(OH)]^{2-} + Cl^-$	1.2×10^7
$[IrCl_5(OH)]^{2-} + OH^- [IrCl_4(OH)_2]^{2-} + Cl^-$	2.8×10^6
$[IrCl_4(OH)_2]^{2-} + OH^- [IrCl_3(OH)_3]^{2-} + Cl^-$	1.1×10^6
$[IrCl_3(OH)_3]^{2-} + OH^- [IrCl_2(OH)_4]^{2-} + Cl^-$	1.5×10^5

In 1953, the potassium salt $K_2[IrCl_6]$ was the subject of a classic electron spin resonance experiment.[29] Results were consistent with the presence of one unpaired electron ($5d^5$ low-spin) delocalized over all the ligands. This was one of the first pieces of evidence for the existence of metal–ligand π-bonding (*see π-Bond*). Significant π-bonding is also observed between the Ir(IV) center and nitrate ligands (Ir d → NO_3 π^*) in $K_2[Ir(NO_3)_6]$. Salts of $[IrBr_6]^{2-}$ may be made from $IrO_2 \cdot xH_2O$ and HBr in the presence of a suitable cation, or by the reaction of $[IrCl_6]^{2-}$ with HBr. Reaction of $[IrCl_6]^{2-}$ with NaSCN results in reduction of Ir and formation of linkage isomers of *trans*-$[IrCl_2(SCN)_4]^{3-}$.[30] Heating $[NH_4]_2[Ir^{IV}Cl_6]$ with NH_4Cl in a sealed ampoule yields $[NH_4]_2[Ir^{III}(NH_3)Cl_5]$; changing the reaction conditions allows for isolation of $[Ir^{III}(NH_3)_5Cl]Cl_2$ and *trans*-$[Ir^{IV}(NH_3)_4Cl_2]Cl_2$.[31]

Mononuclear iridium(IV) compounds involving O-donor ligands are few. The hydroxide $Ir(OH)_4$ is formed when aqueous $K_2[IrBr_6]$ is treated with carbonate ions. Reaction of $Na_2[IrCl_6]$ with KOH at 120 °C leads to the red salt $K_2[Ir(OH)_6]$, and heating this salt to 270 °C converts it to $K_2[IrO_2(OH)_2]$. The reaction of N_2O_5 with $K_2[IrBr_6]$ (or the corresponding Cs^+ or Rb^+ salt) produces $K_2[Ir(NO_3)_6]$. The complex $[Ir(C_2O_4)_3]^{2-}$ is produced by oxidizing the corresponding Ir(III) species.

Iridium(IV) complexes with group 15 ligands include *trans*-$IrCl_4(PPr_3)_2$ and *trans*-$IrCl_4(AsPh_3)_2$. These complexes are potential oxidizing agents for organic transformations. An apparently similar iodo complex $IrI_4(PPh_2Me)_2$ is actually the Ir(III) complex $[Ir_2I_5(PPh_2Me)_4][I_3]$ (**2**).[32]



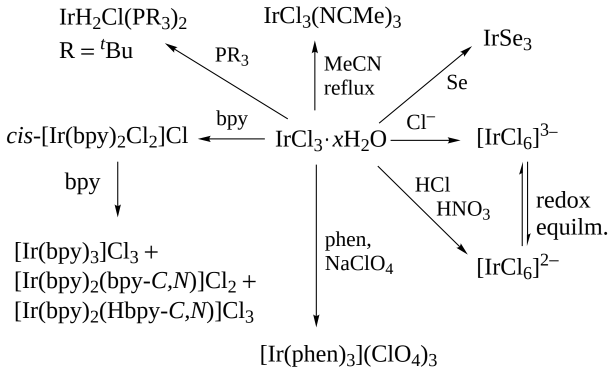
(**2**)

6 MONONUCLEAR COMPLEXES OF IRIDIUM(III)

The Ir(III) ion has a d^6 configuration. In octahedral complexes, the low-spin state ($t_{2g}{}^6$) is favored and the Ir center is kinetically inert.

6.1 Complexes with Halide and Related Ligands

Iridium(III) fluoride is a dark brown solid, insoluble in water and dilute acids. It is prepared by heating Ir metal with IrF_6 and N_2 at 500 °C. Direct fluorination of Ir in the correct stoichiometric ratio gives a mixture of IrF_3



Scheme 2

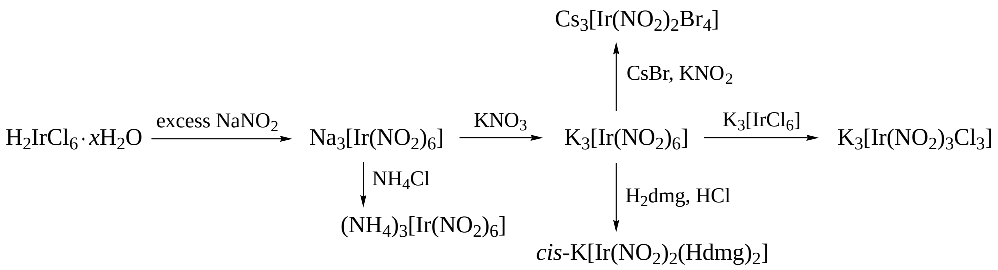
and IrF_5. Iridium(III) chloride is dimorphic: the α-form (made from Ir and Cl_2 at 600 °C) is brown and the β-form (made by heating α-$IrCl_3$) is red. Other color variations are observed under varying preparative conditions. Both forms of anhydrous $IrCl_3$ are insoluble in water. The hydrated complex $IrCl_3 \cdot xH_2O$ is dark green and is water soluble; $IrCl_3 \cdot xH_2O$ is a precursor to a range of Ir(III) complexes, examples of which are given in Scheme 2. Insoluble $IrBr_3$ can be made from Ir and Br_2 (8 atm) at 540 °C. Early reports of $IrBr_3$ may refer to Ir_2OBr_6. Critical discussions of various forms of iridium(III) halides are available.[1,3,4,15] In addition, chloro and bromo complexes of Ir(III) have been reviewed.[13,14]

The reduction of octahedral $[IrCl_6]^{2-}$ (Scheme 1) by oxalate or nitrite ion gives octahedral $[IrCl_6]^{3-}$. Alternative routes to particular salts include heating Ir metal with NaCl and Cl_2 to give $Na_3[IrCl_6]$, or the reduction of $M_2[IrCl_6]$ ($M^+ = K^+$ or $NH_4{}^+$) with H_2 to give $M_3[IrCl_6]$. The use of $[IrCl_6]^{3-}$ as a precursor to a variety of Ir(III) complexes is illustrated in Schemes 3–6. Complexes of Ir(III) with ligands other than halides are discussed in more detail in later sections. The $[IrCl_6]^{3-}$ anion hydrolyzes to give $[IrCl_5(H_2O)]^{2-}$, $[IrCl_4(H_2O)_2]^-$, and $IrCl_3(H_2O)_3$; a dissociative mechanism has been proposed for this hydrolysis.

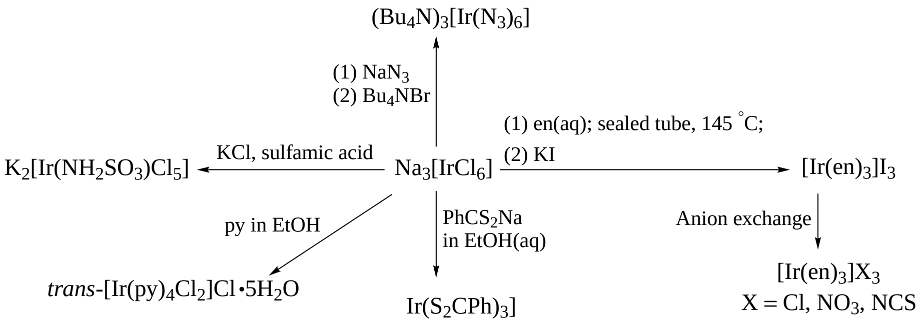
The cyanide ligand[33] is often considered as a pseudohalide (*see Pseudohalide*). Fusion of $(NH_4)_3[IrCl_6]$ with KCN gives $K_3[Ir(CN)_6]$, which can be isolated as pale yellow crystals after recrystallization from water. Derivative anions of the type $[Ir(CN)_5X]^{n-}$ (X = halide or hydroxide, $n = 3$; X = MeCN, $n = 2$) can be prepared as shown in Scheme 7.

6.2 Complexes with Nitrogen Donor Ligands

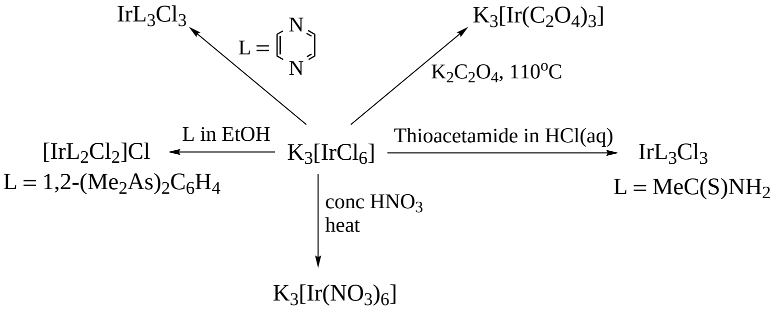
Methods of preparing nitrito complexes of Ir(III) are shown in Scheme 3. Structural characterization of $(NH_4)_3[Ir(NO_2)_6]$ shows that each $NO_2{}^-$ ligand coordinates through the nitrogen atom (Ir–N = 2.060 Å). The coordination of thiocyanate ligands (NCS^-) is discussed in Section 6.6; in $[Ir(NCS)_6]^{3-}$, the ligand exhibits *Linkage Isomerism* and



Scheme 3

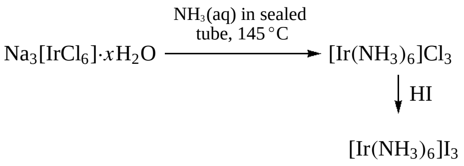


Scheme 4



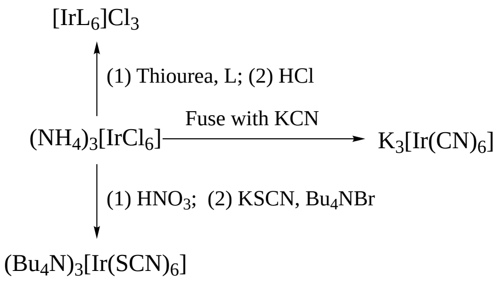
Scheme 5

the mixture of isomers can be separated by ion-exchange chromatography.[34]



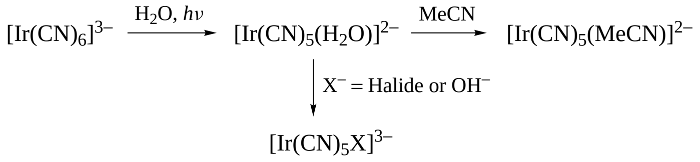
(7)

Syntheses of octahedral Ir(III) hexammine complexes are shown in equation (7). The cation $[Ir(NH_3)_5(H_2O)]^{3+}$ can be made indirectly (Scheme 8) or by photolyzing (254 or 313 nm) $[Ir(NH_3)_6]^{3+}$ in aqueous solution. A high-yield route to $Ir(NH_3)_3Cl_3$ involves the reaction of $IrCl_3{\cdot}xH_2O$ with 12 M



Scheme 6

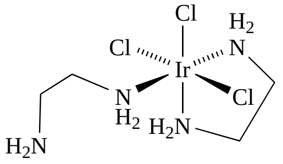
NH_3 at 150 °C.[35] The introduction of 1,2-ethanediamine (en) gives $[Ir(en)_3]^{3+}$ (Scheme 4). Both *cis* and *trans* isomers of



Scheme 7

$[IrX_2(en)_2]^+$ have been prepared for X = halide; the complex cations *trans*-$[Ir(X)(Cl)(en)_2]^+$ are known for X = Br^-, I^-, OH^-, NCS^-, NO_2^-. A halide ligand in *trans*-$[IrX_2(en)_2]^+$ is rapidly substituted by H_2O when the complex is irradiated (350 nm). This reaction gives a useful route to several other complexes of the general type *trans*-$[Ir(X)(Y)(en)_2]^{n+}$ (equation 8). Although less common than a didentate mode, the en ligand can also act as a monodentate ligand, for example, in *mer*-$IrCl_3(en)_2$ (**3**).[36]

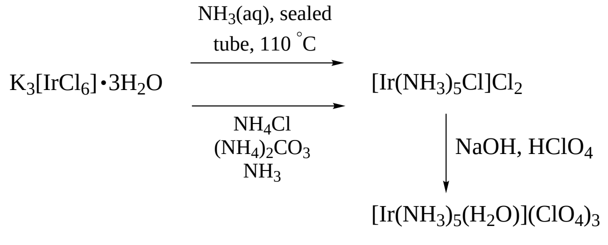
$$\textit{trans}\text{-}[IrCl_2(en)_2]^+ \xrightarrow{h\nu,\ I^-} \textit{trans}\text{-}[IrCl(I)(en)_2]^+ \downarrow \textit{trans}\text{-}[IrI_2(en)_2]^+ \quad (8)$$



(**3**)

The azide ion coordinates to Ir(III) in complexes such as $[Ir(N_3)_6]^{3-}$ (Scheme 4), *trans*-$[Ir(en)_2(N_3)_2]^+$ (equation 9), and $[Ir(N_3)(NH_3)_5]^{2+}$. Both *trans*-$[Ir(en)_2(N_3)_2]^+$ and $[Ir(N_3)(NH_3)_5]^{2+}$ liberate N_2 on addition of acid; a mechanism via a nitrene intermediate has been proposed.[4] The complex *trans*-$[Ir(en)_2(NH_2Cl)_2]Cl_3$ is formed when *trans*-$[Ir(en)_2(N_3)_2]Cl$ reacts with HCl.

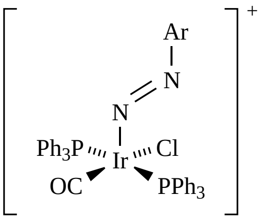
$$\textit{trans}\text{-}[Ir(en)_2Cl_2]^+ + 2N_3^- \xrightarrow[\text{tube, 140 °C}]{\text{aq, sealed}} \textit{trans}\text{-}[Ir(en)_2(N_3)_2]^+ + 2Cl^- \quad (9)$$



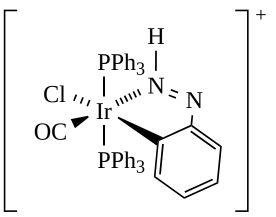
Scheme 8

Coordination of N_2H_4 is exemplified in $Ir(N_2H_4)_3Br_3{\cdot}0.5\,H_2O$ (equation 10). The coordination of diazonato ligands is well established; diazonato complexes are useful models for catalytic intermediates in the activation of N_2. Vaska's compound, *trans*-$IrCl(CO)(PPh_3)_2$, reacts with $[ArN{=}N](BF_4)$ in the presence of LiCl to give octahedral $IrCl_2(CO)(N{=}NAr)(PPh_3)_2$ in which the diazonato ligand has a bent geometry. In the absence of LiCl, the five-coordinate complex (**4**) is obtained. Conditions for the reaction are important: in EtOH, Vaska's compound reacts with $[ArN{=}N]^+$ to give the cyclometalated product (**5**) (*see Cyclometalation*), in addition to complex (**6**).

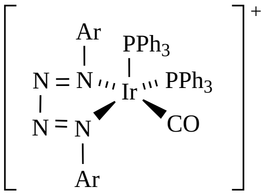
$$K[Ir(NO)Br_5] + N_2H_4{\cdot}nH_2O \longrightarrow Ir(N_2H_4)_3Br_3{\cdot}0.5H_2O \quad (10)$$



(**4**)

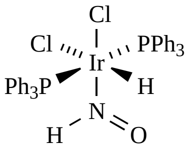


(**5**)



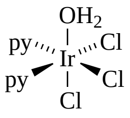
(**6**)

Complex (**7**) is an unusual example of a nitroxyl derivative, formed from the reaction of $Ir(NO)(PPh_3)_3$ with anhydrous HCl.[37]

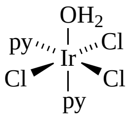


(**7**)

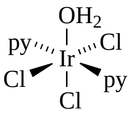
Many Ir(III) complexes containing heterocyclic N-donor ligands are known. Pyridine (py) reacts with $Na_3[IrCl_6]$ (Scheme 4) to yield *trans*-$[Ir(py)_4Cl_2]Cl{\cdot}5H_2O$. Photolysis of this complex in py gives *mer*-$Ir(py)_3Cl_3$ which, in a $CHCl_3$ solution in light, converts to $[Ir(py)_2Cl_3]_n$ and other products. The Ir(IV) complex $(NH_4)_2[IrCl_6]$ reacts with $[C_2O_4]^{2-}$ and py to give $[pyH][Ir(py)_2Cl_4]$; both the *trans* (red) and *cis* (yellow) isomers are formed, and the $[pyH]^+$ cation can be exchanged for Na^+ or $NH_4{}^+$. Water exchanges for a chloride ligand in the *trans* isomer without disruption of the *trans* arrangement of the py ligands; in the *cis* isomer, the H_2O-for-Cl^- exchange results in a mixture of isomers of $Ir(py)_2Cl_3(H_2O)$. Structures (**8**) to (**10**) show the three isomers of $Ir(py)_2Cl_3(H_2O)$. Complex (**8**) is prepared from *cis*-$(NH_4)[Ir(py)_2Cl_4]$ with py in water (110 °C). Complex (**9**) is made by photolyzing *cis*-$K[Ir(py)_2Cl_4]{\cdot}H_2O$, and (**10**) is formed from *trans*-$Na[Ir(py)_2Cl_4]$ in water. Related monodentate ligands that complex to Ir(III) are substituted pyridines, pyrazine, pyridazine, and pyrimidine.



(**8**)



(**9**)



(**10**)

Over the years, reports of '$[Ir(bpy)_3]^{3+}$' (bpy = 2,2′-bipyridine) have been unclear.[38] Early studies most probably refer to $[Ir(bpy)_2Cl_2]^+$ rather than the tris-bpy complex. Under chloride-free conditions, a complex containing three bpy ligands was isolated, but it exhibited properties that were unexpected for an N_6-donor set. X-ray diffraction data confirmed that one bpy ligand was C,N- rather than *N*,*N*′-bound to Ir(III), that is, $[Ir(bpy\text{-}N,N')_2(bpy\text{-}C,N)]^{2+}$ (**11**) formed after cyclometallation had occurred.[39] The dication (**11**) can be prepared from bpy and a mixture of $K_2[IrCl_6]$ and $K_3[IrCl_6]$; the presence of Ir(IV) facilitates cyclometallation. The uncoordinated N atom in (**11**) can be protonated to give trication (**12**). Interest in the bipyridine complexes of this family arises in part from their particular photochemical and photophysical properties. The noncyclometalated complex $[Ir(bpy)_3]^{3+}$ can be prepared by treating $[Ir(bpy)_2(O_3SCF_3)_2]^+$ with bpy, and the presence of three *N*,*N*′-bound ligands has been confirmed crystallographically. Ligands related to bpy are 1,10-phenanthroline, (phen, **13**), and oligopyridines. Again, the literature is not definitive. Although complexes with phen are reported to exhibit anomalous behavior related to that of the bpy complexes, this clearly cannot originate from cyclometallation because the phen ligand, unlike bpy, is not flexible enough to adopt the conformation needed to become an *N*,*C*-chelate. The luminescent properties of Ir(III) polyimine complexes (with charge-transfer or ligand-centered emissive states) have stimulated a range of studies, which have been reviewed.[40] The lifetimes of the Ir(III) excited states range from nanoseconds to microseconds. Complexes with $IrN_6{}^{3+}$ units behave as photooxidants; in contrast, those with cyclometalated IrN_3C_3 units are photoreductants. The luminescent, cyclometalated complexes $[Ir(ppy)_2(phen\text{-}NCS)]^+$ and $[Ir(ppy)_2(phen\text{-}NHCOCH_2I)]^+$ (Hppy = 2-phenylpyridine, phen-NCS = 5-isothiocyanato-1,10-phenanthroline, $phenHNCOCH_2I$ = 5-(iodoacetamido)-1,10-phenanthroline) and related complexes have been used to label modified oligonucleotides and proteins, thereby producing luminescent bioconjugates.[41,42] The long-lived luminescence of bis-tpy (tpy = **14**) complexes of Ir(III) in which the tpy ligands carry *N*-methylpyridyl substituents is quenched by Cl, providing the basis for a chloride ion sensor.[43]

6.3 Complexes with Phosphorus Donor Ligands

Since phosphine ligands[16] stabilize low oxidation states of d-block metals, it is not surprising that a large number of phosphine-containing complexes of iridium exhibit the metal in oxidation states $+1$ and below. Nonetheless, there is a large group of complexes of general formula $Ir(PR_3)_3H_3$, $Ir(PR_3)_3H_2X$, $Ir(PR_3)_3HX_2$ and $Ir(PR_3)_3X_3$ (X = halide ligand; R = alkyl or aryl substituent) that formally contain Ir(III).[3,4] Selected syntheses are given in equations (11–14). Related species in which other ligands take the place of the halides include $Ir(PPh_3)_3H_2(O_2CMe)$ (**16**), $Ir(PPh_3)_2HCl(O_2CMe)$ (**17**), and $Ir(PPh_3)_2HCl_2(py)$ (**18**). The entire range of complexes known is too varied[3,12] to describe in detail here. Some of these iridium(III) complexes are used as catalysts, for example, $Ir(PEt_2Ph)_3HCl_2$ is a catalyst for the isomerization of dienes and of 1-octene, and $Ir(PPh_3)_2H_2(O_2CR)$ (R = Me, Et, Pr) catalyzes the homogeneous hydrogenation of nonactivated α-alkenes. Complexes $[Ir(PR_3)_2H_2L_2]^+$ containing *trans*-PR_3 and *cis*-H are known, for example, L = MeI, H_2, Me_2CO, R_3SiH, and H_2O. The anionic complex $[Ir(P^iPr_3)_2HI_3]^-$ forms when $Ir(P^iPr_3)_2HI_2$ dissolves in Bu_4NI; $[Ir(P^iPr_3)_2HCl_3]^-$ has also been prepared and characterized.[45]

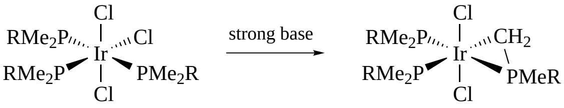
$$Ir(PMe_3)_2H_5 \xrightarrow{PMe_3\text{ in benzene}} fac\text{-}Ir(PMe_3)_2H_3 \qquad (11)$$

$$\underset{R\,=\,Et,\,Pr}{mer\text{-}Ir(PR_3)_3Cl_3} \xrightarrow{EtOH,\ KOH\ (aq)} mer\text{-}Ir(PR_3)_3Cl_2H \qquad (12)$$

$$\left.\begin{array}{l} Na_2[IrCl_6]\cdot xH_2O \\ IrCl_3\cdot xH_2O \end{array}\right\} \xrightarrow{PPh_3/NaBH_4/EtOH} \begin{array}{c} mer\text{-}Ir(PPh_3)_3H_3 \\ + \\ fac\text{-}Ir(PPh_3)_3H_3 \end{array} \qquad (13)$$

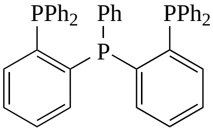
An interesting property of *mer*-$Ir(PMe_3)_3Cl_3$ and *mer*-$Ir(PMe_2Ph)_3Cl_3$ is their reactions with strong bases such as $^iPr_2NLi$ or BuLi (equation 15). When the cyclometalated product with R=Ph is treated with Cl_2, ring opening occurs to yield *mer*-$IrCl_3(PMe_2Ph)_2(PMePhCH_2Cl)$, which rearranges to the *fac* isomer.

$$H_2[IrCl_6]\cdot xH_2O \xrightarrow[\text{in } MeOCH_2CH_2OH]{PMe_2Ph,\ HCl} mer\text{-}Ir(PMe_2Ph)_3Cl_3 \xrightarrow{\text{reflux in } CCl_4} fac\text{-}Ir(PMe_2Ph)_3Cl_3 \qquad (14)$$

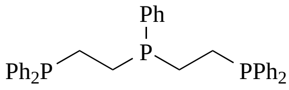


(15)

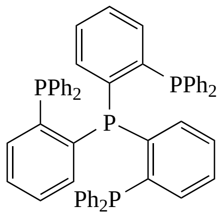
The coordination of didentate phosphine ligands to Ir(III) is illustrated by the formation of *cis*-$[Ir(dppe)_2H_2]X$ (prepared by the *Oxidative Addition* of H_2 to $[Ir(dppe)_2]X$), where X = Br or Cl; *cis*-$[Ir(dppe)_2HCl]Cl$ (by the oxidative addition of HCl to $[Ir(dppe)_2]Cl$); and $[Ir(dppp)_2HCl](PF_6)$ (from the oxidative addition of HCl to $[Ir(dppp)_2]Cl$ in the presence of HPF_6). Complexes containing multidentate phosphine ligands include IrL^1Cl_3 (L^1 = **19**) (prepared from $H_2[IrCl_6]\cdot xH_2O$ and L^1), IrL^2Cl_3 (L^2 = **20**) (prepared from $Na_2[IrCl_6]\cdot 6H_2O$ and L^2 in ethanolic HCl), IrL^2H_3 (made from IrL^2Cl_3), $[Ir(L^3)HBr](BPh_4)$ (L^3 = **21**) (from $Ir(PPh_3)_3HBr_2$ and L^3, with anion exchange), and $[Ir(L^3)Br_2](BPh_4)$ (prepared from $[Ir(L^3)HBr]Br$ and Br_2 in the presence of $[BPh_4]^-$). Other related systems have been prepared.[3,4,12] The formation of bridged multinuclear complexes may also be a possibility.



(**19**)



(**20**)



(**21**)

6.4 Complexes with Arsenic or Antimony Donor Ligands

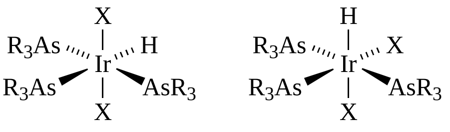
Complexes of the type $Ir(AsR_3)_3X_3$ (X = halide)[3] are fairly large and selected synthesis methods are given

in equations (16) to (18); most compounds are either yellow, orange, or brown. Complexes of the general formula $Ir(AsR_3)_3HX_2$ (X = halide)[3] tend to be white, yellow, or orange. Several complexes exist in both the isomeric forms shown in (**22**) and (**23**), but the tendency for isomerization from (**22**) to (**23**) is less for the arsine complexes than for the corresponding phosphine derivatives. The complexes *fac*-$Ir(AsEt_2Ph)_3H_3$, *fac*-$Ir(AsPh_3)_3H_3$, and *mer*-$Ir(AsPh_3)_3H_3$ can be prepared from corresponding halo complexes $Ir(AsPh_3)_3HX_2$ using $[BH_4]^-$ or $[AlH_4]^-$ as the hydride source.

$$H_2[IrCl_6]\cdot xH_2O \xrightarrow{AsEt_3,\ HCl\ in\ EtOH} mer\text{-}Ir(AsEt_3)_3Cl_3 \quad (16)$$

$$Na_3[IrCl_6]\cdot xH_2O \xrightarrow{AsMePh_2,\ HI\ in\ EtOH} Ir(AsMePh_2)_3I_3 \quad (17)$$

$$Ir(AsPh_3)_3H_3 \xrightarrow{Br_2,\ benzene} Ir(AsPh_3)_3Br_3 \quad (18)$$



(**22**) (**23**)

Multidentate arsine ligands that coordinate to Ir(III) include $Ph_2AsCH_2CH_2AsPh_2$, 1,2-$(AsMe_2)_2C_6H_4$ (Scheme 5), $PhAs(C_6H_4AsPh_2\text{-}2)_2$, and $As(C_6H_4AsPh_2\text{-}2)_3$.

Only a few complexes exhibiting stibine ligands have been prepared and characterized. Amongst them are *mer*- and *fac*-$Ir(SbPh_3)_3Cl_3$, $Ir(SbPh_3)(PEt_2Ph)_2H_3$, $[Ir(SbPh_3)_2Cl_4]^-$, $Ir(SbPh_3)_3HCl_2$, $Ir(SbPh_3)_3H_2Cl$, and related bromo complexes.[3]

6.5 Complexes with Oxygen Donor Ligands

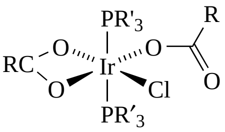
The hexaaqua ion $[Ir(H_2O)_6]^{3+}$ is air sensitive. It is prepared (with difficulty) from the hydrolysis product of $(NH_4)_2[Ir^{IV}Cl_6]$ but is not a well-characterized ion. Iridium(III) hydroxide is formed as an olive-green precipitate by hydrolyzing $H_2[IrCl_6]$ with NaOH in ethanol (at pH 12, 40 °C), by treating $K_3[IrCl_6]$ with KOH under a CO atmosphere, or by dissolving $IrO_2\cdot xH_2O$ in sulfuric acid and adding NaOH. It is not well characterized but can be used to prepare other complexes, for example, yellow $Ir(acac)_3$ (equation 19) and orange–yellow IrL_3, where HL = $CF_3COCH_2COCF_3$. The structures of $Ir(acac)_3$ and $Ir(acacX)_3$ (X = Cl, Br, and I in the γ-position) have been determined.[46]

'Ir(OH)$_3$' + 3Hacac ⟶  + $3H_2O$ (19)

Scheme 5 shows a route to the violet-colored $K_3[Ir(NO_3)_6]$. The reaction of HNO_3 with $K_3[Ir(NO_2)_6]$ leads to $K_3[Ir(NO_3)_3(NO_2)_3]$. A range of mixed ligand complexes involving coordinated NO_3^- or NO_2^- anions is known,[3,4] for example, $[Ir(NO_2)_2(en)_2]^+$, $[Ir(NO_2)_3Cl_3]^{3-}$, $[Ir(NO_2)_2(C_2O_4)_2]^{3-}$, $IrCl(NO_3)_2(CO)(PPh_3)_2$, and $Ir(NO_2)(NO_3)_2(CO)(PPh_3)_2$. The NO_2^- ligand can be O- or N-bonded (the structure of $[Ir(NO_2)_6]^{3-}$ is described later); the NO_2^- ligand in the complex $[Ir(NH_3)_5(NO_2)]^{2+}$ undergoes a change from O- to N-coordination in aqueous basic solution.

Coordination of sulfate ligands to Ir(III) often leads to multinuclear complexes (see Section 8), and a similar trend is observed for carboxylate complexes. In equation (20), acetate acts as a monodentate ligand; structures (**16**) and (**17**) give examples of monodentate and didentate modes. Iridium(III) complexes of the type $Ir(H)X(CO)(PR'_3)_2(O_2CR)$ are formed via the oxidative addition of RCO_2H (e.g. R = H, Me, Ph) to $Ir^IX(CO)(PR'_3)_2$ (X = Cl, Br, I; e.g. R′ = Et, Ph). The complexes $IrCl(PR'_3)_2(O_2CR)_2$ (e.g. R = R′ = Ph; R = Me, R′ = Ph) are formed by the reaction of $IrCl(PR'_3)_2(CO)$ or $IrCl(PR'_3)_2(N_2)$ with RCO_3H (a peroxycarboxylic acid) and possess both mono- and didentate carboxylates (**24**).

$$[Ir(NH_3)_5(OH)]^{2+} + MeCO_2H \longrightarrow [Ir(NH_3)_5(MeCO_2)]^{2+} + H_2O \quad (20)$$



(**24**)

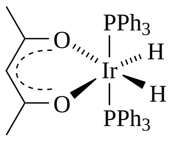
The complex anion $[Ir(C_2O_4)_3]^{3-}$ may be prepared from Ir(III) or Ir(IV) precursors (Scheme 5, and equations 21 and 22). Studies on the complex have been quite extensive.[4] The structures of optically active $K_3[Ir(C_2O_4)_3]\cdot 2H_2O$ and racemic $K_3[Ir(C_2O_4)_3]\cdot 4.5H_2O$ have been crystallographically determined; Ir is octahedral as expected (Ir–O = 1.96 Å in $K_3[Ir(C_2O_4)_3]\cdot 2H_2O$).

$$K_2[IrCl_6] \xrightarrow{K_2C_2O_4\ heat\ in\ aq.\ slurry} K_3[Ir(C_2O_4)_3]\cdot 4H_2O \quad (21)$$

$$IrO_2\cdot nH_2O \xrightarrow[2.\ Ca^{2+}]{1.\ H_2C_2O_4/KHCO_3} Ca_3[Ir(C_2O_4)_3]_2 \quad (22)$$

Iridium(III) complexes incorporating β-diketonate ligands include $Ir(acac)_3$ (equation 19), γ-halogenated derivatives,[46]

and IrL_3 (HL = $CF_3C(O)CH_2C(O)CF_3$) (see above). The reaction of $Ir(PPh_3)_2H_3$ with Hacac leads to complex (**25**); similar reactions occur with other β-diketones.



(**25**)

6.6 Complexes with Sulfur Donor Ligands

The thiocyanate ion, NCS^-, may be N-bonded (thiocyanate ligand) or S-bonded (isothiocyanate ligand) to a transition metal ion (*see d–d Transitions*), and in the absence of X-ray diffraction results, IR spectroscopic data are an important means of assigning the coordination mode. Linkage isomers of $[Ir(SCN)_6]^{3-}$ can be separated by ion-exchange chromatography.[34] In $(NH_4)_3[Ir(SCN)_6]$ (Scheme 6), IR spectral data are consistent with S-bonded ligands (ν_{CN} = 2127, 2098 cm^{-1}, ν_{CS} = 822, 693 cm^{-1} in the solid state) and this has been confirmed by X-ray diffraction data.[34] $[Ir(NH_3)_5(H_2O)]^{3+}$ reacts with aqueous NaSCN to yield $[Ir(NH_3)_5(SCN)]^{2+}$. Both linkage isomers are observed; the N-bonded isomer dominates and crystallizes out before the S-bonded complex.

A variety of Ir(III) complexes with SR^- (R = H, alkyl, or aryl) ligands are known. The oxidative addition of H_2S to Ir(I) is shown in equation (23); similar oxidative addition reactions between $Ir(PPh_3)_3Cl$ and RSH lead to complexes of the type $Ir(SR)(H)Cl(PPh_3)_2$. Arsine analogs are also known. $Cp^*IrCl_2(PMe_3)$ reacts with NaSH and H_2S to give $Cp^*Ir(SH)_2(PMe_3)$. Dialkyl or diaryl sulfide ligands can be introduced as in equation (24) and Scheme 9. The red product gained after chloroform extraction in Scheme 9 has been referred to in the literature as '*trans*-$Ir(SEt_2)_3Cl_3$', but in a $MeNO_2$ solution, it is a 1:1 electrolyte.

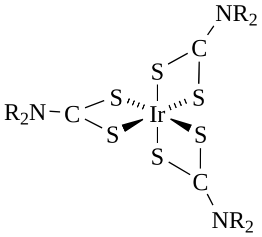
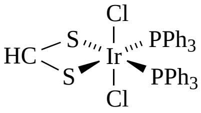
Iridium(III) complexes containing thiourea, thioacetamide, and dithioacetylacetonate ligands are known (Schemes 1, 5 and 6), and Ir(III) dithiocarbamate complexes $Ir(S_2CNR_2)_3$ (**26**) have been prepared from either $Na_2[Ir^{IV}Cl_6]$ or $(NH_4)_3[Ir^{III}Cl_6]$ with the appropriate sodium dithiocarbamate. Hydride transfer from $Ir(H)Cl_2(PPh_3)_3$ to CS_2 yields the dithioformato ligand and complex (**27**). The hydrido analog of (**27**), $Ir(S_2CH)H_2(PPh_3)_2$, is prepared by the reaction of CS_2 with *mer*-$IrH_3(PPh_3)_3$.

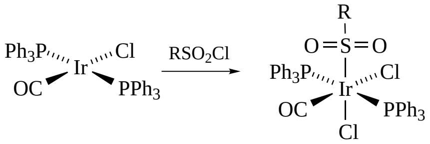


(**26**)



(**27**)

The reaction of RSO_2Cl (e.g. R = Me, Et, Pr) with Vaska's complex (an oxidative addition, equation 25) gives an S-bound sulfinato ligand. (See Section 6.7 for the oxidative addition of CX_2 (X = S or Se) to Vaska's compound.)



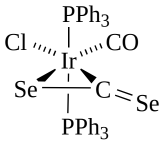
(25)

Polysulfide complexes of iridium(III) include $[Ir(S_5)_3]^{3-}$ and $[Ir(S_6)_3]^{3-}$, the latter being prepared from the reaction of $IrCl_3\cdot xH_2O$ with aqueous $(NH_4)_2S_n$.[47]

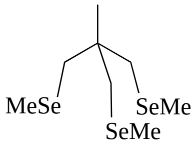
6.7 Complexes with Selenium Donor Ligands

Relatively few nonorganometallic, seleno complexes of Ir(III) have been synthesized and characterized. Treating $(NH_4)_2[IrCl_6]$ with Et_2Se in refluxing ethanol leads to $Ir(SeEt_2)_3Cl_3$, for which a *fac* arrangement of ligands is suggested (compare Scheme 9). The oxidative addition of CSe_2 to *trans*-$IrCl(CO)(PPh_3)_2$ gives an octahedral

complex (**28**); similar reactions with CS_2 have also been reported. The tripodal ligand (**29**) forms the octahedral complex $[Ir(\mathbf{29})_2]^{3+}$.[48]

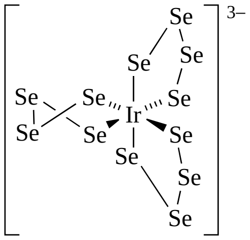


(**28**)



(**29**)

Complex (**26**) and its seleno analogs react with $AgBF_4$ to give $[Ag\{IrL_3\}_2][BF_4]$ (L = dithiocarbamate or diselenocarbamate) in which two octahedral IrL_3 act as ligands to Ag^+ to give a trinuclear complex.[49] Iridium(III) complexes involving polyselenide ligands are represented by $[Ir(Se_4)_3]^{3-}$ (**30**) and $[Ir(Se_4)_2(MeCN)_2]^-$. In the solid-state structure of $[K(2.2.2\text{-cryptand})]_3[Ir(Se_4)_3]\cdot$toluene, the anion exists as a $\Delta\lambda\lambda\delta/\Lambda\delta\delta\lambda$ racemate.[47]



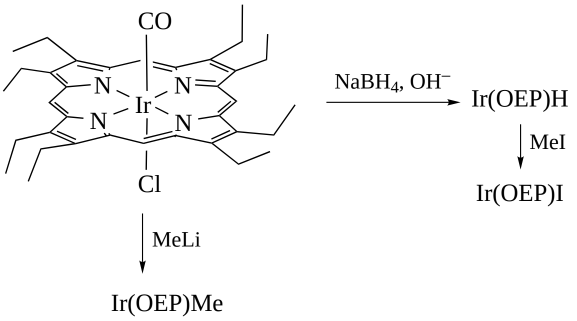
(**30**)

Related complexes with formally O_2^{2-}, S_2^{2-}, or Se_2^{2-} ligands are considered together here. Dioxygen binds in a 'side-on' fashion in $[Ir(dppe)_2(\eta^2\text{-}O_2)]^+$, formed when O_2 reacts with $[Ir(dppe)_2]^+$; the IR spectrum exhibits an absorption at $830\,cm^{-1}$ assigned to ν(O–O), and structural data give an O–O bond length of 1 to 52 Å.[50] The potential for this and related peroxo complexes to undergo photochemical elimination of singlet oxygen has been investigated.[51] Reactions of $[Ir(dppe)_2]^+$ or $[Ir(Me_2PCH_2CH_2PMe_2)_2]^+$ with S_8 or Se_8 give $[IrL_2(\eta^2\text{-}E_2)]^+$. Characteristic IR spectroscopic absorptions are $\nu_{SS} = 510$ to $550\,cm^{-1}$ and $\nu_{SeSe} = 300$ to $310\,cm^{-1}$.[52] Members of this group of complexes are photochromic.[53]

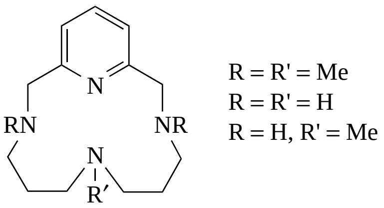
6.8 Macrocyclic Ligands

Octaethylporphyrin, H_2OEP, reacts with $[IrCl(CO_3)]_2$ to give Ir(OEP)Cl(CO) in which the four N-donors of the OEP^{2-} ligand lie in the equatorial plane of the octahedral Ir(III). Ir(OEP)Cl(CO) is a precursor to other complexes containing the Ir(OEP) unit (Scheme 10).

Macrocyclic ligands (**31**) encapsulate Ir^{3+} to give octahedral $[Ir(\mathbf{30})(Cl)(Et)]^+$ in which the Et and Cl^- ligands are in axial sites.[54]

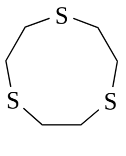


Scheme 10

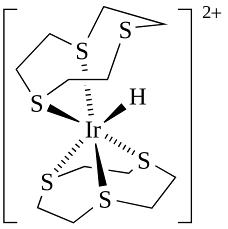


(**31**)

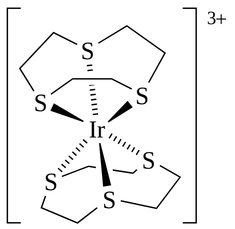
Several Ir(III) complexes with macrocyclic ligands containing S-donors have been prepared and characterized.[55] The macrocyclic thioether (**32**) reacts with $[(C_8H_{14})IrCl]_2$ (C_8H_{14} = cyclooctene) to give $[Ir(\mathbf{32})_2(H)]^{2+}$ (**33**), isolated and structurally characterized as the $[PF_6]^-$ salt. The presence of the hydride ligand forces one S-donor to be uncoordinated. In (**34**), the two macrocyclic ligands act as S_3-donor sets (average Ir–S distance = 2.340 Å). Ligand (**35**) reacts with $IrCl_3\cdot xH_2O$ to give *cis*-$[IrCl_2(\mathbf{35})]^+$. The selenoether macrocycle (**36**) forms the complex *trans*-$[Ir(\mathbf{36})Br_2]^+$.[56]



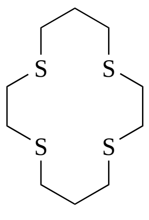
(**32**)



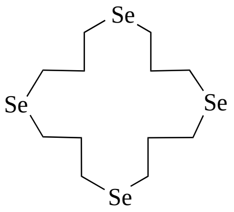
(**33**)



(**34**)



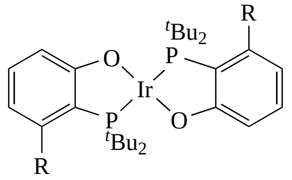
(**35**)



(**36**)

7 THE LOWER OXIDATION STATES: MONONUCLEAR COMPLEXES

Iridium(II) is not a common oxidation state for the metal and the d^7 electronic configuration leads to *Paramagnetism* in mononuclear complexes. A representative example is square planar (**37**).



(**37**) R = H, OMe

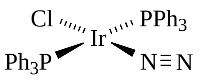
The iridium(I) state is commonly observed in an organometallic environment[7,8] (*see* ***Iridium: Organometallic Chemistry***). Thus, only selected Ir(I) complexes are considered here. The Ir(I) state is not usually stabilized by ligands that are unable to act as π-acceptors. Therefore, simple complexes such as $[IrL_4]^+$, where L = H_2O or NH_3; or $[IrL_4]^{3-}$, where L = F^-, Cl^-, Br^-; or OH^- are not known. There is some evidence for the existence of the binary halides IrCl, IrBr, and IrI. In $Mg_6Ir_2H_{11}$, the square pyramidal $[IrH_5]^{4-}$ hydrido complex is present along with $[IrH_4]^{5-}$.[57]

Common precursors for the formation of iridium(I) complexes are *trans*-$IrCl(CO)(PPh_3)_2$ (Vaska's compound), $[IrCl(CO)_3]_n$, $[IrCl(C_8H_{14})_2]_2$ (C_8H_{14} = cyclooctene), and $[(cod)IrCl]_2$ (cod = cycloocta-1,5-diene). Complexes of Ir(I) are usually either four-coordinate (square planar) or five-coordinate (trigonal bipyramidal). In solution, five-coordinate complexes are typically stereochemically nonrigid (*see Fluxional Molecule*). Although low oxidation state d-block metal complexes are typically expected to obey the 18-electron rule (*see Effective Atomic Number Rule*), square-planar iridium(I) complexes, in particular, are stable with a 16-electron configuration, for example, in $IrCl(CO)(PPh_3)_2$. It follows that such complexes tend to undergo oxidative addition reactions in which the Ir(I) is oxidized to Ir(III) (*see* ***Mechanisms of Reaction of Organometallic Complexes***).

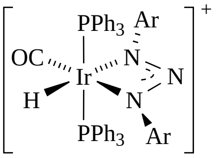
The reaction of $[IrCl(CO)_3]_n$ with an isocyanide, CNR (R = alkyl or aryl), leads to the square-planar $[Ir(CNR)_4]^+$ representative oxidative additions, which are given in equation (26).[4,7]

$$[Ir(CNR)_4]^+ \xrightarrow{MeI} [IrI(Me)(CNR)_4]^+$$
$$\xrightarrow{X_2\ (halogen)} [IrX_2(CNR)_4]^+ \qquad (26)$$

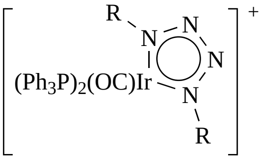
Complexes (**38**) to (**41**) illustrate mononuclear Ir(I) complexes with N-donor ligands. The N_2 ligand in (**38**) is introduced by the reaction of ArC(O)NNN with *trans*-$IrCl(CO)(PPh_3)_2$, and it is bound in an 'end-on' fashion (*see End-On Coordination*).[58] Cation (**39**) contains Ir(III) and is formed from the neutral triazenido Ir(I) complex $Ir(CO)(PPh_3)(ArNNNAr)$ (Ar = aryl).[59] The tetrazene ligand in (**38**) is a 4-electron donor, and complex (**38**) is an 18-electron complex.[60] Pyrazine can act as a monodentate (**41**) or a bridging (**42**) ligand.[61]



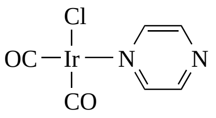
(**38**)



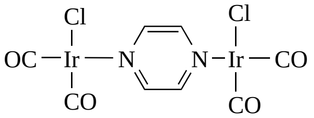
(**39**)



(**40**)



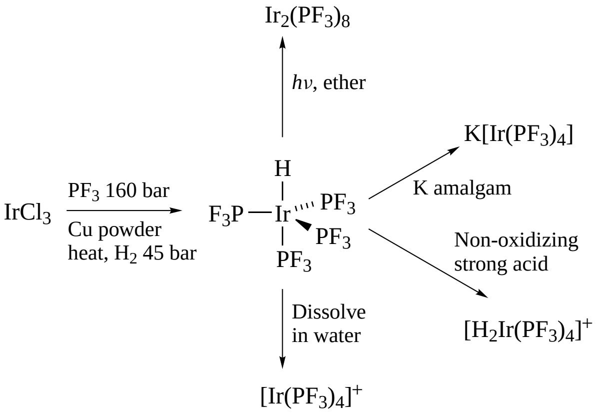
(**41**)



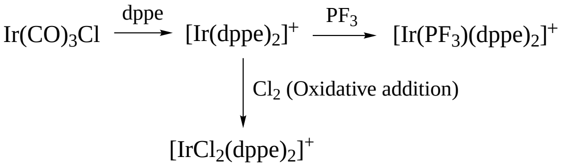
(**42**)

There are many Ir(I) complexes containing phosphine ligands (*see* ***P-donor Ligands***).[16] Phosphorus trifluoride is a π-acid ligand and coordinates to low oxidation state d-block metals (e.g. Scheme 11). Some cationic complexes of the type $[Ir(PR_3)_4]^+$ for R $\neq$ F have also been prepared. The crystal structure of $[Ir(PPh_2Me)_4](BF_4)$ shows a distorted square planar Ir(I), the distortion being toward tetrahedral.[62] The $[Ir(PPh_2Me)_4]^+$ cation undergoes oxidative additions. For addition of I_2, a complex of stoichiometry IrL_2I_4 is obtained; structural characterization shows it to be the dinuclear complex $[Ir_2L_4I_2(\mu\text{-}I)_3][I_3]$, (**2**).[32,63] Related complex cations with secondary phosphines are $[Ir(PEt_2H)_4]^+$ and $[Ir(PPh_2H)_4]^+$, prepared from $\{IrCl(C_8H_{14})_2\}_2$ and the phosphine. The reaction of $IrH_3(PPh_3)_3$ with $P(OPh)_3$ results in reduction of the metal (equation 27); $IrH\{P(OPh)_3\}_4$ is a catalyst for the reduction of alkenes and acetylenes by formic acid or formates.

$$IrH_2(PPh_3)_3 \xrightarrow{P(OPh)_3,\ 110\,^\circ C} IrH\{P(OPh)_3\}_4 \qquad (27)$$

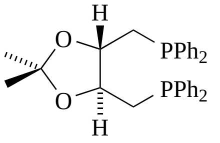


Scheme 11

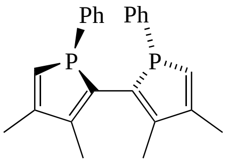


Scheme 12

Iridium(I) complexes incorporating multidentate phosphine ligands are varied. The simplest are the square-planar $[IrL_2]^+$ cations, where, for example, L = dppe (Scheme 12), dppp, and the *Chiral* ligands (**43**) and (**44**). The complex $[Ir(dppp)_2]Cl$ is made from Vaska's compound and dppp; $[Ir(\mathbf{43})_2](BPh_4)$ is prepared from $[IrCl(cod)]_2$ and (**43**). The reaction of (**44**) with $[IrCl(cod)]_2$ in the presence of $AgBF_4$ gives $[Ir(cod)(\mathbf{44})][BF_4]$; using enantiomerically pure ligand (**44**), the enantiomerically pure $[Ir(cod)(\mathbf{44})]^+$ can be isolated.[64] The complex cation $[Ir(\mathbf{43})_2]^+$ is a precursor to optically active hydrido complexes, and $[Ir(dppe)_2]Cl$ catalyzes the homogeneous oxidation of styrene. Ligand (**21**) forms the complexes Ir(**21**)Cl and Ir(**21**)Br, and $Ph_2P(CH_2)_2P(Ph)(CH_2)_2P(Ph)(CH_2)_2PPh_2$ (L) forms IrLCl. In contrast to the chelating nature of theses ligands, dppm ($Ph_2PCH_2PPh_2$) tends to bridge two metal centers (see Section 8.5). Ligand (**45**) draws together two iridium atoms such that each is coordinated to three phosphorus atoms in the complex ClIr(μ-L)IrCl.[65]

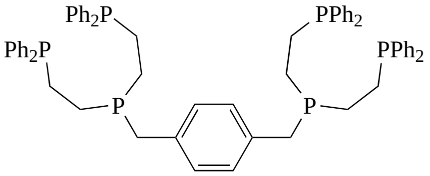


(**43**)

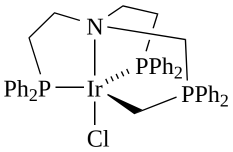


(**44**)

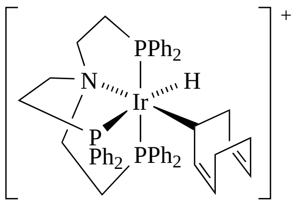
The ligand $N(CH_2CH_2PPh_2)_3$ is potentially tetradentate, and it reacts with $[IrCl(cod)]_2$ to give (**46**). Oxidative addition of a C–H bond of cod occurs in the reaction of (**46**) with cod to give the Ir(III) complex (**47**).[66]



(**45**)

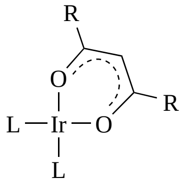


(**46**)



(**47**)

Oxygen donor ligands on their own do not stabilize iridium(I) but can do so in the presence of suitable π-acceptor ligands, for example, (**48**).

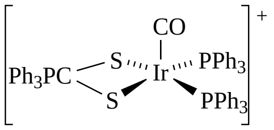


L = alkene or CO

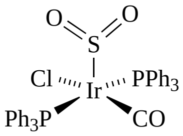
R = Me, CF_3 or Ph

(**48**)

The reaction of *trans*-$IrCl(CO)(PPh_3)_2$ with carbon disulfide in the presence of $NaBPh_4$ yields $[(\mathbf{49})](BPh_4)$ in which the S-donor ligand is the zwitterion $S_2C^-PPh_3{}^+$.[67] Sulfur dioxide is S-bonded to an iridium(I) atom in the trigonal bipyramidal complex $IrH(PPh_3)_2(CO)(SO_2)$; in the related chloro complex (**50**), the Ir–S distance is 2.45 Å.[68]



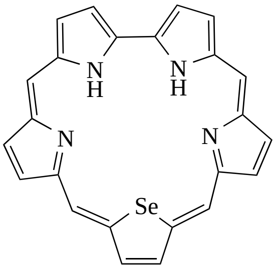
(**49**)



(**50**)

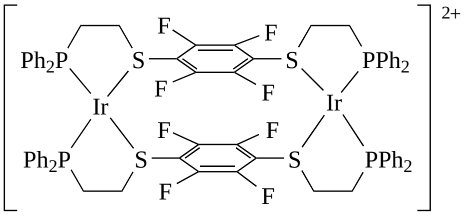
Examples of the interaction between Ir(I) and macrocyclic ligands include $(CO)_3Ir(\mu\text{-TPP})Ir(CO)_3$ (H_2TPP = tetraphenylporphyrin). The complex undergoes three irreversible electrochemical oxidations leading to $[Ir(TPP)]^+$.[69]

Softer donor atoms are involved in the following examples. Reaction of $Ir_2(C_8H_{14})_4Cl_2$ (C_8H_{14} = cyclooctene) or $Ir(C_2H_4)_4Cl$ with 1,4,7-trithiacyclononane, L, gives $[IrL(C_8H_{14})_2]^+$ and $[IrL(C_2H_4)_2]^+$.[70] Ligand (**51**), H_2L, reacts with $[Ir(CO)_3Cl]_n$ to give $L\{Ir(CO)_2\}_2$ in which the deprotonated ligands bind two $Ir(CO)_2{}^+$ units through coordination to N,N'-donor sites.[71]

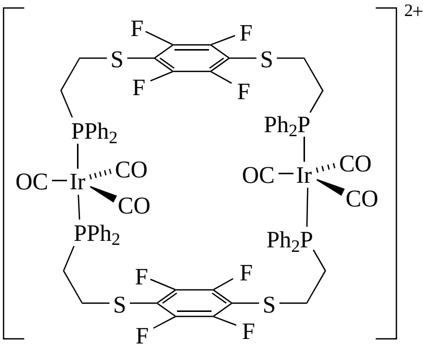


(**51**)

The area of metallamacrocycles, in which the metal centers are an integral part of the cyclic structure, is rapidly expanding. Complexes (**52**) and (**53**) involve Ir(I) centers.[72]



(**52**)



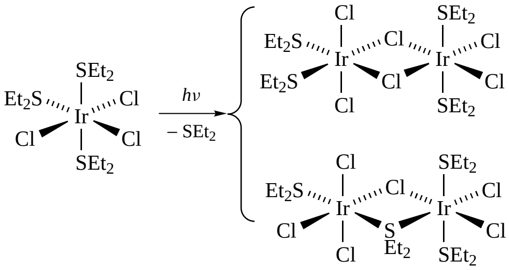
(**53**)

8 DINUCLEAR AND MULTINUCLEAR IRIDIUM COMPLEXES

The control of molecular assemblies through ligand design is of active interest, and this theme has been addressed in a review concerned specifically with low nuclearity Rh and Ir complexes.[73]

8.1 Halide Ligands

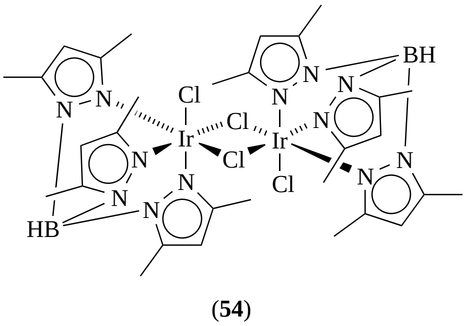
Halide ions and common bridging ligands (*see Bridging Ligand*), examples of bridging fluoride and iodide ligands in (**1**) and (**2**), respectively. When $(Et_4N)_2[IrCl_6]$ is heated with CF_3CO_2H, the $[Ir_2Cl_{10}]^{2-}$ (D_{2h}) ion forms.[74] Chloro bridges are present in a variety of organometallic complexes, for example, $[Ir(\mu\text{-}Cl)(C_8H_{14})_2]_2$, $[(cod)Ir(\mu\text{-}Cl)]_2$, and $[Ir(CO)_2(\mu\text{-}Br)]_2$; the latter catalyzes the carboxylation of alkenes. A wide range of Ir(III) complexes possess halide bridges, for example, $[CpIrCl(\mu\text{-}Cl)]_2$ and the hydrotris(3,5-dimethylpyrazolyl)borato complex (**54**), which is a precursor to related complexes. In some cases, the loss of a ligand may induce bridge formation, for example, during the photolysis of the mononuclear iridium(III) complex *mer*-$IrCl_3(SEt_2)_3$ (equation 28). Iodo-bridges support the two square-planar Ir(I) centers in $Ir_2(\mu\text{-}I)_2(^tBu_2PCH_2P^tBu_2)_2$.[75]



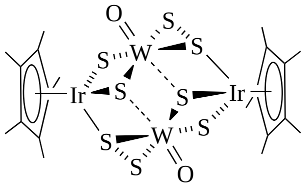
(28)

8.2 Sulfur Donor Ligands

Sulfur-containing bridges are typically S^{2-}, SR^-, or SR_2 (e.g. equation 28) (*see d–d Transitions*). Derivatives of the type $Ir_2H_2Cl_2(SAr)_2(PAr_3)_4$ (Ar = aryl) react in $CHCl_3$ to give triply bridged complexes $[Ir_2H_2(PAr_3)_4(\mu\text{-}Cl)(\mu\text{-}SAr)_2]^+$, although triple-bridge formation is not observed when PAr_3=$P(C_6H_4\text{-}4\text{-}F)_3$.[76] The reaction of $[Cp^*IrCl_2]_2$ with $(NH_4)_2[WS_4]$ and $NaBH_4$ yields the double (but incomplete) iridium(III)/tungsten(VI) cubane (**55**) in which the sulfido ligands support the framework.[77]



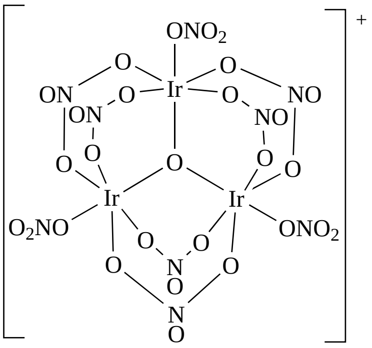
(**54**)



(**55**)

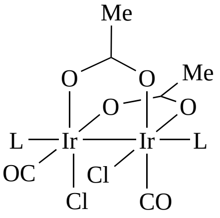
8.3 Oxygen Donor Ligands

Ligands such as carboxylate, nitrate, and sulfate ions stabilize a number of trinuclear iridium complexes.[78] Each complex contains a triangular Ir_3, supported by bridging O,O′-donor ligands and a capping (μ_3) ligand. The reaction of iridium(III) bromide with N_2O_5 gives $[Ir_3(NO_3)_9(\mu_3\text{-}O)](NO_3)$,[79] which is a deep purple, paramagnetic complex, soluble in HNO_3; it is a deliquescent solid and is hydrolyzed to $IrO_2 \cdot nH_2O$. The structure of $[Ir_3(NO_3)_9(\mu_3\text{-}O)]^+$ (**56**) has similar features to that of $[Ir_3(SO_4)_9(\mu_3\text{-}O)]^{10-}$. The blue–green salt $K_{10}[Ir_3(SO_4)_9(\mu_3\text{-}O)]\cdot H_2O$ is prepared from $Na_2[IrCl_6]\cdot 6H_2O$ by treatment with H_2SO_4 and K_2SO_4; known as 'Boisbaudron's blue salt', $K_{10}[Ir_3(SO_4)_9(\mu_3\text{-}O)]$ was originally formulated as '$K_3[Ir(SO_4)_3]\cdot H_2O$'. The $[Ir_3(SO_4)_9(\mu_3\text{-}O)]^{10-}$ anion exhibits one Ir(IV) and two Ir(III) centers. In 1906, Delépine discovered the green salt $K_4[Ir_3(SO_4)_6(H_2O)_3(\mu_3\text{-}N)]$; this complex can be formed by the reaction of $K_3[Ir(C_2O_4)_3]\cdot 4.5H_2O$ with concentrated sulfuric acid and ammonium sulfate. The structure of $(NH_4)_4[Ir_3(SO_4)_6(H_2O)_3(\mu_3\text{-}N)]$ has been determined,[80] as have the structures of related salts.[81] The terminal water ligands are quite labile and can be replaced by Cl^-, Br^-, N_3^-, OH^-, or NCS^- ligands. Acetate ligands feature in a series of complexes of the type $[Ir_3(O_2CMe)_6(\mu_3\text{-}O)L_3]^{x+}$ (Scheme 13), and structural studies include those of salts of $[Ir_3(O_2CMe)_6(\mu_3\text{-}O)(H_2O)_3]^+$.[82] The related nitrido-capped complex $[Ir_3(O_2CMe)_6(\mu_3\text{-}N)(py)_3]^+$ has been the subject of detailed electrochemical studies,[83] the results of which are compared with those of the analogous oxo-capped species.[83,84]



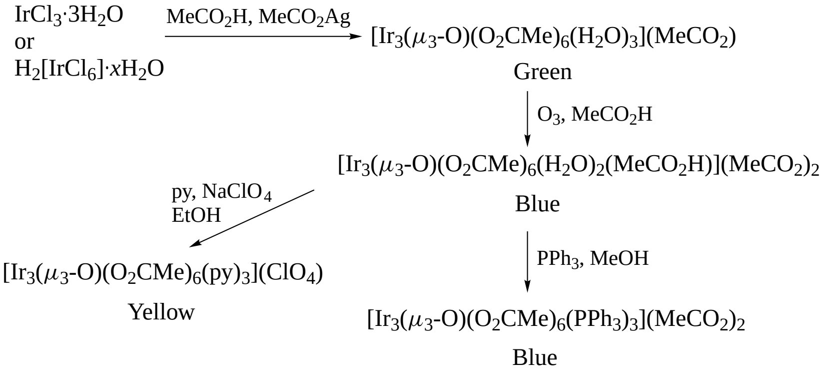
(**56**)

Carboxylate ligands also support several dinuclear complexes of iridium, for example, $[Cp^*Ir(\mu\text{-}O_2CCF_3)(\mu\text{-}H)_2IrCp^*]^+$ and $[Cp^*Ir(\mu\text{-}O_2CCF_3)_2(\mu\text{-}H)IrCp^*]^+$, which are moderately air-stable crystalline solids. The reaction of H_2IrCl_6 with $MeCO_2Li$ under O_2 in acetic acid/acetic anhydride gives $[Ir_2(\mu\text{-}O_2CMe)_2Cl_2(CO)_2]$ to which axial ligands can be added (**57**).[85]



e.g. L = MeCN, DMSO, py
(**57**)

The hydroxide ion is a well-established bridging ligand, and hydroxo-bridged complexes of iridium(III) have been reviewed.[86] Among the dinuclear iridium(I) complexes that have structures supported by OH^- ligands is $[Cp^*Ir(\mu\text{-}OH)_3IrCp^*]^+$, and closely related to this is $(cod)Ir(\mu\text{-}OPh)_2Ir(cod)$. The presence of the three OH

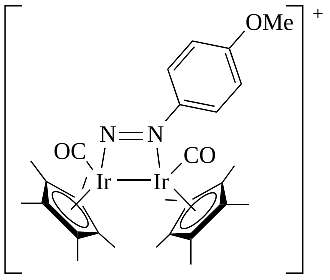


Scheme 13

units in $[Cp^*Ir(\mu\text{-}OH)_3IrCp^*]^+$ draws the Ir atoms relatively close together, for example, Ir–Ir = 3.07 Å in the hydrated acetate salt;[87] the dichromate salt displays a hydrogen-bonded 2-D–network in the solid state.[88] In Δ,Λ-$[(H_2O)(en)_2Ir(\mu\text{-}OH)Ir(en)_2(OH)]^{4+}$, the terminal OH^- ligand on one Ir atom is associated with the H_2O ligand on the second Ir atom via a hydrogen bridge.[89] This fixes the conformation of the complex. A feature of Λ,Λ-$[(H_2O)(en)_2Ir(\mu\text{-}OH)Ir(en)_2(H_2O)]^{5+}$ is that the acid dissociation constants (i.e. dissociation of H^+ from coordinated H_2O) are greater ($pK_{a1} = 1.91$) and smaller ($pK_{a2} = 9.04$) than predicted on the basis of values of pK_a for related mononuclear complexes. Equilibration between *cis*-$[Ir(NH_3)_4(H_2O)_2]^{3+}$ and *cis,cis*-$[(H_2O)(NH_3)_4Ir(\mu\text{-}OH)Ir(NH_3)_4(H_2O)]^{5+}$ and $[(NH_3)_4Ir(\mu\text{-}OH)_2Ir(NH_3)_4]^{4+}$ (and for analogous en complexes) has been studied.[90]

8.4 Nitrogen Donor Ligands

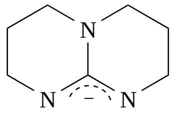
Nitrogen donor ligands supporting dinuclear complexes include amido (NR_2^-) groups, diazonato ligands, and a range of heterocyclic N-donors. The flexibility of the diazonato ligand is seen in $[Cp^*Ir(\eta^2\text{-}C_2H_4)(NNAr)]^+$.[91] Here, the diazonato ligand coordinates in a monodentate mode, but when $[Cp^*Ir(\eta^2\text{-}C_2H_4)(NNAr)]^+$ reacts with $Cp^*Ir(CO)_2$, the diazonato group converts to a bridging mode as shown in (**58**).[92]



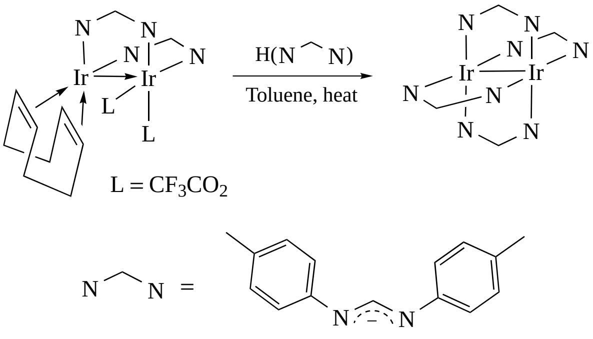
(**58**)

Pyrazoles (Hpz) react with $[Cp^*Ir(\mu\text{-}OH)_3IrCp^*]^+$ in Me_2CHOH to give $[Cp^*Ir(\mu\text{-}H)_2(\mu\text{-}pz)IrCp^*]^+$.[93] This is one of a number of ways of introducing the bridging pz ligand. An alternative route is via deprotonation of the mononuclear $IrH_2(PPh_3)_2(OCMe_2)(Hpz)$ using KOH to give $H_2(PPh_3)_2Ir(\mu\text{-}pz)Ir(PPh_3)_2H_2$. Reaction of this with HBF_4 reprotonates the bridging ligand, generating the five-coordinate $IrH_2(PPh_3)_2(Hpz)$.[94] The doubly bridged complex $(^tBuNC)_2Ir(\mu\text{-}pz)_2Ir(^tBuNC)_2$ reacts with HCl to give $[(H)Cl(^tBuNC)_2Ir(\mu\text{-}pz)_2Ir(^tBuNC)_2Cl(H)]$, which in solution loses Cl^- with concomitant movement of the remaining terminal Cl^- ligand into a bridging site.[95] When equimolar amounts of $(^tBuNC)_2Ir(\mu\text{-}pz)_2Ir(^tBuNC)_2$ and $[(MeCN)(^tBuNC)_2Ir(\mu\text{-}pz)_2Ir(^tBuNC)_2(MeCN)]^{2+}$ react together, a redox condensation occurs to yield tetranuclear, blue complexes ('iridium blues').[96]

While Rh(II) chemistry has many examples of $Rh_2(\mu\text{-}L)_4$-type complexes (e.g. $L^- = RCO_2^-$), related examples within iridium chemistry are rare. Scheme 14 shows the formation of the first example of an $Ir^{II}_2(\mu\text{-}L)_4$ complex.[97] Reaction of $IrCl_3$ with Hhpp (hpp^- = **59**) in EtOH at reflux leads to $Ir_2(\mu\text{-}hpp)_4Cl_2$ (Ir–Ir = 2.495 Å), the first 'paddle-wheel' complex with an Ir_2^{6+} core.[98]



(**59**)



Scheme 14

8.5 Phosphine Ligands Including 'A-Frame' Complexes

Many multidentate phosphorus ligands have the ability to chelate to a single metal center or bridge between two or more metal centers.[16] The ligand dppm stabilizes the so-called 'A-frame' complexes, for example, the diiridium(I) complex (**60**) in which the Ir atoms are not directly bonded. The $Ir_2(dppm)_2$ framework is quite robust; oxidative addition of H_2 leads to the formation of an Ir–Ir bond in complex (**61**). A range of related hydrido complexes is known; these and other polynuclear hydrido complexes of iridium have been reviewed[99] (*see* ***Hydride Complexes of the Transition Metals***). Heterometallic 'A-frame' complexes in which one metal is iridium are also known. By choosing appropriate ligands, the framework can be extended, for example, $Ph_2PCH_2As(Ph)CH_2PPh_2$ has a P,As,P′-donor set that has the same ligand 'bite' (*see Bite Angle*) as two adjacent dppm ligands.

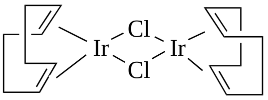
1 INTRODUCTION

The organometallic chemistry of iridium is rich in both numbers of investigations as well as in the breadth of the areas explored. Iridium complexes possess an incredible array of properties that make them ideal for quite a number of bond-breaking and bond-making reactions. On a large scale, which clearly must involve organometallic chemistry at some point, iridium has found use in petroleum refining catalysis, especially reforming.[1,2] Although rhodium has found greater application in catalysis, a great deal of attention has been focused on iridium complexes as models for the reaction chemistry of other systems since many iridium(I) and iridium(III) complexes with ligand sets similar to those proposed in rhodium chemistry can be isolated more readily. Special attention has been paid to iridium for C–H activation chemistry and the implications that chemistry has for potentially valuable catalytic applications. This article simply cannot provide an exhaustive and detailed coverage of the field of organoiridium chemistry nor can it provide much detail in those areas it does cover. Rather it will attempt to survey a few important areas in the organometallic chemistry of iridium and point the reader to sources that will provide them with further detail. (Since the chemistry of iridium closely parallels that of rhodium, the reader should also *see* ***Rhodium: Organometallic Chemistry***.) Some important monographs[3–5] and reviews[6–10] dealing with the organometallic chemistry of iridium are available. There are some journals that have had periodical reviews and surveys of the chemistry of iridium.[11–15] Excellent texts are available that cover the general aspects of the organometallic chemistry of the transition elements including iridium.[16,17] The bond-making and bond-breaking capabilities of iridium and their relevance to organic synthesis have been reviewed.[18] Where a particular area of research has been investigated in depth by a research group, several key references are provided with the expectation that additional references to that group's work can easily be found from references within those articles.

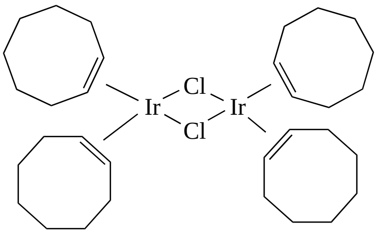
In the following sections, general classes of organoiridium compounds will be discussed followed by brief reviews of some important types of reactions involving organoiridium compounds.

2 IRIDIUM OLEFIN COMPLEXES

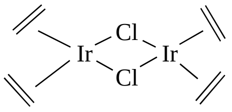
Olefin complexes (*see Alkene Complexes*) of iridium play a very important role in the organic chemistry of iridium since, in addition to being the simplest of the organic compounds of iridium to prepare, they are the starting point for the preparation of many other complexes. The two most often utilized complexes are the cyclooctadiene complex $[Ir(COD)Cl]_2$ (**1**) and the bis-cyclooctene complex $[Ir(COE)_2Cl]_2$ (**2**). Interestingly, the pricey iridium cyclooctadiene complex has made its way into the undergraduate chemistry curriculum.[19] Both of these may be prepared from either $IrCl_3{\cdot}3H_2O$ or $[NH_4][IrCl_6]$ and the olefin in refluxing alcoholic solvent.[20,21] Unlike the corresponding rhodium complex, $[Ir(C_2H_4)_2Cl]_2$ (**3**) cannot be prepared by this direct reaction but can be synthesized via (**2**). For this reaction, the first product that is formed is the mononuclear $[Ir(C_2H_4)_4Cl]$ (**4**), which is only stable at low temperatures under an ethylene atmosphere. When this is allowed to warm up, it decomposes into the red dimeric (**3**).[22] Although the rhodium norbornadiene complex may be synthesized, the norbornadiene complex of iridium cannot be prepared and the product obtained when attempting to make such a complex apparently contains norbornene fragments coupled by carbon–carbon bonds. However, the similar tetrafluorobenzobarrelene (**5**) can be used as a diolefin ligand and a rich chemistry



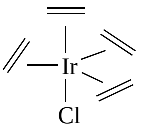
(**1**)



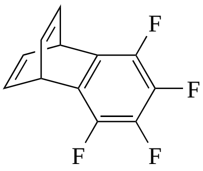
(**2**)



(**3**)



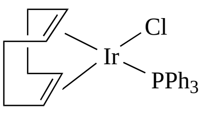
(**4**)



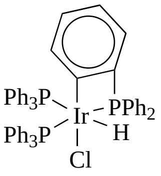
(**5**)

has been developed with iridium tetrafluorobenzobarrelene complexes.[23]

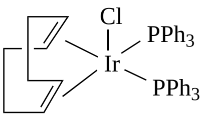
The iridium olefin complexes provide the entryways into a number of other complexes of iridium. The simplest reactions that the dinuclear complexes undergo are bridge-splitting reactions with phosphine and nitrogen donor ligands (*see* ***P-donor Ligands***). The exact nature of the product obtained depends on the ligand, the stoichiometry, and the reaction conditions employed. With large, bulky phosphines employing a 1:1 PR_3: Ir ratio at room temperature, the bridge may be split with no further reaction taking place. Thus, $[Ir(COD)Cl]_2$ (**1**) will react with one equivalent of triphenylphosphine per iridium at room temperature in hydrocarbon solvent to yield $Ir(COD)(PPh_3)Cl$ (**6**). However, if larger ratios of PPh_3 to iridium are employed at higher reaction temperatures, ''$Ir(PPh_3)_3Cl$'' is produced but rapidly converts to an orthometallated (*see Orthometalation*) form (**7**). On the other hand, if dichloromethane is employed as the reaction medium, the bis-phosphine product $Ir(COD)(PPh_3)_2Cl$ (**8**) is prepared.[24] With cold alcohol as the solvent, $[Ir(COD)(PR_3)_2]^+$ (**9**) or even $[Ir(COD)(PR_3)_3]^+$ (**10**) complexes are obtained, the number of phosphines attached dependent upon the size of the ligand.[25] If the ligand is very small, such as in the case of PMe_3, tri-substitution to form $[Ir(COD)(PMe_3)_3]Cl$ (**11**) occurs readily at room temperature even in nonpolar solvents.[26] Various tripodal tris-phosphine ligands have also been shown to attach all three phosphorus atoms providing $[Ir(COD)P_3]^+$ compounds.[26–28]



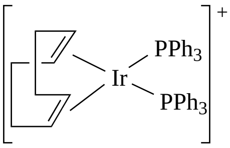
(**6**)



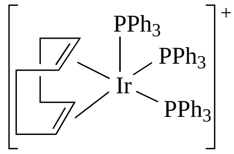
(**7**)



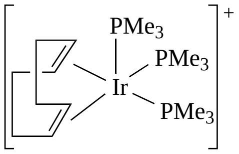
(**8**)



(**9**)

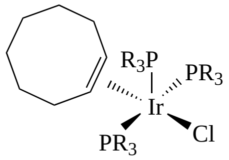


(**10**)

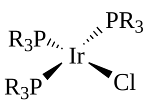


(**11**)

For the most part, displacement of the chelating COD ligand (*see Chelating Ligands*) is difficult to achieve as a simple substitution under mild conditions. So, the cyclooctene complex $[Ir(COE)_2Cl]_2$ (**2**) is typically employed as a starting material for the preparation of $[Ir(COE)(PR_3)_3]$ (**12**) or $[Ir(PR_3)_3Cl]$ (**13**) complexes.[29] In the case of $PR_3 = PMe_3$, these complexes are extremely reactive and undergo a number of oxidative addition reactions (*see Oxidative Addition*).

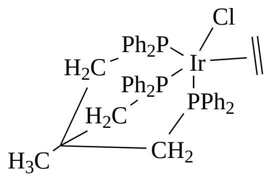


(**12**)

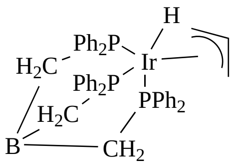


(**13**)

Bianchini's group has been investigating the chemistry of iridium with tripodal (*see Tripodal Ligand*) phosphine ligands.[30] One very interesting olefin complex, which provides a starting point for a number of their studies, is the ethylene complex $(tripod)IrCl(C_2H_4)$ (**14**) where tripod $= HC(CH_2PPh_2)_3$.[31] This particular ethylene complex has been a rich source of unusual iridium chemistry. An intriguing variant of the tripod ligand is one in which the tertiary carbon is replaced by boron yielding tripod $B = PhB(CH_2PPh_2)_3^-$. Since the ligand is overall negatively charged, iridium(I) compounds with this ligand are zwitterionic, which leads to some subtle differences in chemistry of compounds such as (**15**).[28]



(**14**)



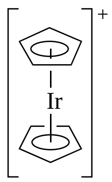
(**15**)

The reactions of iridium olefin complexes are not restricted to reactions with phosphines. Amines have also employed in bridge-splitting and substitution reactions with $[Ir(COD)Cl]_2$, especially chelating diamines. The reactions proceed to yield $[Ir(COD)N–N]_2$ compounds.[32] A fertile chemical area involves the *tris*(pyrazolyl)borate (*see Tris(pyrazolyl)borates*) family of compounds with the monoethylene and bisethylene complexes serving as reactive entries in this field.[33–37]

The bridging chloride ligands in these $[Ir(olefin)_2Cl]_2$ compounds are susceptible to metathesis reactions, yielding new dimeric compounds of the form $[Ir(olefin)_2B]_2$ where 'B' represents a new bridging ligand. Alkoxides, thiolates, and carboxylates have all been employed successfully in the replacement of chloride. The complexes with B = Br, I have also been prepared, both by metathesis reactions and by direct reaction of cyclooctene or cyclooctadiene with $IrBr_3$ or IrI_3.[22] The olefin complexes also provide excellent starting materials for the syntheses of arene and cyclopentadienyl iridium complexes, a subject that will be discussed in the next section.

3 IRIDIUM ARENE (*See Arene Complexes*) AND CYCLOPENTADIENYL (*See Cyclopentadienyl*) COMPLEXES

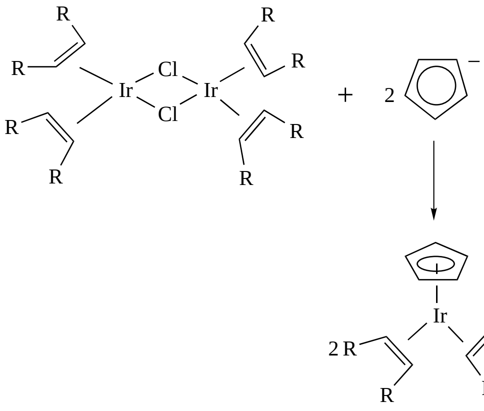
In this section, the syntheses and some chemistry of two important classes of π-ligand complexes of iridium are described (*see* ***Organic Synthesis using Transition Metal Complexes Containing π-Bonded Ligands***).



(**16**)

3.1 Cyclopentadienyl Complexes

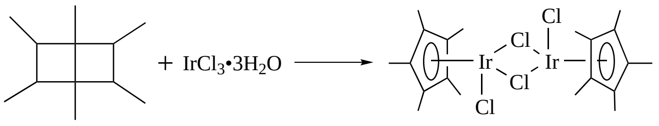
Historically, pentahapto (*see Hapticity*) cyclopentadienyl complexes of iridium have been a very popular area for research, with many examples of cyclopentadienyl and substituted cyclopentadienyl compounds having been synthesized. The iridium analog of cobaltacinium, $[Cp_2Ir]^+$ (**16**), may be prepared via the reaction between a suitable iridium(III) precursor such as $IrCl_3$ and cyclopentadienyl magnesium chloride. Other ring substituted derivatives have also been prepared, but attempts to prepare neutral iridacene have been unsuccessful. More commonly investigated are the mono-cyclopentadienyl or half-sandwich (*see Half-sandwich Complexes*) complexes of iridium. Again, using $[Ir(olefin)_2Cl]_2$ complexes as starting materials, reactions with cyclopentadienylating reagents lead to the formation of $CpIr(olefin)_2$ compounds (**17**) (equation 1). These may be used to synthesize additional compounds via substitution of the olefin ligands, but in general this substitution is sluggish and forcing conditions are required in order to carry out these substitutions. A better route to substituted CpIr complexes is via the $[CpIrCl_2]_2$ family of compounds.



(**17**)

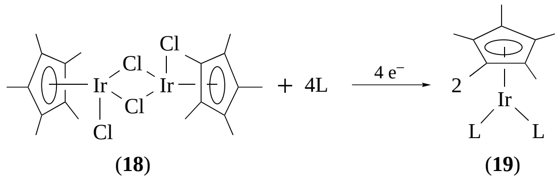
(1)

Initially, $[Cp^*IrCl_2]_2$ (**18**) was synthesized via the reaction between hexamethyldewarbenzene and $IrCl_3{\cdot}H_2O$ (equation 2).[38] However, a more convenient and efficient synthesis is via direct reaction between pentamethylcyclopentadiene and $IrCl_3{\cdot}H_2O$.[39] The chloride bridge may then be split with donor ligands such as phosphines to yield $Cp^*Ir(PR_3)Cl_2$ compounds. The chloride ligands may then be replaced by alkyl or hydrido groups in further transformations. Reduction of (**18**) in the presence of CO and other donors will produce the iridium(I) bis-ligand complexes (**19**) (equation 3). Using a combination of the above reactions, quite a variety of half-sandwich (*see Half-sandwich Complexes*) iridium complexes may be synthesized.[40]



(**18**)

(2)



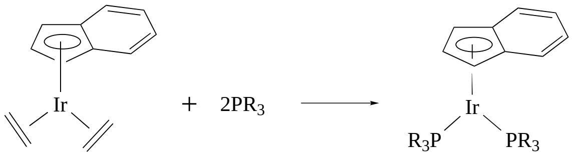
(**18**) (**19**)

(3)

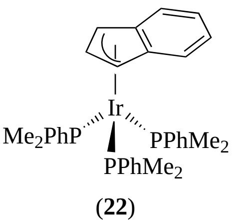
From $[Cp^*IrCl_2]_2$, removal of the chloride ligands in the presence of weakly coordinating solvents leads to the production of a host of $[Cp^*IrS_3]^{2+}$ compounds that provide an easy entry into the chemistry of the Cp^*Ir^{2+} fragment as well as an excellent starting material for other Cp*Ir complexes.[41] A very large body of work has been added to this field by the Maitlis group.[42–44]

An interesting variant in the family of cyclopentadienlyiridium complexes are those containing η^5-indenyl ligands. It had been shown by Mawby and coworkers that indenyl metal complexes are far more reactive with respect to ligand substitution chemistry than their cyclopentadienyl analogues.[45] Basolo quantified this greatly accelerated reaction chemistry for a number of indenyl metal systems and dubbed this acceleration the 'indenyl effect'.[46–48] The indenyl effect also appears to play an important role in the chemistry of indenyl iridium complexes. Indenyliridium complexes may be prepared in much the same way as the cyclopentadienyl and pentamethylcyclopentadienyl iridium complexes. However, once formed, they are far more reactive in terms of substitution chemistry.

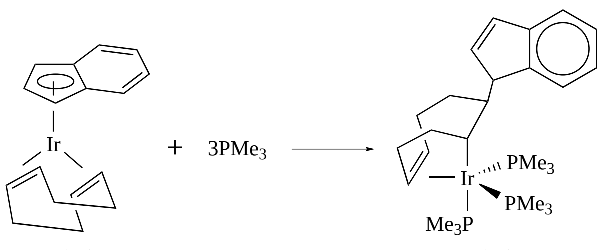
For example, $CpIr(C_2H_4)_2$ only reacts with phosphines at elevated temperatures for long reaction times to produce $CpIr(PR_3)_2$ complexes. On the other hand, $IndIr(C_2H_4)_2$ (**20**) reacts with phosphine ligands rapidly at room temperature to produce $IndIr(PR_3)_2$ (**21**) (equation 4). In this area, the first example of an η^5 to η^3 ring-slip (*see Slip Processes in Ligands*) transformation was demonstrated and the crystal structure of η^3-$IndIr(PMe_3)_3$ (**22**) has been reported.[49] Perhaps one of the more unusual manifestations of the reactivity of the indenyl ligand was found in the chemistry of IndIr(COD) (**23**). Here, reaction with PMe_3 led to the displacement of the indenyl ligand (as indenide) from the iridium followed by nucleophilic attack of the indenide on the coordinated COD yielding the unusual cyclooctenyl structure (**24**) shown (equation 5).[50] (See Section 7 of this article on an important utilization of the indenyl effect in C–H activation chemistry.)



(**20**) (**21**) (4)



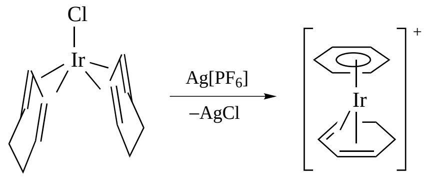
(**22**)



(**23**) (**24**) (5)

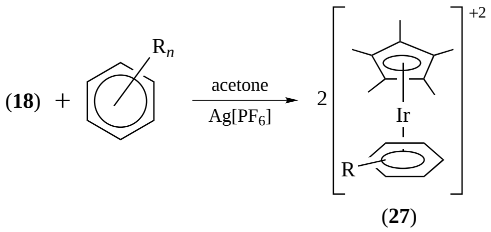
3.2 Arene Complexes

Sandwich (*see Sandwich Compound*) and half-sandwich (*see Half-sandwich Complexes*) complexes of iridium may also be readily prepared by the reaction of an arene with an iridium complex possessing three labile ligands.[51,52] So, $[Ir(COD)]^+$ (solvated) will react with an arene to form $[Ir(COD)(arene)]^+$ through displacement of the loosely bound solvates. Iridium may also catalyze the disproportion of cyclohexadiene to cyclohexene and in the process produce an arene complex. Thus, $IrCl(1,3\text{-}C_6H_8)_2$ (**25**) will undergo a transformation to $[Ir(\eta^6\text{-}C_6H_6)(h^4\text{-}C_6H_4)]^+$ (**26**) upon removal of the chloride by Ag^+ (equation 6).[44] The coordinated benzene can then be displaced by other arenes providing a route to additional arene complexes. Crabtree also discovered that arene complexes may be obtained from an iridium system active for the dehydrogenation of alkanes when a C_6 cycloalkane capable of converting into an arene was used as the substrate.[53–55] Arene compounds with three very loosely solvated ligands may be prepared from $[(Arene)IrCl_2]_2$ compounds via the removal of chloride in the presence of weekly coordinating ligands.[56]



(**25**) (**26**) (6)

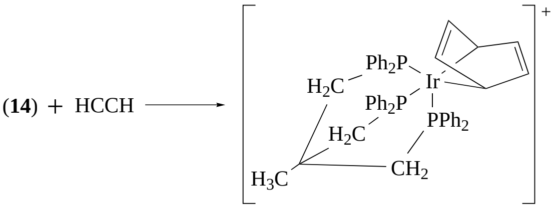
More commonly encountered are the arene complexes also containing Cp or Cp* ligands. Since $[Cp^*IrCl_2]_2$ (**18**) may be prepared so readily (see above), this provides a useful starting material for the formation of $[Cp^*Ir(\eta^6\text{-}arene)]^{+2}$ compounds.[40] (**18**) may be easily converted into $[Cp^*Ir(acetone)_3]^{+2}$ by dissolution in acetone and treatment with $Ag[PF_6]$. Maitlis has shown in a number of cases that this dication will then react with a variety of arenes including benzene, toluene, xylene, and naphthalene to yield arene complexes (**27**) by displacement of the acetones (equation 7). Maitlis has also used $[Cp^*Ir(OAc)_2(OH_2)]$ and $[Cp^*Ir(NCCH_3)_3]^{+2}$ as sources of iridium.



(**27**) (7)

Arenes bound to iridium are susceptible to nucleophilic attack to form first cyclohexadienyl and then cyclohexadiene complexes. For example, Maitlis showed that $[Cp^*Ir(\eta^6\text{-}toluene)]^{+2}$ reacts with $NaBH_4$ yielded the cyclohexadiene

complex with H attack always occurring exo. Treatment of the cyclohexadiene complex with HCl liberated the organic fragment as cyclohexene. Bianchini and Caulton *et al.* have shown that reaction between (triphos)Ir(Cl)(C_2H_4) (**14**) and acetylene in the presence of Tl[PF_6] yields an η^4-benzene complex (**28**) via cyclotrimerization (*see Cyclodimerization & -trimerization Reactions*) of the alkyne (see Section 4) (equation 8).[57] In a series of H^+, H^- addition sequences, it was shown that the η^4-benzene can be reduced to cyclohexene.[58] Arene iridium complexes have been exploited for their catalytic activity.[59,60]



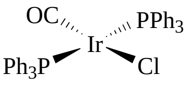
(8)

(**28**)

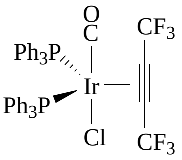
Heteroatom containing arenes have also been made to complex with transition metals, including iridium. For example, borabenzene has been shown to complex to iridium and iron in a single complex.[61]

4 IRIDIUM ALKYNE AND RELATED COMPLEXES (*See Alkyne Complexes*)

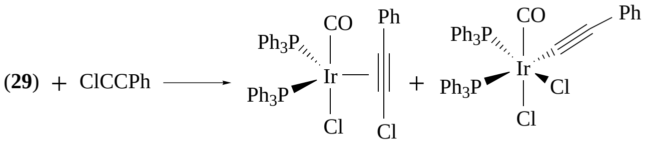
Simple alkyne adducts of iridium may be readily formed with a variety of ancillary ligands.[62] Reaction between Vaska's compound Ir(CO)Cl(PPh_3)$_2$ (**29**) (*see Vaska's Complex*) and electron-deficient alkynes results in the formation of simple adducts. For example, (**29**) and $F_3CC{\equiv}CCF_3$ react to form Ir(CO)Cl(PPh_3)$_2$($F_3CC{\equiv}CCF_3$) (**30**). With chlorophenylacetylene there is a competition between making the simple adduct Ir(CO)Cl(PPh_3)(ClC≡CPh) (**31**) and forming an acetylide complex (**32**) via oxidative addition of the C–Cl bond (equation 9). Werner has prepared trans-[IrCl(RC≡CR)(PPr^i_3)$_2$] complexes (**33**) (R = H, Me, Ph) from the reaction of the alkyne with [IrCl(PPr^i_3)$_2$] prepared in situ. Further reaction of these alkyne complexes with Cp^- leads to the formation of CpIr(RC≡CR)(PPr^i_3) (**34**) compounds (equation 10).[63]



(**29**)

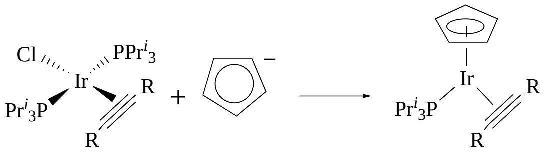


(**30**)



(**31**) (**32**)

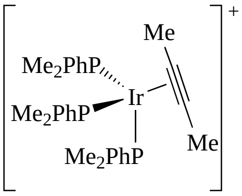
(9)



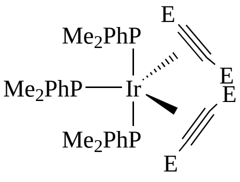
(10)

(**33**) (**34**)

The interaction of alkynes with iridium hydride complexes can lead to a number of different alkyne complexes. Reaction between two equivalents of 2-butyne and [$IrH_4(PPhMe_2)_3$]$^+$ produces one equivalent of butene and the butyne complex [Ir(MeC≡CMe)($PPhMe_2$)$_3$]$^+$ (**35**) with a structure that differs from the expected square planar. Reaction between the same iridium complex and dimethylacetylenedicarboxylate produces a bis-alkyne complex (**36**).[64,65]

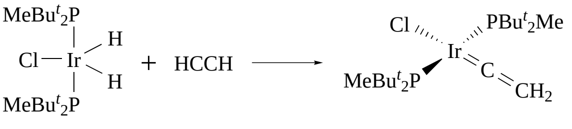


(**35**)



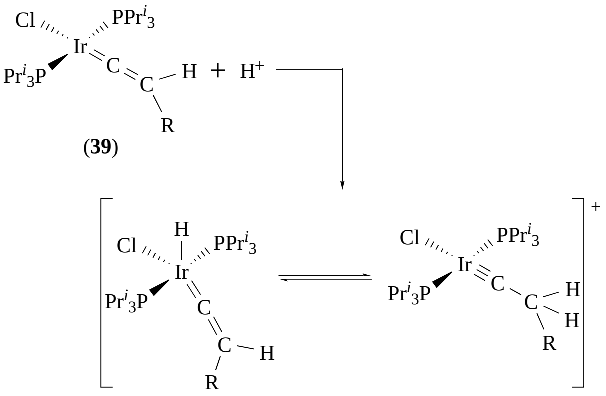
(**36**) E = CO_2Me

When the alkyne is a terminal one, a common reaction path is the formation of a vinylidene iridium complex. Werner's group has extensively studied the chemistry of iridium with bulky phosphine ligands and their ability to form vinylidene complexes. For example, the reaction between $IrH_2Cl(PMeBu^t{}_2)_2$ (**37**) and acetylene yields the vinylidene complex Ir(C=CH_2)Cl($PMeBu^t{}_2$)$_2$ (**38**) (equation 11).[66,67] The square-planar vinylidene complexes IrCl(C=CHR)($PPr^i{}_2$)$_2$ (**39**) were also prepared by Werner's group. A particularly interesting discovery was that these square-planar vinylidene complexes are quantitatively protonated to form [HIrCl(C=CHR)(PPr^i_2)$_2$]$^+$ (**40**) species, which appear to be in equilibrium with the corresponding iridium carbyne complexes [IrCl(CCH_2R)($PPr^i{}_2$)$_2$]$^+$ (**41**) (equation 12).[68]



(11)

(**37**) (**38**)

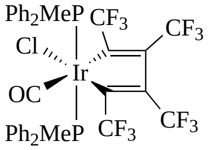


(39)

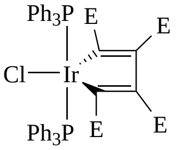
(40) (41)

(12)

Coupling of multiple alkynes at one iridium center can proceed through any one of quite a number of different reaction paths. In some cases, alkynes react with iridium complexes to undergo cyclotrimerization to form arenes. Such a reaction was discussed above concerning the formation of the η^4-benzene complex (**28**).[57] In general, the iridium compounds are not as reactive as some metals for the cyclotrimerization reaction, but the stability of various intermediates along the way has made these systems valuable for studying the steps involved. Common among these reactions is oxidative coupling (*see Oxidative Coupling*) of alkynes to yield iridacyclopentadiene complexes. For example, $Ir(CO)Cl(PMePh_2)_2$ reacts with $F_3CC{\equiv}CCF_3$ to yield metallacycle (**42**, *see Metallacycle*) while $Ir(CO)Cl(PPh_3)_2$ reacts with dimethylacetylene dicarboxylate to form metallacyclopentadiene (**43**).

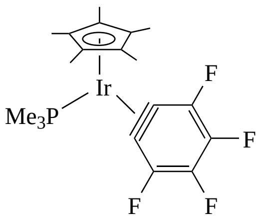


(**42**)



(**43**) $E = CO_2Me$

Metal compounds are often used to stabilize reactive organic fragments via complexation and intriguing ‘alkyne’ ligand in this classification is benzyne. A series of iridium benzyne complexes has been made with compound (**44**) as an example and the reaction chemistry of coordinated benzyne has been explored.[69–71]



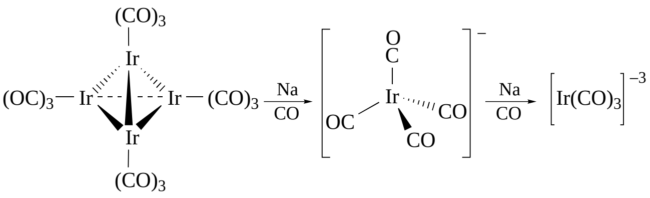
(**44**)

5 IRIDIUM CARBONYL COMPLEXES

The carbonyl complexes of iridium have perhaps not been as extensively studied as those of some other metals (*see* ***Carbonyl Complexes of the Transition Metals***; ***Carbonylation Processes by Homogeneous Catalysis***, and ***Organic Synthesis using Transition Metal Carbonyl Complexes***). Nevertheless some interesting findings in this area both in terms of structure and reactivity have been reported.

5.1 Mononuclear Carbonyl Complexes (*See Metal Carbonyls*)

Several mononuclear carbonyl complexes may be synthesized with iridium(I), but most intriguing of those are the binary carbonyls. $[Ir(CO)_4]^-$ (**46**) may be synthesized by the reduction of $Ir_4(CO)_{12}$ (**45**) with sodium under an atmosphere of carbon monoxide. More vigorous reduction of (**45**) with sodium can also yield the very reactive trianion, $[Ir(CO)_3]^{3-}$ (**47**) (equation 13). These anions may then be used for the synthesis of other mono and polynuclear (*see Polynuclear Complexes*) carbonyl compounds of iridium.

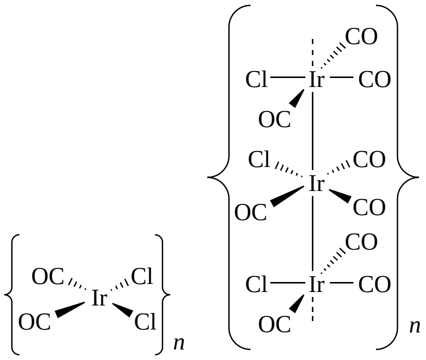


(**45**) (**46**) (**47**)

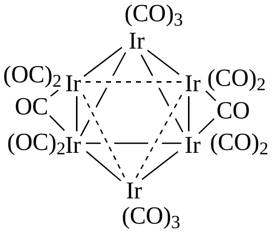
(13)

Chloro- and other halo- containing carbonyl compounds of iridium may also be synthesized under mild conditions. Unlike $[Rh(CO)_2Cl]_2$, $[Ir(CO)_2Cl]$ is not obtainable by the direct reaction of an iridium chloride solution with CO. Instead, $[Ir(CO)_2Cl_2]_n$ (**48**) is obtained in low yields by reaction between $IrCl_3{\cdot}H_2O$ and carbon monoxide. The predominant mononuclear compound obtained upon carbonylation of iridium chloride salts is the tricarbonyl $[Ir(CO)_3Cl]_n$ (**49**), which appears in the solid state to be a polymeric array consisting of stacking square-planar $Ir(CO)_3Cl$ units with short Ir–Ir bonds. Even though $[Ir(CO)_3Cl]_n$ is polymeric, it is sublimable and is still a convenient source of iridium(I) containing carbon monoxide. (**49**) will react with a number of nucleophiles to form mononuclear iridium carbonyl complexes.

The arena of mononuclear carbonyl complexes of iridium is dominated by Vaska’s compound,[72] $[IrCl(CO)(PPh_3)_2]$ (**29**), and its variants. The most common variation found in the literature comes from replacement of the chloride ligand with other monoanionic ligands such as halides and pseudohalides. Infrared spectroscopy has been used (by examining

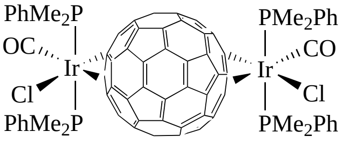


(48) (49)



(51)

ν_{CO}) to determine the electron donor/acceptor properties of various X ligands in $[IrX(CO)(PPh_3)_3]$ compounds. In addition, it is possible to replace the PPh_3 ligands by other phosphine donors thereby widely extending the range of these compounds that can be synthesized. By far the largest number of investigations into the reaction chemistry of Vaska-type compounds delved into their oxidative addition reactions. A large number of X–Y bonds have been added to iridium including C–Br, C–I, H–Cl, H–Br, H–I and H–H. In addition, O_2 adds to Vaska's complex to form a stable O_2 adduct. Because of the relative ease with which oxidative addition reactions take place with the iridium(I) center in Vaska-type complexes, these complexes have been used extensively to model reactions where the oxidative addition step is believed to be an important one. One indication of the reactivity of Vaska-type compounds is a reaction between C_{60} (fullerene, *see Buckminsterfullerene*) and $Ir(CO)Cl(PMe_2Ph)_2$ to yield a C_{60} core with two $Ir(CO)Cl(PMe_2Ph)_2$ moieties bound (**50**) with similar unusual chemistry with C_{70}.[73–75]



(**50**)

Although there is no stable free S analog of CO, nevertheless, several CS compounds of iridium have been synthesized by multistep methods and their reaction chemistry has been investigated.[76–80]

5.2 Polynuclear Iridium Carbonyl Clusters (*See Metal Carbonyl Clusters*)

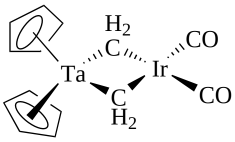
Because of the great strength of iridium–iridium bonds, there is a wealth of information on polynuclear metal-carbonyl cluster compounds of iridium (*see* ***Dinuclear Organometallic Cluster Complexes*** and ***Polynuclear Organometallic Cluster Complexes***). $Ir_4(CO)_{12}$ (**45**) may be synthesized from $IrCl_3{\cdot}H_2O$ via reduction with zinc metal under a carbon monoxide atmosphere. A number of other syntheses involving both high pressures of carbon monoxide as well as involving atmospheric pressures of carbon monoxide have been reported. $Ir_4(CO)_{12}$ (**45**) is a yellow–orange air stable molecule with a tetrahedral arrangement of iridium atoms with only terminal carbonyl ligands.[81,82] $Ir_4(CO)_{12}$ (**45**) serves as a starting point for a number of other cluster compounds of iridium such as $Ir_6(CO)_{16}$ (**51**) via reductive routes. Each of these clusters is susceptible to ligand substitution chemistry not only by phosphines but also by a large number of other neutral and anionic nucleophiles. Higher nuclearity clusters of iridium have been formed including a heptanuclear cluster, $[Ir_7(CO)_{12}(COD)(C_6H_{11})]$ (**52**) and the octanuclear clusters $[Ir_8(CO)_{22}]^{-2}$ (**53**) and $[Ir_8(CO)_{20}]^{-2}$ (**54**). Garlaschelli and coworkers have reported on extensive investigations into the chemistry of $Ir_6(CO)_{16}$ (**51**) as well as that of $[Ir_6(CO)_{15}]^{-2}$ (**52**). In one reaction they find a nonanuclear cluster, $[Ir_9(CO)_{20}]^{3-}$ (**53**), as a by-product.[83] The same group reported on the structure of $[Ir_{11}(CO)_{23}]^{3-}$ (**54**).[84]

An interesting variant in the study of iridium carbonyl cluster compounds comes from studies on inorganic surfaces. From one direction, there have been studies involving the preparation of catalysts by the deposition of discrete metal-carbonyl clusters (*see* ***Heterogeneous Catalysis by Metals***). The deposition of $Ir_4(CO)_{12}$ on SiO_2 yields a catalyst for the isomerization of 1,5-cyclooctadiene. Infrared spectroscopy and thermal analysis have been used to study the nature of the species generated when $Ir_4(CO)_{12}$ is adsorbed onto SiO_2 and MgO. Yet another twist on the supported metal-cluster area is the use of $AlCl_3$/NaCl melts containing $Ir_4(CO)_{12}$. The subject of metal clusters on zeolites has been reviewed.[85]

From the other directions, there have been a number of studies of the cluster species that are formed when mononuclear iridium precursors are deposited onto inorganic supports and then subjected to carbon monoxide pressures. Gates and coworkers have shown that $Ir(CO)_2(acac)$ will form higher nuclearity iridium carbonyl clusters, the exact nature of which depends on the substrate and the carbonylation conditions.[86,87] For zeolite NaY, they have observed that $Ir(CO)_2(acac)$ will yield both $Ir_4(CO)_{12}$ (**45**) and $Ir_6(CO)_{16}$ (**51**). Using zeolite NaX, they find that the predominant species that may be removed from the zeolite is $[Ir_6(CO)_{15}]^{-2}$ (**52**). On the other hand, $Ir(CO)_2(acac)$ (**55**) on MgO

typically yields $[HIr_4(CO)_{11}]^-$ (**56**) and $[Ir_8(CO)_{22}]^{-2}$ (**57**). Deposition of $IrCl_3$ onto MgO apparently yields only $[Ir(CO)_3Cl]_n$ (**49**) upon carbonylation while silica gel can be used for the syntheses of a number of carbonyl clusters.[88]

Mixed-metal clusters containing iridium also have been formed combining iridium with a number of other metals such as rhodium, rhenium, nickel, copper, and gold. A variety of structures have been reported from these studies. The most unusual of 'mixed-metal' complexes involving iridium are those that contain an 'early-late' metal combination. A driving force for the syntheses of such compounds is the potential synergistic effect of having an electron-deficient (*see Electron Deficient Compound*), Lewis-acidic metal (*see Lewis Acids & Bases*) in combination with an electron-rich, Lewis-basic metal (*see Lewis Acids & Bases*) for unusual organic transformations. A methylene bridged tantalum–iridium carbonyl compound (**58**) has been reported by Bergman and it has very interesting catalytic properties.

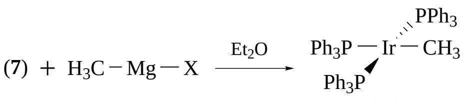


(**58**)

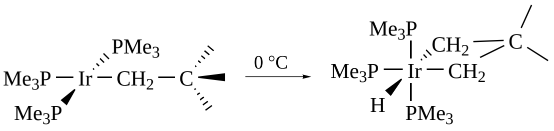
6 IRIDIUM ALKYL (*See Alkyl Complexes*) AND ARYL COMPLEXES

6.1 Iridium(I)

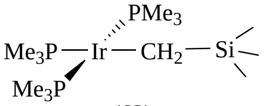
In general, iridium(I) alkyl complexes are easily prepared via the reaction between an iridium halide and a suitable alkylating or arylating reagent, the stability of the complex depending on the nature of the other ligands on iridium. $H_3C–Ir(PPh_3)_3$ (**59**) may be prepared by treating $IrCl(PPh_3)_3$ (**7**) with H_3CMgX (equation 14) but is not very thermally stable decomposing via a presumed radical pathway. $(Me_3P)_3IrCH_2C(CH_3)_3$ (**60**) is stable at −20 °C but decomposes rapidly at 0 °C to form a cyclometallated (*see Cyclometalation*) product (**61**) (equation 15). The analogous silyl compound, $(Me_3P)_3IrCH_2Si(CH_3)_3$ (**62**), is somewhat more stable but still cyclometallates at room temperature.[89–91]



(**59**) (14)

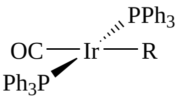


(**60**) (**61**) (15)



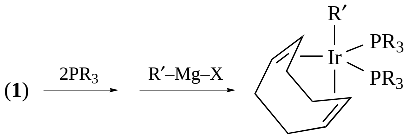
(**62**)

Treatment of $Ir(CO)Cl(PPh_3)_2$ (**29**) with alkyl or aryl grignard reagents produces the corresponding alkyl or aryl iridium complexes $R–Ir(CO)(PPh_3)_2$ (**63**). These compounds are substantially more stable than the fully phosphinated alkyl iridium compounds. The stability of these compounds also increases in the order aryl > alkyl with the fluoro substituted aryl complexes being the most stable.



(**63**) R = alkyl, aryl

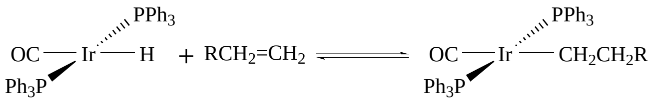
Alkyl complexes with both phosphine ligands and COD have been extensively studied, especially their dynamic processes (*see* ***Stereochemical Nonrigidity of Organometallic Complexes***) in solution. Treating $[Ir(COD)Cl]_2$ (**1**) with two equivalents of PR_3 per iridium followed by an equivalent of an alkyl grignard reagents leads to the formation of $R–Ir(COD)(PR_3)_2$ (**64**) complexes (equation 16). These compounds appear to be quite stable, especially for R = CH_3 and CH_2Ph. A number of structural studies on these compounds were carried out by Churchill and coworkers showing them to be trigonal bipyramidal molecules. Shapley and Osborn studied their dynamic NMR processes and found them to be consistent with Berry pseudo-rotation.



(**64**) (16)

Alkyl iridium compounds are also accessible via insertion (*see Migratory Insertion*) of alkenes into Ir–H bonds. Analogously, alkenyl iridium compounds may be formed via insertion of alkynes into Ir–H bonds. These types of reactions have been studied to shed light on the mechanism of alkene and alkyne hydrogenation processes. For example, $HIr(CO)(PPh_3)_2$ (**65**) will react with ethylene and higher olefins to produce the alkyl iridium compounds (equation 17).

These are reversible reactions with β-hydride elimination (*see β-Hydride Elimination*) competing with insertion and the alkyl complexes are generally only stable in the presence of excess olefin.



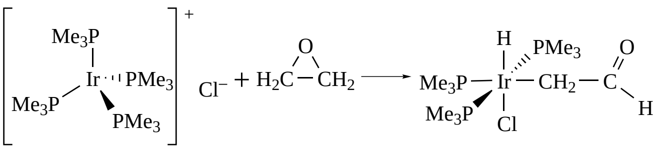
(**65**)

(17)

6.2 Iridium(III)

There are quite a number of routes available for the production of iridium(III) alkyl compounds. In addition to the halide displacement and olefin insertion pathways noted above for iridium(I) compounds, oxidative addition of C–H bonds to iridium(I) to form iridium(III) hydrido alkyl complexes is also a possibility. This subject will be covered in detail in Section 9 and will not be discussed here. However, there are other oxidative addition routes that lead to the formation of iridium(III) alkyls. First, oxidative addition of O_2 or HCl to some alkyl and aryl iridium(I) complexes can produce iridium(III) alkyl or aryl compounds. In some cases, $HgCl_2$ can add, but this appears to lead to tractable products only for the very stable pentafluorophenyl complex. Of course, oxidative addition (*see Oxidative Addition*) of alkyl halides such as H_3CI will also yield alkyl iridium(III) compounds. Addition of MeI to Vaska's compound yields a stable iridium(III) complex, but addition of EtI does not produce a stable compound, presumably due to subsequent β-hydride elimination (*see β-Hydride Elimination*). A number of mechanistic studies have been done on the oxidative addition of alkyl halides to iridium(I), especially Vaska's complex (*see Vaska's Complex*).

$[Ir(PMe_3)_4]Cl$ (**66**) is a very reactive iridium(I) species, which undergoes oxidative addition reactions with a number of substrates. Reactions between (**66**) and ethylene oxide remarkably lead to the formation of formylmethyl iridium(III) complex (**67**) (equation 18).[92]



(**66**) (**67**)

(18)

The synthesis of iridium(III) alkyl and aryl compounds via nucleophilic displacement is straightforward starting from a suitable L_3IrX_3 complex with X most commonly being chloride. Chatt and Shaw carried out early work on the syntheses of iridium(III) alkyl complexes showing that fac$[IrMe_3(PR_3)_3]$ (**69**) could be formed by reaction between $[IrCl_3(PR_3)_3]$ (**68**) and methyl grignard (equation 19). The homoleptic (*see Homoleptic Compound*) metal aryl and alkyl compounds have also been described. Reaction of $IrCl_3$(THT) (**70**) (THT = tetrahydrothiophene) with mesitylmagnesium bromide yields the tris-mesityliridium complex (**71**) free of other ligands (equation 20).[93] Reaction of (**70**) with methyllithium followed by addition of (tetramethylethylenediamine) TMEDA yields the hexamethyliridium(III) complex (**72**) (equation 21).[94]

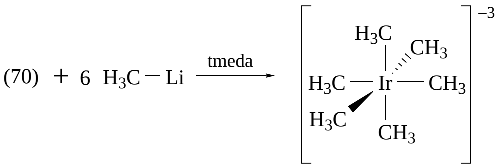
(**70**)

(**71**)

(20)



(**72**)

(21)

6.3 Iridium(V) Complexes

As a third-row transition element, iridium does have a propensity to attain higher oxidation states than the first and second row congeners. Thus, it is possible to isolate and study a variety of Ir(V) alkyl compounds.[93,95]

6.3.1 Iridium Fullerene Complexes

With the discovery of C_{60} and other fullerenes (*see* ***Carbon: Fullerenes***), it was not long before investigations into the possible reactions of fullerenes and iridium complexes were undertaken. Quite a variety of exohedral iridium fullerene compounds have been characterized including complexes of

C_{60}, C_{70}, C_{84} and nanotubes.[96–98] An example of such a complex was shown earlier in compound (**50**).

7 IRIDIUM CARBENE AND CARBYNE (*See Carbyne Complexes*) COMPLEXES[99–101]

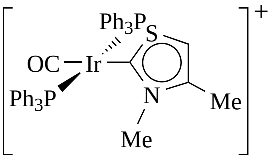
Carbene and related complexes have been shown to be important players in a number of catalytic processes, including olefin metathesis (*see* ***Organic Synthesis Using Metal-mediated Metathesis Reactions***). The following briefly surveys some of the structural types found in iridium chemistry.

7.1 Mononuclear Systems[102]

An early synthesis of an iridium carbene complex (**74**) involved the three fragment oxidative addition reaction of $[Me_2NHCl]Cl$ with $Ir(N_2)(Cl)(PPh_3)_2$ (**73**) (equation 22). A related complex containing a thiazolidinylidene ligand (**75**) has also been synthesized, although in this case it is unclear how much carbene character the Ir–C bond possesses. Lappert and coworkers performed a number of studies on the reactions between electron-rich alkenes and iridum complexes that yielded iridium carbene complexes. A sulfur stabilized carbene complex of iridium may be prepared via the alkylation of an iridium thiocarbonyl (*see Thiocarbonyl*) compound with MeI. A dichlorocarbene complex was prepared by Roper's group via the reaction between $IrHCl_2(PPh_3)_3$ and $Hg(CCl_3)_2$.

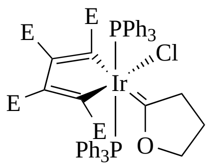
(**73**) (**74**)

(22)

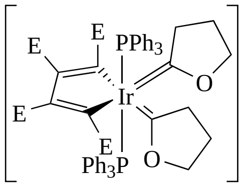


(**75**)

Another route to heteroatom stabilized carbenes involves first the interaction of a terminal alkyne with an iridium complex to yield an iridium vinylidene compound. The vinylidene complex then reacts with nucleophiles, typically alcohols, to form oxa stabilized carbene complexes. O'Connor extended this strategy to form a carbene ligand on the same iridium center as a metallacycle (**76**)[103] and was also able to

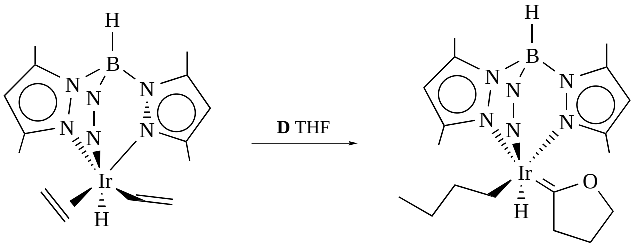


(**76**) E = CO_2Me



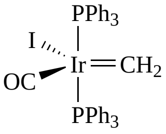
(**77**) E = CO_2Me

synthesize a bis-carbene complex of iridium (**77**).[104] Carmona and coworkers have reported that similar cyclic carbene ligands may be prepared from $Tp^*Ir(H)(CH{=}CH_2)(C_2H_4)$ (**78**) (where Tp^* = tris-(3,5-dimethylpyrazolyl)borate) and THF, where a double C–H activation is invoked to account for the formation of the carbene complex (**79**) (equation 23).[105]



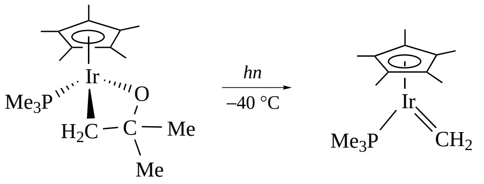
(**78**) (One pyrazolyl ring removed for clarity) (**79**)

(23)



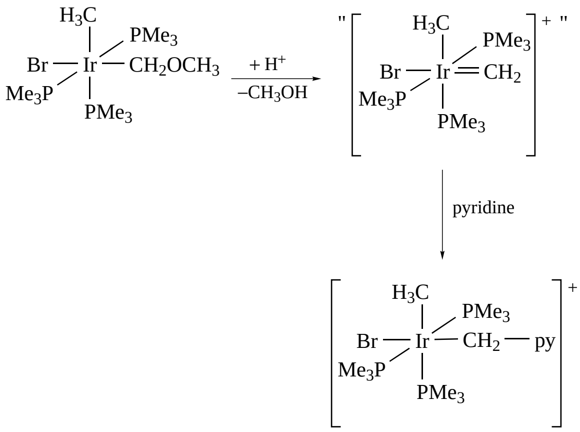
(**80**)

Unsubstituted iridium carbene complexes have been formed in several different ways. Roper found that addition of diazomethane to $IrI(CO)(PPh_3)_2$ yielded the terminal methylene complex $Ir(CH_2)(I)(CO)(PPh_3)_2$ (**80**). Bergman and Klein prepared $Cp^*Ir(PMe_3)(CH_2)$ (**82**) via photolysis of an oxametallacycle of iridium (**81**), but this is only stable in solution below −40 °C (equation 24). Although it was not isolated, a terminal methylene complex of iridium was prepared by Thorn from the reaction between $MeIrBr(CH_2OMe)(PMe_3)_3$ and H^+ and trapped by pyridine to form (**83**) (equation 25).[106]



(**81**) (**82**)

(24)

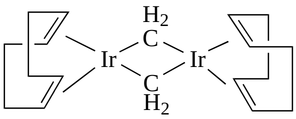


(25)

(**83**)

7.2 Polynuclear Compounds

Complexes with bridging carbene or carbyne ligands have been prepared with the ligands bridging a number of different metals (*see* ***Dinuclear Organometallic Cluster Complexes*** and ***Polynuclear Organometallic Cluster Complexes***). F. G. A. Stone and coworkers have published numerous papers on bridging carbene and carbyne ligands in polynuclear compounds. The simplest complex containing methylene bridging two iridium centers would appear to be (COD)Ir(μ-CH_2)$_2$Ir(COD) (**84**) formed by reaction between $[Ir(COD)Cl]_2$ and methyllithium.[107]



(**84**)

8 CATALYSIS (*See Catalysis*)

Results from studies on organoiridium compounds have made significant contributions in the area of catalysis. In some transformations, organometallic iridium compounds are the most active catalysts available. In others, where iridium may not yield the most active catalysts, iridium complexes nevertheless yield important information about the structure and reactivity of important catalytic intermediates. The following sections attempt to briefly cover some of the most important homogeneous catalytic process where iridium chemistry has had some impact.

8.1 Hydrogenation[108,109]

Since iridium(I) readily undergoes oxidative addition with H_2, studying hydrogenation catalysis with iridium complexes was a natural progression (*see* ***Hydrogenation & Isomerization of Alkenes*** and ***Hydride Complexes of the Transition Metals***). Vaska's complex has been shown to be an active catalyst for the hydrogenation of unsaturated compounds. While there have been numerous studies of hydrogenation with iridium catalysts, the most active catalysts are formed via the hydrogenation of cationic $[Ir(COD)L_2]^+$ complexes in noncoordinating solvents. This process yields highly coordinatively unsaturated iridium complexes that are among the most active for olefin hydrogenation even for hindered double bonds. The most active complex would appear to be of the form $[Ir(COD)LL']^+$ where L = a bulky phosphine such as tricyclohexylphosphine or triisopropylphosphine and L′ = pyridine.[110] These catalysts show activities several orders of magnitude higher than $RhCl(PPh_3)_3$ and can hydrogenate even very hindered olefins. The general method of generating cationic iridium complexes for hydrogenation has been applied to a number of systems for the hydrogenation of olefins, the hydrogenation of ketones, the hydrogenation of nitriles and the hydrogenation of imines. There have also been a number of systems that are capable of carrying out asymmetric hydrogenation of pro-chiral olefins with the use of chiral bis-phosphine ligands.[111]

8.2 Hydroformylation (*See Hydroformylation*)

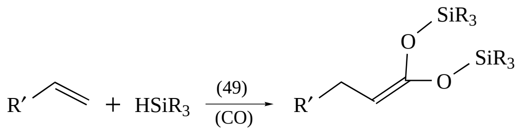
Unlike the hydrogenation catalysts, most iridium catalysts studied for hydroformylation chemistry are not particularly active and are usually much less active than their rhodium counterparts (*see* ***Carbonylation Processes by Homogeneous Catalysis***). However, this lower activity was useful in utilizing iridium complexes to study separate steps in the hydroformylation mechanism. Using iridium complexes, several steps important in the hydroformylation cycle such as alkyl migration to carbon monoxide were studied. Another carbonylation reaction in which iridum catalysis appears to be commercially viable is in the carbonylation of methanol.[112]

8.3 Hydrosilation (*See Hydrosilation*)

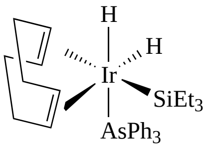
Hydrogenation may be considered a specific case of the addition of H–X molecules to unsaturates where X = H. There has been of late considerable interest in developing systems for which X can be a number of other elements. One of the goals of research into C–H activation (discussed in the next section) is to develop catalysts for the addition of C–H bonds to unsaturates. While this goal has not been met, the addition of Si–H bonds to unsaturates may be accomplished with a number of iridium complexes as catalysts. Although iridium complexes are not among the most active for hydrosilation, there are a number of active ones and studies into the interactions of iridium with silanes has provided useful information about important steps in catalytic hydrosilation.

Many of the systems investigate for hydrosilation chemistry are, not surprisingly, similar to those found for

hydrogenation chemistry. Complexes that have shown activity for hydrosilylation include $[Ir(COE)_2Cl]_2$ (**2**), $Ir_4(CO)_{12}$ (**45**), $[IrCl(COD)(PPh_3)]$ (**6**), $IrH_2(SiEt_3)(COD)(AsPh_3)$ (**85**), and $Ir(CO)Cl(PPh_3)_2$ (**29**). Bergman has shown that a heterobimetallic complex of tantalum and iridium discussed previously (**58**) is also an active catalyst for olefin hydrosilylation.[113] In a combined reaction similar to hydroformylation (*see Hydroformylation*), hydrosilylation has been combined with carbonylation chemistry using an $[Ir(CO)_3Cl]_n$ (**49**) catalyst to form silyl enol silyl ethers (equation 26).[114]



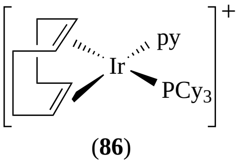
(26)



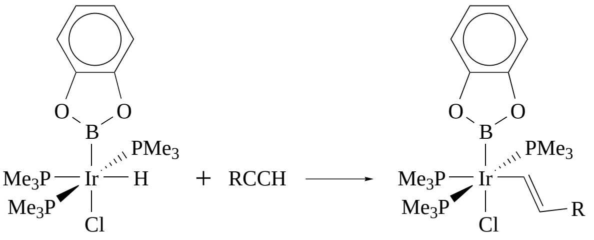
(**85**)

8.4 Hydroboration (*See Hydroboration*)

While the hydroboration of unsaturates is a powerful synthetic tool that does not require the use of a catalyst, research has shown a number of circumstances where a catalyst may improve the speed or the chemoselectivity of the uncatalyzed reaction (*see* ***Hydroboration Catalysis***). Asymmetric hydroboration may also be induced with achiral R_2BH reagents with the use of an appropriate chiral ligand on the metal (*see* ***Asymmetric Synthesis by Homogeneous Catalysis***). Evans *et al.* have shown that $[Ir(COD)(PCy_3)(py)]^+$ (**86**) (one of the most active hydrogenation catalysts) is also effective for catalyzing the addition of catecholborane tounsaturates.[115] Merola and Knorr characterized the product of the addition of catecholborane to $Ir(COE)(PMe_3)_3Cl$ as complex (**87**). This complex, while not a very active catalyst, would react with alkynes to yield isolable alkenyliridiumborane complexes (**88**) and thus serves as a model for the steps in catalytic hydroboration (equation 27).[116] Along these lines Marder, Baker and coworkers have investigated the reactions of a number of boranes with iridium and have characterized a number of fascinating structures with unusual modes of iridium–boron bonding.[117,118]



(**86**)



(**87**) (**88**)

(27)

In addition to using boron-hydrides as the reactive reagent in hydroboration chemistry, compounds with B–B bonds have also been utilized successfully.[119]

8.5 Iridium Catalysts with Oxygen Ligand Environment

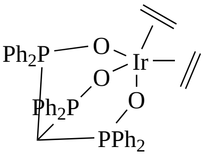
Most of the catalysis using iridium compounds has typically exploited iridium with neutral, soft donor ligands such as phosphines, arsines, olefins, and carbon monoxide. Recent investigations into the chemistry of iridium in atypical environments has shown that oxygen ligand environments can support some very active iridium catalysts and may actually be more akin to the environment that exists around a metal when it is supported on an oxide support (*see* ***Water & O-donor Ligands*** and ***Oxides: Solid-state Chemistry***).

Finke's group has synthesized $[(COD)Ir{\cdot}P_2W_{15}Nb_3O_{62}]^{-8}$ (**89**) in which the iridium is bound, in addition to the COD, to three oxygens from the polyoxoanion (*see* ***Polyoxometalates***). NMR evidence (from ^{17}O NMR) indicates that the iridium is bound to the polyoxoanion at the NbO_3 portion. Under hydrogen, this material converts into a complex that is active for the catalytic hydrogenation of olefins. While the nature of the actual catalyst is not known, evidence suggest that the iridium must still be attached to the polyoxoanion.[120–122]

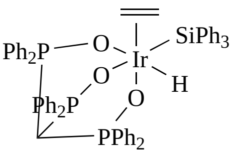
Klemperer's group has also attached iridium to various polyoxoanions.[123] They have synthesized and characterized such complexes as $[\{(COD)Ir\}_2V_4O_{12}]^{-2}$ (**90**), $[\{(COD)Ir\}V_4O_{12}]_{-3}$ (**91**), $[\{(COD)Ir\}_5\{Nb_2W_4O_{19}\}_2]^{-5}$ (**92**), $[(COD)IrP_3O_9]^{-2}$ (**93**), and $[(OC)_2IrP_3O_9]^{-2}$ (**94**). The most intriguing result from this work shows the potential to carry out oxidative reactions as well as the more commonly found reductive reactions using iridium catalysts. They found that the COD ligand in $[(COD)IrP_3O_9]^{-2}$ (**93**) reacts with molecular oxygen to yield a compound containing an oxometallacyclobutane unit derived from insertion of oxygen into a metal–carbon bond. This suggests that placing iridium into this oxygen environment may provide the platform for more unusual catalytic reactions.

Crabtree has also investigated the effect of an oxygen environment on iridium chemistry. Here, using the anion derived from the deprotonation of $HC(Ph_2P{=}O)_3$ (studied also by Grim), which is dubbed 'triso', Crabtree's group showed that this ligand could stabilize not only the $+1$ oxidation state but also the $+3$ and the $+5$ as well. They found that they could synthesize $(triso)Ir(olefin)_2$ (iridium(I))

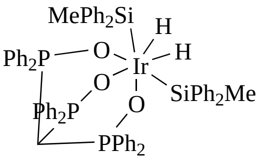
compounds (**95**) and then react those with silanes to yield (triso)Ir($SiPh_3$)(H)(ethylene) (**96**) (iridium(III)) as well as (triso)Ir$(H)_2(SiPh_2Me)_2$ (**97**) (iridium(V)). This system was found to be active for the catalytic hydrosilation (*see Hydrosilation*) of olefins.[124,125]



(**95**)



(**96**)



(**97**)

A relatively recent development in catalysis by iridium with an oxygen-donor environment comes in the form of catalysis by iridium with aquo ligands and in aqueous solvent. Water-soluble compounds of iridium, either by virtue of attachment of water-soluble ligands or by direct interaction of water with the metal, are receiving a great deal of attention because of their potential as catalysts in aqueous solution.[126,127]

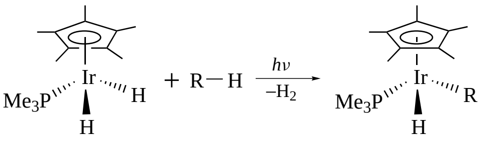
9 C–H ACTIVATION[128–130]

Since 1984, the single largest driving force in iridium chemistry has been the lure of finding a system capable of functionalizing hydrocarbons via C–H activation processes.1984 saw the publication of a report by Bergman and Janowicz on the oxidative addition of C–H bonds to ''Cp*Ir(PMe_3)''(**98**) to yield the alkyliridiumhydride complex Cp*Ir(H)(R)(PMe_3).[131] This was something akin to finding the holy grail: the firm establishment that alkane C–H bonds were reactive with the proper metal complex. Yet, well before this report there was significant evidence of iridium's ability to react with C–H bonds.

The first indications came from reactions of C–H bonds in coordinated ligands with iridium centers. Prominent among this type of reaction are the ortho-metallation (*see Orthometalation*) reactions, especially of arylphosphine ligands in which a C–H bond ortho to the phosphorus adds to the iridium. Beyond this, however, there were also examples of C–H bonds of alkyl chains adding to low-valent iridium centers. These intramolecular C–H reactions seemed to be induced when the alkyl backbone of a chelating ligand place the C–H bond in very close proximity to the metal.

Beyond these intramolecular C–H additions, there were several examples of C–H 'disproportionation' reactions (*see Disproportionation*) that could be induced by iridium. For example, cyclohexadiene could be transformed into benzene and cyclohexane under the influence of an iridium complex. Clearly, C–H bond-making and breaking processes were taking place in these transformations. Reasoning that C–H activation is just the reverse of olefin hydrogenation, Crabtree undertook a detailed investigation into the chemistry of iridium complexes that he had demonstrated were among the most active available, with the goal of finding systems that would catalyze C–H activation processes. Indeed, his group discovered that with the proper choice of H_2 acceptor (3,3-dimethyl-1-butene), iridium complexes could catalyze the dehydrogenation of a number of alkanes to yield the unsaturated organic compound.[132,133]

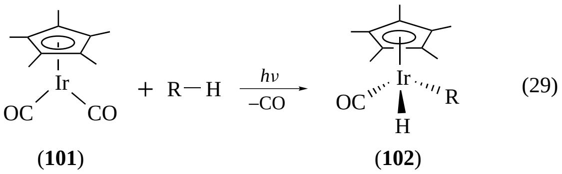
In the Crabtree work, while it was clear that C–H bond-breaking processes must be taking place, there was a general belief that the isolation of a complex that resulted from the oxidative addition of a C–H bond would be required to truly demonstrate that C–H activation was indeed occurring with homogeneous transition metal systems. Bergman and Janowicz were the first the show that such reactions were indeed possible.[134] Using Cp*Ir(PMe_3)H_2 (**99**) as the source of iridium, they discovered that photolysis of this complex induced the elimination of H_2 creating a very reactive, coordinatively unsaturated iridium(I) complex. This complex would then react with alkane C–H bonds to yield alkylhydride iridium complexes of the form Cp*Ir(PMe_3)(R)(H) (**100**) (equation 28). Subsequent studies by the Bergman group on the Cp*Ir(PMe_3)H_2 system delved into the relative reactivities of various C–H bonds and the thermodynamics and mechanism of the C–H activation process.[135]



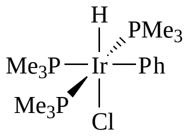
(**99**) (**100**) (28)

The iridium center utilized by the Bergman group contained both PMe_3 and Cp* ligands, both very electron donating. Initially, it was reasoned that in order to effect the oxidative addition of the relatively unreactive C–H bonds to iridium, the iridium center would have to be extremely electron rich and ligands such as PMe_3 and Cp* would be essential. Graham and coworkers, however, showed that the C–H addition of alkanes proceeded well for the less electron-rich carbonyl complexes Cp*Ir$(CO)_2$ (**101**) or even CpIr$(CO)_2$. In the case of the carbonyl complexes, photolysis was also required for the removal of the CO ligand to generate a coordinatively unsaturated mono-carbonyl intermediate, which would then react with the alkyl C–H bonds to yield complexes of the form

(**102**) (equation 29).

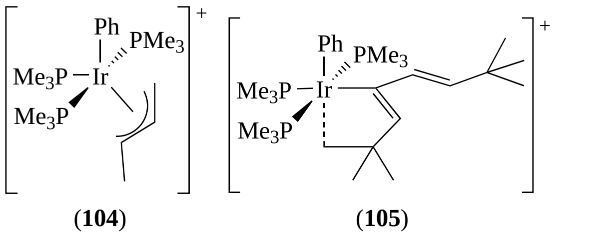


Since those initial reports, there have been a number of reports of C–H activation with iridium complexes, induced both thermally and photochemically. Werner has demonstrated a number of iridium systems with bulky ligands that are capable of adding C–H bonds.[136] $[Ir(COD)(PMe_3)_3]Cl$ (**11**) will react with aromatic C–H bonds thermally to yield octahedral iridium(III) complexes of the form mer-$(Me_3P)_3Ir(H)(Ar)(Cl)$ (**103**).[137,138]

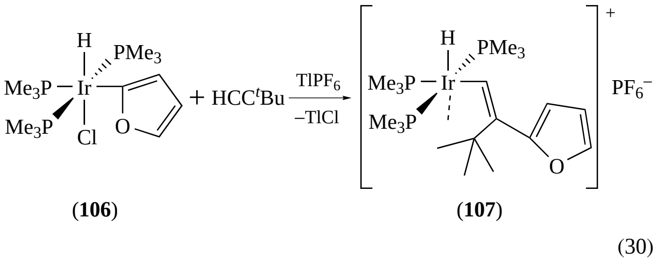


(**103**)

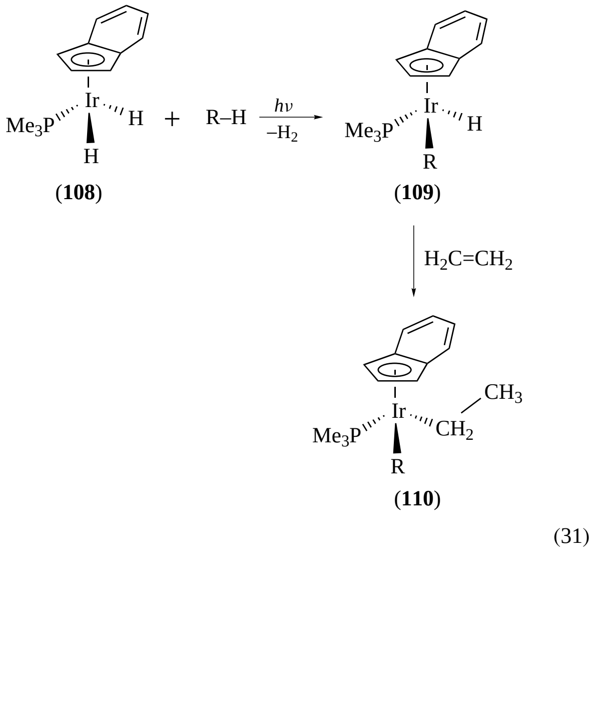
Once the C–H activation step was demonstrated, the search was on to find systems that would not only add the C–H bond, but could also be induced to proceed further down a reaction path that would result in the functionalization of the added hydrocarbon. Unfortunately, with most systems, it is difficult to achieve further reaction beyond the C–H addition step since most conditions employed to effect further reaction usually lead to nonproductive reductive elimination of the hydrocarbon. The Merola group was able to show that for a specific case of benzene C–H addition yielding mer-$(Me_3P)_3Ir(H)(Ph)(Cl)$ (**103**), further reaction was available. In this case, a site of coordinative unsaturation was opened on the metal by removing the bound chloride with $Tl[PF_6]$. This yielded a highly energetic 16-electron complex that would react with alkynes with the exact product dependent on the structure of the alkyne. When the alkyne contained hydrogens on carbon α to the triple bond, the resulting product was the allyliridium complex (**104**, *see Allyl Complexes*).[139] However, with t-butylacetylene, where an arrangement to an allylic ligand was not possible, an unusual dimerization reaction occurred to yield a cyclobutadienyliridium complex (**105**) with the sixth coordination site of the metal being occupied by a δ-agostic (*see Agostic Bonding*) interaction.[140]

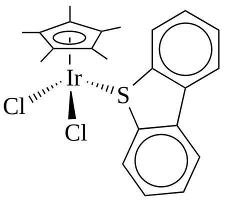


More intriguing is that the product of furan addition to $[Ir(COD)(PMe_3)_3]Cl$ (**106**), undergoes an insertion reaction with t-butylacetylene, not into the Ir–H bond but into the Ir–C bond (equation 30).[138]

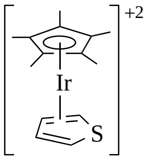


Another approach to developing alkyliridium hydride complexes that would be more reactive toward further substitution reactions utilizes the indenyl effect (see Section 3). Bergman and Foo synthesized the indenyl analogs of the $Cp^*Ir(PMe_3)H_2$ (**99**) system for C–H activation and discovered that $IndIr(PMe_3)H_2$ (**108**) is also capable of activating C–H bonds upon photolysis yielding indenyliridium alkyl hydride compounds (**109**).[141] However, in the case of the indenyl complexes, the η^5 to η^3 indenyl transformation allows reagents to enter the iridium coordination sphere under mild conditions and insert into the Ir–H bond to yield (**110**) (equation 31).[142]





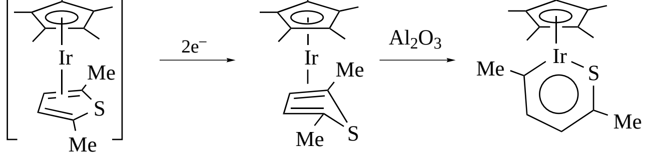
(111)



(112)

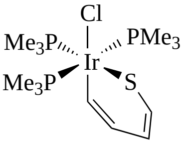
10 HDS CHEMISTRY[143]

Hydrodesulfurization (HDS) is the process for the removal of sulfur from petroleum feedstocks (*see* ***Hydrodesulfurization & Hydrodenitrogenation***). While iridium is not used in commercial HDS catalysts, organometallic complexes of iridium have nevertheless played an important role in developing an understanding of the mechanism of HDS chemistry. Since sulfur is present in petroleum feedstocks primarily as thiophenic sulfur, there have been many investigations into the coordination chemistry of thiophene. While a number of different metals have been examined to synthesize compounds that may serve as models for HDS chemistry, iridium has provided some unusual insights into possible reactions of thiophenic molecules. One mode of coordination of thiophenic molecules is simple bonding through sulfur. Angelici has reported that $[Cp^*IrCl_2]_2$ (**18**) may be split by dibenzothiophene to yield $Cp^*IrCl_2(\eta^1$-dibenzothiophene) (**111**). Angelici has also shown that π-bonded thiophene and benzothiophene complexes of iridium may be synthesized including $[Cp^*Ir(\eta^5$-thiophene)$]^{+2}$ (**112**). His group also found that thiophene and benzothiophene coordinated to iridium is susceptible to nucleophilic attack (*see Nucleophilic Addition: Rules for Predicting Direction*) by H^-, MeO^-, EtS^- and phosphines. The η^5 complexes may be converted into η^4 complexes by a two-electron reduction.[144] Thus, $[Cp^*Ir(\eta^5$-dimethylthiophene)$]^{+2}$ (**113**) is transformed into $Cp^*Ir(\eta^4$-dimethylthiophene) (**114**) where the iridium is bound to the four carbons of the thiophene ring and not to the sulfur atom. This η^4 complex is further transformed via isomerization over alumina into an unusual thiairidametallacycle (*see Inorganic Heterocycle*) complex (**115**)[145] (equation 32). This metallacycle would appear to have considerable aromatic character based on both crystallographic and NMR data.



(113) (114) (115)

(32)



(116)

Merola also has shown that thiophene and benzothiophene will undergo a ring-opening C–S addition reaction with $[Ir(COD)(PMe_3)_3]Cl$ (**10**) to yield (**116**).[139] Unlike the Angelici complex, this thiairidacycle does not have aromatic character, although it is a planar six-membered ring. In both of these cases, it is unclear how much of a connection there is between these models and the actual intermediates in HDS catalysis. Nevertheless, these models have shed a great deal of light on the possible modes of bonding and reactivity of thiophenic molecules with metal centers.

11 SUMMARY

This review of some aspects of the organometallic chemistry of iridium is certainly not exhaustive. There have been some types of complexes that have receive little notice such as those containing polyolefinic ligands and related compounds. Also, there are other organic transformations that may be catalyzed by iridium complexes. However, throughout this chapter the reader has been directed to a number of primary references as well as a number of review articles that will delve into some areas of iridium organometallic chemistry more deeply.

1 INTRODUCTION

Myoglobin and hemoglobin have been studied intensively for over 100 years and are two of the most well-known metalloproteins, because they were the first two proteins for which 3D structures were determined by X-ray crystallography in 1958 and 1960, respectively (Figure 1).[1,2] As a result, they have always been described in inorganic chemistry and biochemistry text books.[3,4] The physiological functions of myoglobins and vertebrate hemoglobins are O_2 storage and transport, respectively. Particularly, hemoglobins are the most widely distributed family of O_2 carriers (*see* ***Iron Proteins with Dinuclear Active Sites***; ***Copper Proteins with Dinuclear Active Sites***), although the role of some hemoglobins is still not clear. They can bind O_2 reversibly at a heme prosthetic group, a protoporphyrin IX iron complex (Figure 2), in their protein matrix (equation 1; P = porphyrin ring). Thus, it is of particular interest not only for biologists but also for chemists to understand the molecular mechanism of O_2-binding and its stabilization.[5]

$$\mathrm{PFe(II)} + \mathrm{O_2} \rightleftharpoons \mathrm{PFe(II)\bullet O_2} \qquad (1)$$

Myoglobin consists of a single peptide chain of 150–160 amino acids and one heme with a molecular weight of approximately 17 500, and more than three-fourths of the amino acid residues are involved in eight (A–H) helices as shown in Figure 1(a).[6] The prefix 'myo' means muscle in Greek, because myoglobin is mainly located in skeletal and cardiac muscle cells for respiration. O_2 is bound to a ferrous pentacoordinated heme along the Langmuir adsorption isotherm. On the other hand, vertebrate hemoglobins are tetrameric proteins that consist of two α- and two β-globins, and the total molecular weight is approximately 64 000 as shown in Figure 1(b).[7] Each globin has one protoheme; therefore, one hemoglobin can bind a total of four O_2 molecules. The tertiary structure of the globin is mostly identical to that of myoglobin; however, each of the O_2-binding sites is mutually dependent due to the strong interaction between globins. Therefore, hemoglobin can exhibit cooperative O_2-binding behavior with a homotropic allosteric interaction (vide infra). Hemoglobin is located in the erythrocyte, the red blood cell, and 150 g of hemoglobin exists in 1000 mL of blood to solubilize O_2, because the solubility of O_2 in blood plasma is too low to carry sufficient O_2 to target tissues without any O_2 carrier.[8]

In chemistry, it is well known that O_2 can be strongly bound to a ferrous iron porphyrin in solvents without any protein matrix; however, the oxygenated states of most simple iron porphyrins are irreversibly converted into μ-oxodimers (equation 3), PFe(III)–O–PFe(III), via peroxo and ferryl intermediates (equation 2). The μ-oxodimer is usually very stable in solvents, so it is sometimes called a thermodynamic sink. In addition, autoxidation of PFe(II)•O_2 to an inert ferric porphyrin easily occurs under aerobic conditions (equation 4). Thus, it is clear that the heme pockets of myoglobin and hemoglobin play an important role in protecting the O_2-bound heme from dimerization and autoxidation.

$$\mathrm{PFe(II)\bullet O_2} \rightleftharpoons \mathrm{PFe(III){-}O{-}O{-}PFe(III)} \rightleftharpoons \mathrm{2PFe(IV){=}O} \qquad (2)$$

$$\mathrm{PFe(IV){=}O} + \mathrm{PFe(II)} \rightleftharpoons \mathrm{PFe(III){-}O{-}PFe(III)} \qquad (3)$$

$$\mathrm{PFe(II)\bullet O_2} \rightleftharpoons \mathrm{PFe(III)} + \mathrm{O_2}^{\bullet -} \qquad (4)$$

This article focuses on the salient physiological and chemical features of myoglobin and hemoglobin and additional current topics that could serve as a new way to modify the functions of the heme proteins.

2 GENERAL FEATURES OF MYOGLOBIN AND HEMOGLOBIN

2.1 Structural and Electronic Properties of Oxyheme Proteins

The prosthetic group of myoglobin and hemoglobin is a heme-b, protoheme-IX (Figure 2), which is the same as that found in several peroxidases, catalases, and cytochromes. The heme is linked noncovalently at the heme pocket of the protein

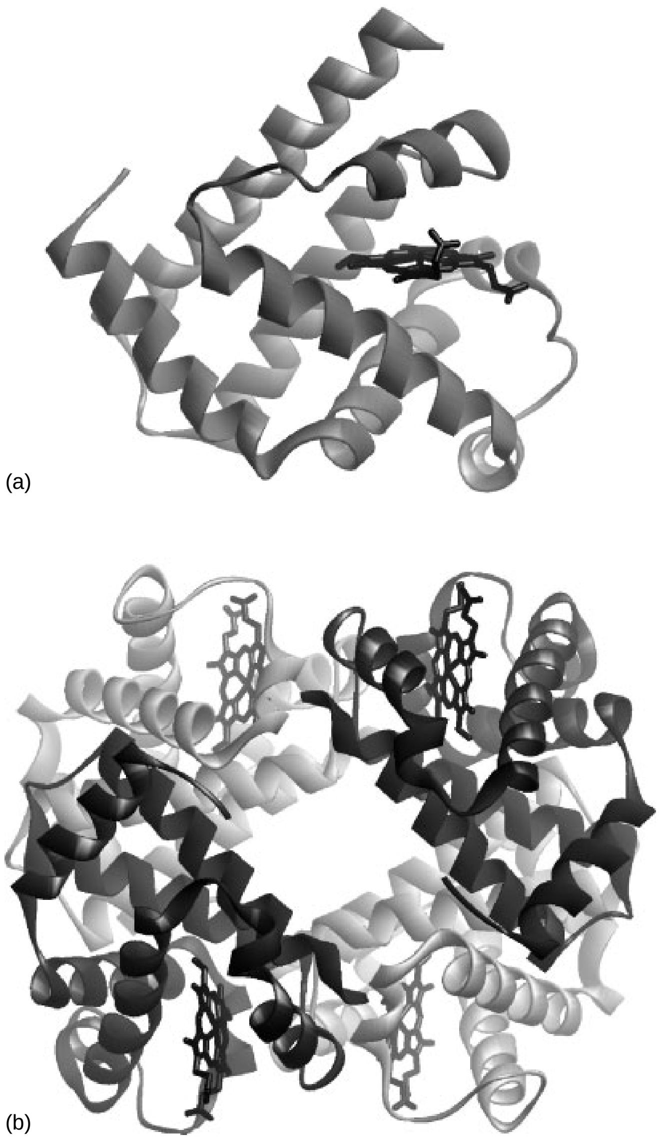

Figure 1 Three-dimensional structures of myoglobin and hemoglobin. (a) Deoxymyoglobin from sperm whale (1A6N) and (b) deoxyhemoglobin from human (1BZ0). Black and gray stick molecules are protoheme-IX. Hemoglobin consists of two $\alpha\beta$ dimers, dark and light gray pairs

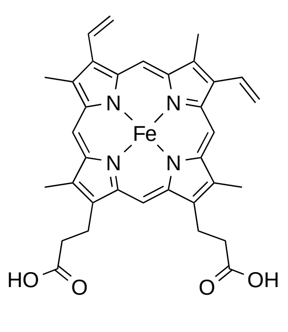

Figure 2 Structural formula of protoheme-IX

matrix through multiple interactions. The heme pocket has two characteristic histidines, the proximal and distal histidines, and the imidazole Nε of the former histidine is coordinated to heme-iron directly, whereas the latter histidine plays an important role in the stabilization of heme-bound dioxygen via hydrogen bonding (Figure 3). The heme is furthermore fixed in the protein matrix through a salt bridge between the heme-propionate side chains and amino acid residues near the heme pocket. In addition, the asymmetric peripheral heme side chains at the β-pyrrolic carbons of the A and B pyrrole rings, two vinyl and two methyl groups, contact the hydrophobic amino acid residues in the heme pocket and determine the orientation of the heme plane. The ratio of normal and backward porphyrin planes is approximately 11:1 for sperm whale myoglobin.[9]

The characteristic property of the oxygenated species of heme protein has been discussed for a long time. O_2 is reversibly bound to a ferrous high-spin heme-iron ($S = 2$) species to form the diamagnetic oxygenated species ($S = 0$) in biological systems. In general, the reduced Fe(II) state and the O_2-bound state are described as the deoxy and oxy species, respectively, whereas the functionally inactive oxidized Fe(III) form is referred to as the met species. The argument on the structural and electronic properties of the oxygenated heme complex in the protein matrix began in 1936 when Pauling and Coryell suggested the nature of the PFe(II)•O_2 species was the combination of low-spin Fe(II) and singlet oxygen with a σ donor and a π acceptor character, by measuring the magnetic moment of oxyhemoglobin.[10] In addition, a bent end-on geometry of the Fe–O–O species was proposed by Pauling and Weiss in 1964.[11] Moreover, Weiss has reported an alternative formulation, Fe(III)$-O_2^{\bullet-}$, which is regarded as a single-electron transfer from Fe(II)

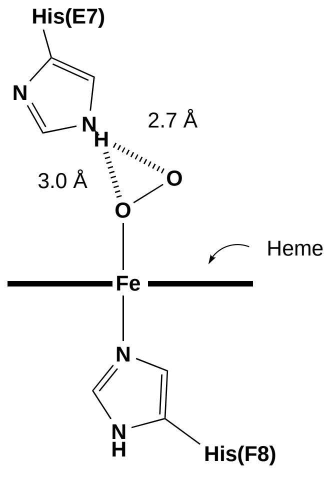

Figure 3 Simplified structure of the oxyheme unit in myoglobin and hemoglobin. There are two characteristic histidines in the heme pocket, proximal (F8) and distal (E7) histidines. The latter histidine strongly stabilizes the iron-bound O_2 via hydrogen-bonding interaction

to the bound O_2.[12] This charge-separated species, which is a combination of low-spin Fe(III) and superoxide, seems to show strong antiferromagnetic coupling between iron and O_2. The Fe–O–O geometry in the protein matrix was first demonstrated by Phillips in 1978, and his data supported the nonlinear Fe–O–O geometry proposed by Pauling and Weiss.[13] The crystal structural data also suggest the charge-separated character of oxygenated heme proteins. For example, the O–O distance of the O_2 bound onto the heme-iron in the proteins was determined to be 1.2–1.3 Å by X-ray crystal-structure analysis, which is comparable with that observed for a metal-superoxide. From recent results at 1.0 Å resolution in sperm whale myoglobin, the O–O bond length is 1.24 Å, which is slightly longer than that of molecular oxygen.[14] In addition, the O–O stretching mode in the oxygenated complex by IR and resonance Raman spectroscopies appears at 1130–1140 cm^{-1}, which is a lower frequency compared to that observed for molecular oxygen (ca. 1550 cm^{-1}).[15–17] These experimental results support the fact that the charge-separated formulation, Fe(III)–$O_2^{\bullet -}$, is the predominant state in oxygenated heme proteins. Thus, the following equation, the combination between low-spin Fe(III) and superoxide, could be an appropriate representation for the O_2-binding equilibrium in the protein matrix (equation 1′).

$$\text{PFe(II)} + O_2 \rightleftharpoons \text{PFe(III)}\cdot O_2^{\bullet -} \qquad (1')$$

2.2 Thermodynamic and Kinetic Properties of O_2 Binding to Heme Proteins

Thermodynamic and kinetic measurements of the O_2 binding process for the heme proteins are essential to discuss their physiological and chemical properties. Representative parameters are depicted in Table 1. The oxygen equilibrium can be directly determined by a polarographic-spectrophotometic method with an O_2 electrode.[18,19] The P_{50} value, the O_2 pressure when half of the heme protein's O_2-binding sites are occupied, is quite often used for the evaluation of O_2 affinity. The P_{50} of sperm whale myoglobin is 0.51 torr, whereas the P_{50}s of the R- and T-states for human hemoglobin A are 0.15–1.5 torr and 9–160 torr, respectively.[8] Kinetic studies on O_2 binding also provide us an important insight into the physiological properties of the heme proteins. The association process for O_2 binding is usually monitored by laser flash photolysis or the T-jump method. From these experiments, the second-order rate constant of O_2 binding, k_{on}, is determined (ca. 10–20 $\mu M^{-1}\,s^{-1}$ at 20 °C for a series of native myoglobins).[20] On the other hand, the first-order rate constant of O_2 dissociation, k_{off}, is obtained by monitoring the replacement with a CO or NO ligand or mixing of an O_2 scavenger such as ferricyanide or dithionite using a typical rapid-stopped flow apparatus (ca. 10–25 s^{-1} at 20 °C for a series of wild-type myoglobins).[20] Therefore, O_2 affinity can be calculated from the ratio of k_{on}/k_{off}, which is in good agreement with the O_2 affinity measured by the equilibrium process described above. These association-dissociation rate constants are very helpful in evaluating the physiological function of a variety of species of heme proteins and/or their mutants.[21] In the case of hemoglobin, ligand-binding kinetics are not simple compared to those of myoglobin, and the analytical method has been summarized in detail elsewhere.[22]

2.3 Models for Heme Proteins

To understand the chemical properties of oxygenated heme in the protein, many inorganic and bioinorganic chemists have devoted their efforts to preparing effective models, which provided many important insights into the molecular mechanisms and structure of oxygenated heme proteins.[23,26–28] One of the representative models is the picket fence iron porphyrin reported by Collman and his coworkers (Figure 4).[29] The picket fence porphyrin as a structural model for myoglobin has four bulky pivaloyl groups at the peripheral positions to prevent two of these iron porphyrins from coming together to form a μ-oxo dimer. The first significant result in their study was to demonstrate the 3D structure of the stable

(a) T-state model; each iron may be deviated from the porphyrin planes due to 'short' bidentate ligand, bisimidazolylmethane. (b) R-state model; each iron is in-plane because of the sufficient length of bisimidazolylpropane compared to the distance between two Fe atoms

oxygenated iron porphyrin in 1974 before the crystal structure of oxymyoglobin was available. O_2 is bound to the iron porphyrin in end-on style with an Fe–O–O bond angle of 136° and an O–O distance of 1.24 Å, which strongly supported the nonlinear end-on O_2 binding postulated by Pauling and Weiss. Furthermore, the picket fence iron porphyrin was a useful functional model because it was able to bind O_2 reversibly for a long time.[25] In addition, there have been many functionalized iron porphyrins to mimic the function of myoglobins and hemoglobins for over 30 years, and these unique properties have been described in several reviews.[23,26–28] On the other hand, there are a limited number of synthetic models for hemoglobin, because it seems to be difficult to totally mimic the molecular trigger of cooperative oxygenation observed in hemoglobin. For example, Tabushi and his coworkers reported a unique model demonstrating reversible cooperative O_2 binding by a metalloporphyrin dimer and a bidentate bisimidazole ligand (Figure 5).[30,31]

3 MECHANISM OF O_2 BINDING BY MYOGLOBIN AND HEMOGLOBIN

3.1 Molecular Mechanism of O_2 Binding

In the synthetic iron porphyrin, O_2 affinity mainly depends on the strengths of the σ-donation from the lone pair of O_2 to the heme-iron dz^2 orbital and π-back donation from the $d\pi$ orbital on the iron to the π^* orbital of O_2.[32] To evaluate the O_2 affinity and/or O_2 binding dynamics in myoglobin and hemoglobin, O_2–protein interaction is a further important factor. For example, the O_2 dissociation rate constant for oxymyoglobin is relatively smaller than those of O_2 complexes of the synthetic model (e.g. $k_{off} = 4.6 \times 10^4\ s^{-1}$ for the picket fence iron porphyrin in the presence of 1,2-dimethylimidazole at 20 °C in toluene).[25] Figure 6 illustrates the heme pocket of sperm whale deoxymyoglobin. The role of each amino acid residue has been nearly clarified by a series of kinetic studies and X-ray crystal-structure analysis of oxy and deoxymyoglobin. Table 2 displays a comparison of kinetic parameters for several mutants with those for the wild type.

On the distal side, there are at least three important moieties to regulate O_2 binding. First, His64 on the distal side strongly stabilizes the bound O_2 via hydrogen-bonding interaction between the imidazole moiety of His64 and polar O_2. In fact, the replacement of His64 with Gly drastically accelerates the O_2 dissociation by more than 100-fold, and the O_2 affinity dramatically decreases to $K_a = 8.8 \times 10^4\ M^{-1}$.[35] In addition, autoxidation of the H64G oxymyoglobin is more than 500-fold faster than that observed for wild-type myoglobin ($k_{ox} = 0.055\ h^{-1}$ for wild-type myoglobin at 37 °C, pH = 7.0).[36] Vertebrate hemoglobins also have a distal histidine (E7) for each heme pocket, and it is well known that the histidine interacts with the heme-bound O_2 via hydrogen bonding. Second, Table 2 shows that the residues Leu29(B10) or Val68(E11) in myoglobin regulate O_2 binding. Olson and his coworkers have carried out site-directed mutagenesis studies systematically on mammalian myoglobin to examine pathways for ligand movement inside the protein and proposed that O_2 is first captured by a part of

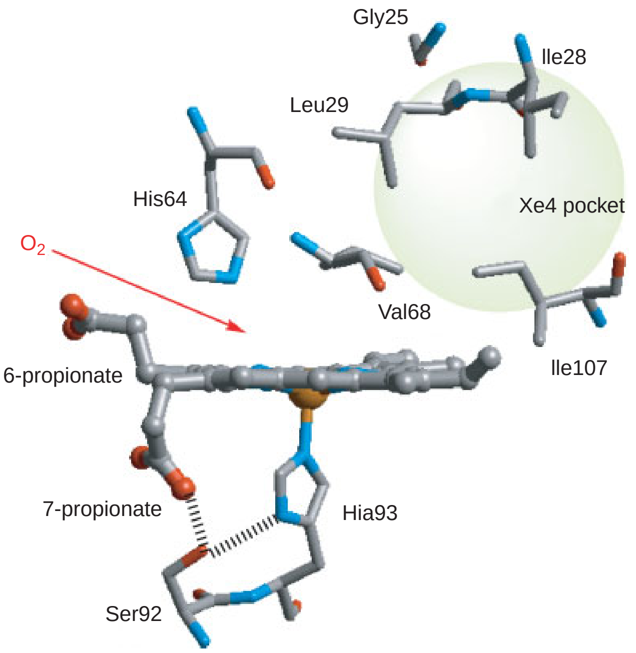

Figure 6 Distal and proximal heme pockets of sperm whale deoxymyoglobin. O_2 enters into the heme pocket and is noncovalently bound at the distal side or hydrophobic Xe4 pocket, and then forms the covalent bond with heme-iron. The iron-bound O_2 is stabilized by His64 via hydrogen-bonding interaction

the heme pocket formed by these hydrophobic residues and then binds to heme-iron.[37,38] In fact, the replacement of several hydrophobic residues on the distal side such as Leu29 and Val68 with more polar or larger residues clearly influences the O_2-binding kinetics parameters and autoxidation process.[39–41] Thus, these residues may serve as an appropriate size and hydrophobicity of the distal pocket to regulate O_2 binding and prevent unfavorable autoxidation. In addition, Scott and Olson pointed out that hydrophobic Xe binding cavities, particularly Xe4 (formed by Gly25, Ile28, Leu29, Val68, and Ile107) as shown in Figure 6 and Xe1 (formed by Leu89, His93, Leu104, and Phe138) behind the proximal side, play a role in the modulation of O_2 binding.[38,42] O_2 can partially diffuse to and from these hydrophobic cavities inside the protein. In contrast, the replacement of the heme-6-propionate side chain with a methyl group enhances the O_2-dissociation (3.1-fold) and the autoxidation of oxymyoglobin (6.2-fold) compared to the reference oxymyoglobin,[43] suggesting that the propionate–residue 45 (Arg or Lys) salt bridge is also important for stabilizing oxygenated heme. In fact, the crystal structure of oxymyoglobin demonstrates that there is a hydrogen-bonding network from the propionate to the bound O_2 via residues 45 and 64; thus, one can expect that the lack of the 6-propionate disrupts the stabilization system of the O_2 complex.[44]

On the proximal side, Ser92 is an important residue modulating O_2 affinity. According to the crystal structure, the hydroxyl group of Ser92 interacts with N_δ–H of the proximal His93 and heme-7-propionate via hydrogen bonding. For the S92L mutant of recombinant pig myoglobin, there is an approximately 1.5-fold increase in the O_2 association rate and a 2.5-fold decrease in the O_2 dissociation rate; thus, the increase in O_2 affinity is 3.8-fold.[33] These kinetic results suggest that the loss of the hydrogen bonding between His93 and Ser92 promotes the proximal histidine flexibility, and heme-iron may then easily return to the plane of the porphyrin ring, although the replacement of Ser92 with Asp or Ala causes no drastic changes in ligand binding.[34]

3.2 O_2/CO Discrimination

Another important debate on the O_2 binding mechanism is how to control the discrimination between O_2 and CO for deoxymyoglobin and deoxyhemoglobin. It is well known that a synthetic pentacoordinated ferrous porphyrin, such as the chelated protoheme reported by Traylor, binds CO more tightly by 1300-fold compared to O_2.[24] This result could be very serious for a biological system if the CO selectivity would be reflected in red blood, because CO is generated by heme degradation of heme oxygenase. Interestingly, the $K\text{co}/K\text{o}_2$ ratio in the hemoproteins is drastically reduced ($K\text{co}/K\text{o}_2 = 25$ for sperm whale Mb and 310 for the R-state of human hemoglobin), because O_2 affinity for the deoxy species clearly increases while CO affinity decreases compared to those observed for the synthetic models.[45] The sharp difference between the heme proteins and the synthetic models is explained as follows. First, the enhancement of O_2 affinity is derived from the remarkably slow dissociation of bound O_2. Thus, the O_2 complexes in myoglobins and hemoglobins are stabilized by hydrogen bonding between the distal histidine and the charge-separated oxyheme, PFe(III)$-O_2^{\bullet -}$.[35] Second, the relatively nonpolar Fe–CO species is not strongly stabilized by the distal residue, whereas the bound CO molecule is found to cause steric hindrance to the distal residues, because the Fe–C–O unit prefers a linear geometry owing to the back donation from the iron dπ orbitals.[14,46,47] Although there are still several arguments about Fe–C–O geometry,[14,48] model studies on CO binding by capped or strapped metal porphyrins also support the steric factors which exhibit CO discrimination in the proteins.[23,26–28,49]

4 IMPROVEMENT OF O_2 AFFINITY IN HEME PROTEINS

4.1 Naturally Occurring Hemoglobins with Unusually High O_2 Affinity

Under physiological conditions, O_2 binding constants for mammalian myoglobins and hemoglobins are $10^5-10^6\ M^{-1}$. Some synthetic models for myoglobin also exhibit a similar order of O_2 affinity in water and organic solvents. In contrast, there are special O_2-binding heme proteins, which show extremely high O_2 affinity in nature. One of these proteins is a hemoglobin from *Ascaris suum* which is a family of nematodes.[50] The O_2-binding constant of the *Ascaris* hemoglobin is determined to be $3.7 \times 10^8\ M^{-1}$. In addition, interestingly, the O_2 affinity is higher than the CO affinity with a $K\text{co}/K\text{o}_2$ of 0.03.[51] Table 3 shows that there is a 350-fold increase in O_2 affinity and 2.5-fold decrease in CO affinity compared with the corresponding parameters for wild-type sperm whale myoglobin. This unusual thermodynamic property is derived from the extremely slow O_2 dissociation as shown in Table 3, because bound O_2 is strongly stabilized by two amino acid residues, Tyr(B10) and Gln(E7), via a hydrogen-bonding network in the distal pocket (Figure 7a and b),[52] although in normal myoglobin and hemoglobin, only a distal histidine stabilizes the bound O_2.

Leghemoglobin, a small monomeric heme protein, is another unique O_2-binding protein with a large O_2 affinity in nature.[58] It is found in the root nodules of leguminous plants, and its physiological function may be O_2 transport as well as O_2 scavenging.[53] The O_2-binding mechanism of leghemoglobin is slightly different from those of other O_2 binding hemoproteins, although it is still not completely clear. Interestingly, the replacement of a distal histidine with several amino acid residues causes no serious decrease in O_2 affinity, suggesting that the hydrogen bonding of the distal histidine to bound O_2 is not essential for the stabilization of oxyleghemoglobin.[59] Table 3 shows that the large O_2 affinity in leghemoglobin is mainly derived from the fast O_2 association with heme-iron. It is likely that the large distal heme pocket reduces the barrier to O_2 association in leghemoglobin compared to myoglobin, whereas O_2 dissociation is modulated from the proximal side.[60]

A heme protein which displays the highest O_2 affinity ever observed in nature is the trematode hemoglobin from *Paramphistonum epiclitum*. Table 3 indicates that the exceptionally high O_2 affinity is due to the combination of high O_2 association rate and very low O_2 dissociation rate.[54,61,62] According to the high-resolution structure of the trematode hemoglobin (Figure 7d), there are two tyrosines

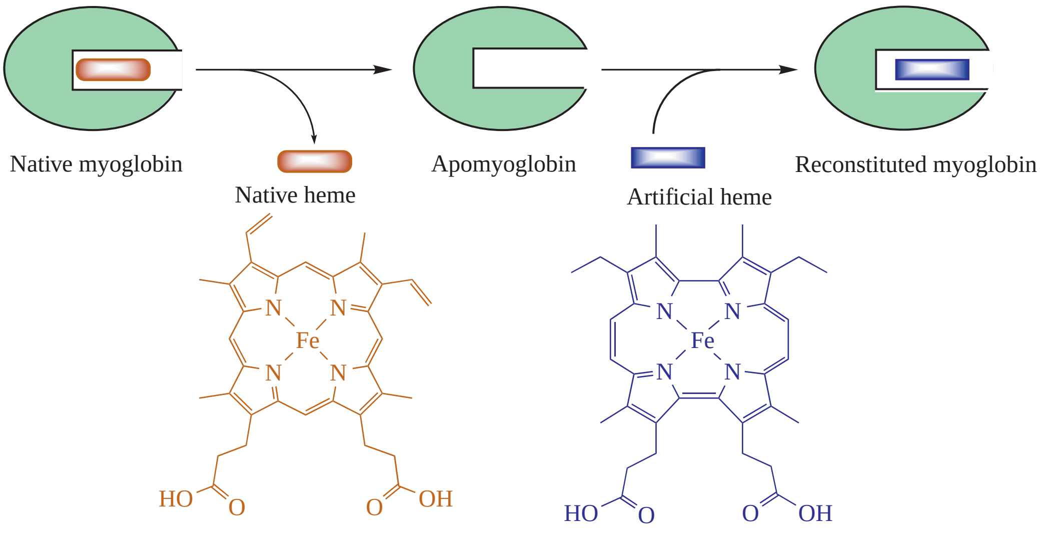
and one histidine in the distal pocket and two tyrosines at the B10 and E7 positions are thought to mainly stabilize O_2 via strong hydrogen-bonding interaction. Tyr(B10) is found at the appropriate position in the distal pocket to make a hydrogen bond with the iron-bound O_2, whereas the hydroxyl group of Tyr(E7) interacts with heme-6-propionate via hydrogen bonding and is not oriented towards the ligand-binding site. In contrast, computer modeling proposes that the one of the plausible structures is different with the structure obtained by X-ray crystallography analysis, where the Tyr(E7) side chain is inside the distal heme pocket and potentially able to make a second hydrogen bond with the iron-bound O_2.[54,61] The crystal structure of trematode oxyhemoglobin will account for the high O_2 affinity of the trematode hemoglobin in the near future.

4.2 Artificial Modification of Myoglobins to Increase O_2 Affinity

For over a decade, there have been various trials to obtain a special myoglobin with high O_2 affinity. Particularly, several groups have modified the distal side of myoglobin by a mutagenetic approach to mimic the structure found in *Ascaris* hemoglobin.[55,56] Although L29Y/H64Q sperm whale myoglobin was a good candidate, the double mutant to mimic the distal site of the *Ascaris* hemoglobin did not clearly enhance the O_2 binding as shown in Table 3.

In contrast, another approach to the improvement of O_2 affinity is the replacement of the native heme with an artificially created prosthetic group. This method is called ‘reconstitution’ (Scheme 1).[63] Although this method



Scheme 1 Reconstitution of myoglobin with an artificially created heme

could be effective in modulating the physiological function in heme proteins, only a limited number of studies are available on reconstituted myoglobins actually improving O_2 affinity.[64–69] For example, the replacement of native heme with an iron porphycene, a structural isomer of mesoheme, in horse heart myoglobin markedly enhances O_2 affinity, $K_{O_2} = 1.1 \times 10^9\,M^{-1}$, due to the slightly faster O_2 association and dramatically slower O_2 dissociation.[57] In this case, the O_2/CO selectivity of the reconstituted myoglobin is completely different from that observed for the native protein. The ratio K_{CO}/K_{O_2} for the reconstituted myoglobin with the iron porphycene is less than 1. The artificially created prosthetic group stabilizes the bound O_2 due not only to the strong hydrogen bonding with the distal histidine but also to an increase in the strength of the O_2–Fe σ-bond because of the lower-energy dz^2 orbital of the porphycene iron.

5 COOPERATIVITY OF O_2 BINDING FOR HEMOGLOBIN

Hemoglobin is a tetrameric protein, which contains two identical α-subunits and two identical β-subunits. Furthermore, these subunits are paired as two dimers, $\alpha_1\beta_1$ and $\alpha_2\beta_2$, and each subunit has one heme, which can bind O_2 reversibly. The structures of the four subunits are similar to each other and to that of myoglobin. The most essential physiological function of hemoglobin is cooperative O_2 binding; that is, O_2 binding in hemoglobin exhibits a sigmoidal behavior versus O_2 concentration (Figure 8). When we define Y as a fractional saturation of O_2, this cooperativity is represented as follows:

$$\frac{Y}{(1-Y)} = K(P_{O_2})^n \tag{5}$$

where K and P_{O_2} are the association constant and partial pressure of O_2, respectively. The equation is further modified to

$$\log\left[\frac{Y}{(1-Y)}\right] = \log K + n\log(P_{O_2}) \tag{6}$$

Figure 8(b) is called a Hill plot which represents the oxygen equilibrium curve according to equation (6), and n is a Hill coefficient number. The larger the n value is, the more strongly is the curve sigmoidal; that is, the n value indicates the degree of cooperativity. In the case of myoglobin, the n value is 1 and the Hill plot is linear, whereas the curve for human hemoglobin shows a typical sigmoidal curve with an n value of 2.8.

The O_2 binding properties of hemoglobin have been mainly represented by two methods as shown in Figure 9. First, the model proposed by Adair and Koshland uses four successive O_2 affinity constants (K_1, K_2, K_3, and K_4) and the partial O_2 pressure, P_{O_2}, to describe the fractional oxygen saturation;[70,71]

$$Y = \frac{K_1P_{O_2} + 3K_1K_2{P_{O_2}}^2 + 3K_1K_2K_3{P_{O_2}}^3 + K_1K_2K_3K_4{P_{O_2}}^4}{1 + 4K_1P_{O_2} + 6K_1K_2{P_{O_2}}^2 + 4K_1K_2K_3{P_{O_2}}^3 + K_1K_2K_3K_4{P_{O_2}}^4} \tag{7}$$

This equation assumes that each of the four binding sites is identical.

In contrast, Monod, Wyman, and Changeux proposed a simple model, which is called the MWC two-state concerted model.[72] They defined two quaternary T and R states; the T (tense) state exhibits low affinity whereas the R (relaxed) state exhibits high affinity. This model assumes that each

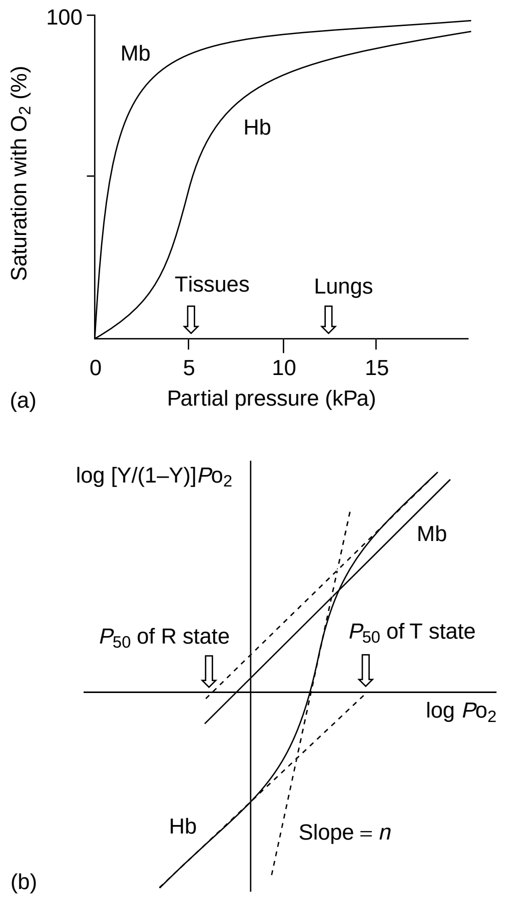


Figure 8 Cooperative and noncooperative binding of O_2. (a) Binding curves of myoglobin and hemoglobin. (b) Hill plot of binding curves. The Hill coefficient number is determined from the first derivative (slope) of the Hill plots

subunit possesses only two conformations, T or R, regardless of the number of bound O_2 molecules. When T_0 and R_0 are defined as the ligand-free T- and R-states, respectively, the equilibrium constant, L_0, between the two states is described as follows:

$$L_0 = \frac{[T_0]}{[R_0]} \tag{8}$$

Therefore, the fractional O_2 saturation value Y is given as

$$Y = \frac{L_0 K_T P\mathrm{o}_2(1 + K_T P\mathrm{o}_2)^3 + K_R P\mathrm{o}_2(1 + K_R P\mathrm{o}_2)^3}{L_0(1 + K_T P\mathrm{o}_2)^4 + (1 + K_R P\mathrm{o}_2)^4} \tag{9}$$

where K_T and K_R are O_2 binding constants for the T_0 and R_0 states, respectively. In addition, K_T and K_R can be estimated from the lower and upper asymptotes in Figure 9 and are approximately equal to K_1 and K_4 determined by the Adair and Koshland method; the K_R/K_T, cooperativity factor, is 30–40 in human hemoglobin. Furthermore, the equilibrium constants, L_0, L_2, and L_4, are roughly estimated to be 10^3, 1, and 10^{-3}, respectively.[73] The MWC two-state concerted model has recently been accepted as the practical allosteric model of hemoglobin.

The 3D structure of hemoglobin suggests a difference in the two quaternary conformations, T and R.[74] The four heme groups are well separated from each other in the tetramer with an Fe–Fe distance of 24–40 Å. The deoxy and oxy forms may be assigned to the T and R states, respectively. Comparison of the structures between the T and R states is indicative of the drastic quaternary conformational change which consists of a rotation of one pair of $\alpha\beta$ dimer relative to the other by 15°. The driving force for the rotation of the α–β subunit pair seems to be adjustments in the tertiary structure upon O_2 binding. X-ray data show that the heme-iron

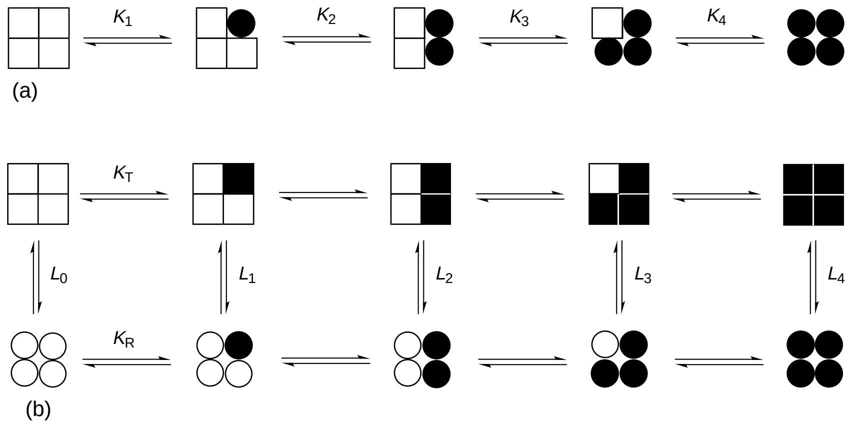

Figure 9 Two proposed models for allosteric interaction observed in hemoglobin. (a) A sequential model of allosteric interaction. When one O_2 molecule binds to a subunit in the T-state, the subunit shifts to R-state and affects the affinity of neighboring subunits for the ligand binding. (b) An MWC two-state concerted model of allosteric interaction. When one O_2 molecule binds to a subunit in all T-states, a concerted conformational change occurs to produce a protein with all R-state subunits. Square and circle represent T- and R-state subunits, respectively. Moreover, opened and closed diagrams represent free and O_2 bound subunits, respectively

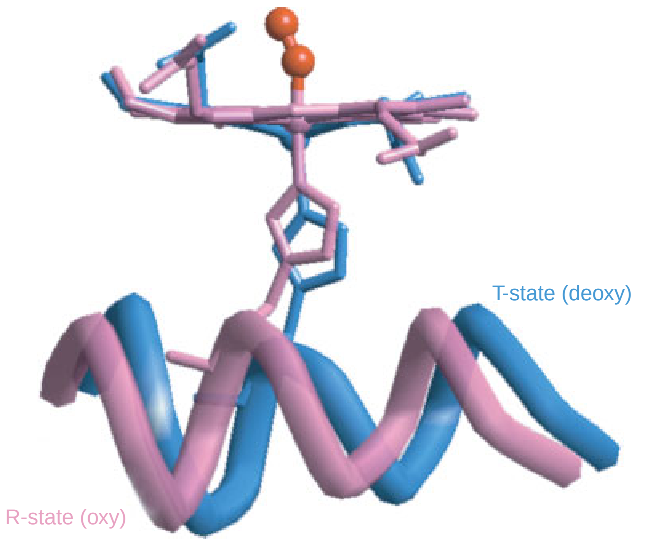

Figure 10 Conformational changes in human hemoglobin upon the O_2 binding. The proximal histidine is pulled toward the porphyrin ring by oxygenation, and then the F-helix shifts position. Purple and blue units represent oxy (R-state) and deoxy (T-state) proteins and hemes, respectively

which is located about 0.4 Å away from the porphyrin plane in the T-state shifts to inside the porphyrin core in the R-state owing to the decrease in ion radius of the oxygenated heme-iron (Figure 10). As a result of this movement, the proximal histidine F8 is pulled along with the heme-iron, and the shift in the F-helix is then thought to be induced. The corresponding conformational shift in the F8-containing α-helix requires rearrangement of the $\alpha_1\beta_1$–$\alpha_2\beta_2$ interface. According to a comparison of the 3D structure between the T and R states, the interface formed by several sets of salt-bridges and hydrogen bonds between the α_1 and β_2 or α_2 and β_1 subunits in the T-state is disrupted, and only one new interaction between the subunits is generated. The arguments on the thermodynamic aspects of the transformation between the T and R states are still continuing, because the apparent free energy changes in cooperative interactions are relatively small (ΔG_{T-R} = ca. 1.9 kcal mol^{-1}). However, several spectroscopic data clearly support Perutz's stereochemical mechanism that the heme-iron movement upon O_2 binding directly induces the structural perturbation of other subunits to regulate cooperatively the next ligand binding.[75]

6 MODULATION OF O_2 BINDING BY SMALL MOLECULES

It is well known that the O_2 affinity of vertebrate hemoglobin affects several physiological effectors such as H^+, CO_2 or 2,3-diphosphoglycerate (2,3-DPG).[5] Particularly, H^+ and CO_2 play a physiologically important role in the regulation of O_2 binding for hemoglobin in the lungs and tissues. This is called the Bohr effect. The negatively charged 2,3-DPG is present in red blood cells and acts as an allosteric effector. According to 3D structure data for the deoxy form in the presence of 2,3-DPG, one molecule of 2,3-DPG preferentially binds to the T-state of hemoglobin via electrostatic interaction and fixes the T-state more tightly, whereas the bound 2,3-DPG is driven away upon O_2 binding, because the 2,3-DPG binding site collapses upon transition from the T- to the R-state.[76] Hill plots of the O_2 binding equilibrium shows that 2,3-DPG mainly decreases the K_T value.[77]

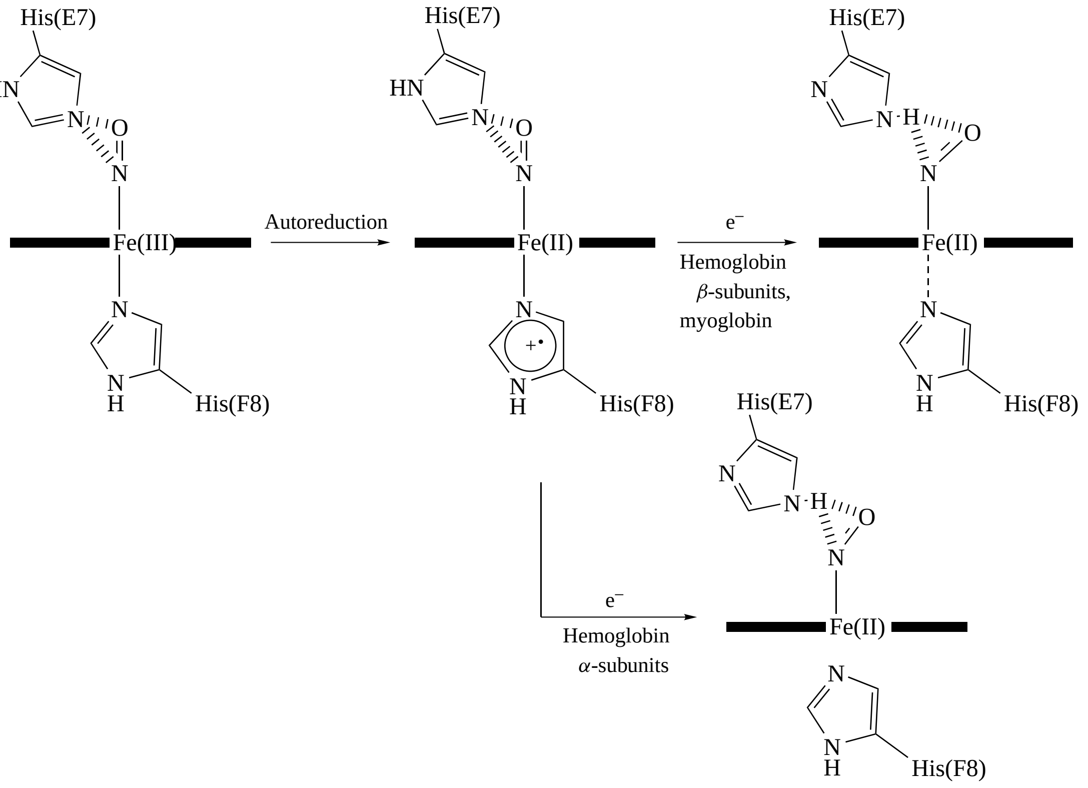
Recently, several heterotropic allosteric effectors have been found such as bezafibrate (BZF) and inositol hexaphosphate (IHP).[78,79] O_2 equilibrium measurements in the presence of these effectors demonstrate that the addition of these effectors particularly reduces K_R (max. 2000-fold). This finding suggests that the effectors can bind not only the T-state but also the R-state tightly, although the binding site of the effectors in the R-state could be different from that of the T-state. The binding of the effectors for the R-state is also estimated by spectroscopic evidence.[79] This finding suggests that the effectors have the potential to drastically modulate the O_2 binding of hemoglobin without any mutation of amino acid residues.

7 OTHER ASPECTS OF MYOGLOBINS AND HEMOGLOBINS

Iron porphyrin as a prosthetic group of heme proteins undergoes a variety of ligand binding and other reactions. Thus, it is no wonder that myoglobin and hemoglobins exhibit multiple functions in vivo and/or in vitro. In the final section of this article, two other reactions of myoglobin and hemoglobin are briefly reviewed.

7.1 NO Binding

In the last decade, nitric oxide (NO) chemistry for biological systems has attracted considerable attention, because NO is not only a toxic agent for organisms but also an important messenger in many vertebrate signal-transduction processes (*see* ***Nitrogen Monoxide (Nitric Oxide): Bioinorganic Chemistry***). For example, a soluble guanylyl cyclase is a famous heme protein which is activated upon NO binding.[80] NO binding to ferrous heme-iron in myoglobin and hemoglobin is very strong with a binding constant of 2×10^7 M^{-1} for wild-type sperm whale myoglobin,[81] whereas NO can also bind to ferric heme-iron in the heme proteins in the range of 10^3–10^4 M^{-1}.[82] In addition, it is of particular interest to compare the ligand-binding structure between O_2 and NO in the heme proteins. Based on several spectroscopic studies, upon NO binding, the Fe–His(E7) bond in the α-subunit of



Scheme 2 NO binding behavior in heme proteins

hemoglobin is ruptured to form a pentacoordinate Fe–NO species, while the corresponding Fe–His bond in myoglobin and the β-subunits of hemoglobin weakens due to a repulsive trans effect as shown in Scheme 2.[83–86] The secondary physiological function of myoglobin is now considered to be a scavenger or reservoir for NO; for example, deoxymyoglobin or oxymyoglobin may prevent NO from inhibiting the cytochrome *c* oxidase reaction.[87] In the case of hemoglobins, the interaction of NO with the protein is more complicated, because NO binds to a β-93 cysteinyl residue as well as heme-iron in hemoglobin and forms an *S*-nitrosothiol.[88–90] Although NO can be transported by hemoglobin linked with O_2 transport, the molecular mechanisms of NO to explain the physiological function of hemoglobin are still being discussed.[91–93]

7.2 Peroxidase Activity of Myoglobin

Myoglobin has the same prosthetic group as some peroxidases, such as horseradish peroxidase (HRP) or cytochrome *c* peroxidase, and reacts with H_2O_2 to produce a ferryl species, PFe(IV)=O, observed in the native peroxidase (*see* ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***). However, the catalytic activity of myoglobin toward substrate oxidation is very low, because the structure of the distal side of myoglobin is slightly different from that of HRP, and myoglobin has no substrate-binding site. To convert myoglobin into a peroxidase or peroxygenase, some groups have modified several residues on the distal side by site-directed mutagenesis.[94–98] For example, the F43H/H64L mutant, which resembles cytochrome *c* peroxidase in distal structure, exhibits high peroxygenase activity toward thioanisole and styrene oxidation; there is a 360-fold increase in turnover of thioanisole oxidation relative to that of wild-type myoglobin.[99] Furthermore, upon the addition of H_2O_2 to the ferric H64D, a transient compound I with a porphyrin ring cation radical, $P^{+\bullet}$Fe(IV)=O, was directly observed by UV-vis spectroscopy at 4 °C, although no evidence of the formation of compound I has been obtained with wild-type sperm whale myoglobin.[100] In contrast, horse heart myoglobin reconstituted with a chemically modified heme having two benzene moieties bound to the terminal propionates has been reported to exhibit 13-fold greater specificity than native myoglobin in the oxidation of guaiacol, because the two benzene moieties located at the exit of the heme pocket will form a substrate-binding domain on the protein surface.[101] In addition, hybridization of the modified heme and an appropriate mutant such as H64D remarkably enhances peroxidase activity toward guaiacol oxidation by ca. a 430-fold increase in the k_{cat}/K_m value relative to wild-type myoglobin.[102]

1 INTRODUCTION

The cytochromes are a class of iron-containing heme proteins that are primarily involved in biological electron-transfer reactions. MacMunn[1] first discovered spectral evidence for the cytochromes in 1886 using a microspectroscope. He found that reduction of a variety of tissues from different organisms with ammonium hydrosulfide led to the appearance of a four-banded spectrum with absorption maxima at 604 nm, 566 nm, 550 nm, and 520 nm (Figure 1). These spectral features disappeared upon oxidation with hydrogen peroxide or ferricyanide. He named the material responsible for these spectral bands ''histohematin''. However, Levy[2] reported that many of these spectroscopic features could be mimicked by mixtures of hemoglobin derivatives. The influential chemist and editor Hoppe–Seyler[3] supported Levy's position and rejected MacMunn's discovery of a new class of compounds. It was not until 1925 that Keilin confirmed MacMunn's spectroscopic studies and named the new class of compounds ''cytochromes'', which means cellular pigments. In an elegant series of experiments, he found that the four-banded spectrum rapidly appeared in the flight muscles of a live wax moth during muscular activity, and then disappeared when the moth rested. Keilin's experiments were the first to establish a direct correlation between the chemical state of a cellular component and the physiological state of the organism. Keilin identified the absorption bands at 604 nm, 566 nm, and 550 nm as the α-bands of three different cytochromes, *a*, *b*, and *c*, respectively. The broadband at 520 nm is due to overlapping β-bands of the three cytochromes. A more detailed account of the discovery of cytochromes can be found in Keilin.[4]

The first isolation of cytochrome *c* (Cc) from yeast[5] was followed by more efficient isolation procedures to obtain highly purified Cc from beef heart with an iron content of 0.43%, corresponding to a MW of 12 600.[6] The interested reader should consult Moore and Pettigrew[7] and Scott and Mauk[8] for recent books on Cc. Mitochondrial Cc has a single iron-containing porphyrin (Figure 2) covalently attached to a polypeptide chain of 103–113 amino acids by thioether bridges to two cysteine sulfhydryl residues (Figure 3). The iron atom is ligated by the nitrogen atom of a histidine residue, and the sulfur atom of a methionine residue. In oxidized ferricytochrome c the Fe(III) has a single unpaired electron and the heme has a formal charge of +1, while in reduced ferrocytochrome *c* Fe(II) has no unpaired electrons and the heme has no formal charge. The reduction potential of mitochondrial Cc is +260 mV versus NHE. Cytochromes *c* have also been isolated from a wide variety of nonmitochondrial sources including bacteria, algae, plants, and animals. These Cc have as many as four heme groups, and reduction potentials ranging from −290 to +400 mV. The amino acid sequences of over 96 Cc have now been determined, more than for any other protein.

The *b* cytochromes contain noncovalently-attached protoheme in which the cysteine bridges are replaced by vinyl groups. The iron atom in most *b* cytochromes is ligated by two histidine nitrogen atoms, and has a redox potential of about 0 V. The 604 nm absorption band in reduced mitochondria is due to two *a*-type cytochromes, cyt *a* and cyt a_3, which are components of cytochrome oxidase (CcO) (*see* ***Cytochrome Oxidase***). A number of other classes of cytochromes have been discovered, including cytochrome peroxidases (CcP) (*see* ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***), cytochrome P-450, and cytochrome o (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***).

2 FUNCTION OF CYTOCHROMES

Eugene Kennedy and Albert Lehninger[9] discovered in 1948 that mitochondria are responsible for carrying out oxidative

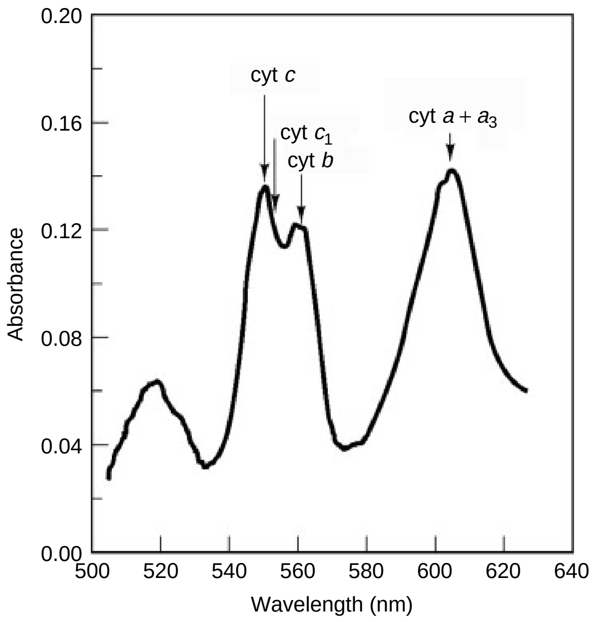

Figure 1 Visible absorption spectrum of cytochromes in beef heart mitochondria. The mitochondria were suspended at a concentration of 1 mg mL^{-1} and the reduced minus oxidized difference spectrum recorded. (Figure 5 (p. 14) from ''Mitochondria: A Practical Approach'' edited by Darley-Usmar *et al.* (1989). By permission of Oxford University Press)

phosphorylation, the major energy transduction process in eukaryotic cells. Mitochondria are small organelles that are believed to have evolved from aerobic bacteria that established a symbiotic relationship inside primitive anaerobic eukaryotic cells. Mitochondria typically have a length of 1 to 2 µm, and have two membranes (Figure 4). The outer membrane is unfolded and is permeable to ions and molecules smaller than about 5000 Da. The inner membrane is highly folded into cristae, and is impermeable to most small molecules and ions. The inside aqueous phase, or matrix, is a very concentrated solution of proteins including the citric acid cycle enzymes, fatty acid oxidation enzymes, as well as many others. The mitochondrial respiratory chain consists of four large protein complexes that are an integral part of the inner mitochondrial membrane. The transport of two electrons from nicotinamide adenine dinucleotide (NADH) to oxygen by this respiratory chain is accompanied by the translocation of about 11 protons from the inside to the outside of the inner mitochondrial membrane. The stored free energy of the resulting proton gradient is then used to translocate protons across the ATP synthase complex, resulting in the synthesis of one molecule of ATP for every three protons transported. Enormous progress has been made in our understanding of the molecular mechanism of the mitochondrial electron-transport chain over the past decade. X-ray crystal structures have been determined for three of the four electron-transfer complexes: succinate–ubiquinone reductase, cytochrome bc_1, and CcO. The X-ray crystal structure has also been determined for the F_1 component of ATP synthase, as well as a portion of the F_o component. The roles of many individual amino acids in these complexes have been determined by site-directed mutagenesis studies, and powerful new techniques have been developed to study rapid electron-transfer reactions within and between the complexes.

The first complex in the respiratory chain, NADH:ubiquinone oxidoreductase (complex I), transfers two electrons from matrix NADH to ubiquinone to form ubiquinol. This

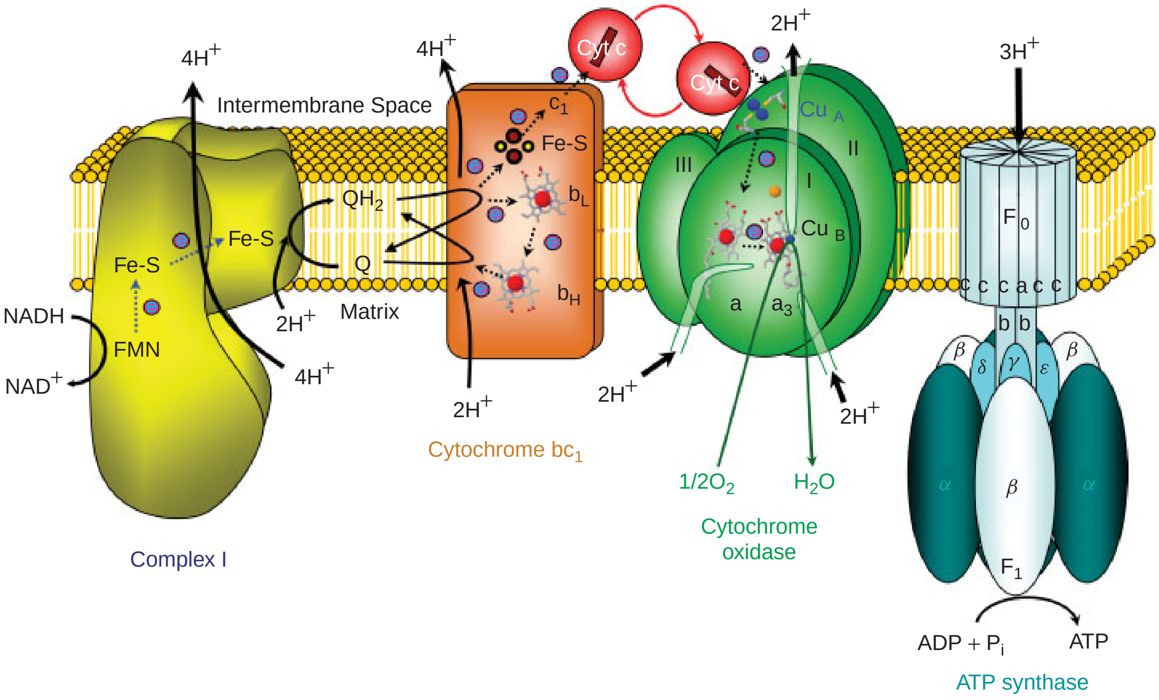

Figure 4 Mitochondrial electron-transport chain

electron-transfer reaction is coupled to the translocation of 4 protons across the inner mitochondrial membrane. NADH:ubiquinone oxidoreductase is the largest and least understood complex of the mitochondrial respiratory chain, containing 45 polypeptide chains, seven iron–sulfur centers, and one flavin mononucleotide (FMN), with a total molecular weight of nearly 1 million Da. The cyt bc_1 complex is perhaps the most universal electron-transfer complex, and is found in many prokaryotes and photosynthetic bacteria as well as eukaryotic mitochondria.[10] The X-ray crystal structure has been determined for cyt bc_1 from bovine, chicken, and yeast mitochondria.[11–14] The enzyme from bovine mitochondria is a dimer with 11 polypeptide chains and molecular weight of 250 000 Da monomer. The complex contains two b cytochromes (b_L and b_H) located on a single transmembrane polypeptide chain, and cyt c_1 and the Rieske iron–sulfur protein (2Fe2S) located on the cytoplasmic side of the membrane. Electron transfer through the complex involves a Q-cycle mechanism in which four protons are translocated to the positive (P) side of the membrane per two electrons transferred from ubiquinol to Cc (see Section 8). The major function of Cc is to transport electrons from the cyt bc_1 complex to CcO. It is a very positively charged protein, and is known to bind to both cyt c_1 and CcO by means of electrostatic interactions. Detailed chemical modification experiments in three separate laboratories have shown that the lysine amino groups immediately surrounding the heme crevice of Cc are involved in binding to negatively charged domains on both cyt c_1 and CcO (see Section 3.). Since the binding domain on Cc for these two proteins is nearly identical, Cc must function as a mobile electron shuttle during electron transport. Cytochrome *c* oxidase, the terminal member of the mitochondrial electron-transport chain, sequentially accepts four electrons from Cc and uses them to reduce molecular oxygen to water. This electron-transfer reaction is coupled to the pumping of four protons across the mitochondrial membrane. CcO from bovine heart is a dimer with 13 subunits and a molecular weight of 200 000 Da per monomer. The enzyme contains four redox centers, Cu_A, heme a, heme a_3, and Cu_B. The X-ray crystal structure has been determined for CcO from bovine heart and *Paracoccus denitrificans* (*P. denitrificans*).[15,16] (see Section 9; *see* ***Cytochrome Oxidase***).

A number of other cytochromes are located in the intermembrane space and the inner surface of the outer mitochondrial membrane. Cyt b_5 (cytochrome b_5) is a small heme protein with a hydrophilic domain of about 95 amino acids and a carboxyl terminus of about 45 hydrophobic amino acids that serve to anchor the protein to the inner surface of the outer mitochondrial membrane.[17] Cyt b_5 is reduced by NADH-cyt b_5 reductase, also located on the inner surface of the outer membrane. Under conditions of high intermembrane ionic strength, Cc is released from the inner membrane, and can transport electrons from cyt b_5 on the outer membrane to CcO on the inner membrane. Cyt b_5 contains protoheme *b* with the iron atom ligated by two histidine nitrogen atoms. The heme group has a reduction potential of +10 mV versus NHE. Cyt b_5 is also found on the liver endoplasmic reticulum membrane, where it transfers electrons from NADH-cyt b_5

reductase to fatty acid desaturase and cytochrome P-450. A form of cyt b_5 lacking the hydrophobic tail is found in red blood cells, where it reduces the ferric iron of Met-hemoglobin back to the ferrous state that is active in oxygen transport.

Several larger enzymes present in the intermembrane space contain a cyt *b* domain that is homologous to cyt b_5. Sulfite oxidase located in the intermembrane space of liver mitochondria carries out the terminal step in the degradation of sulfur amino acids, the oxidation of sulfite to sulfate accompanied by the reduction of two molecules of Cc.[18] Sulfite oxidase is a dimer of two identical chains of 60 000 Da. Each subunit contains two domains, a large domain of 50 000 Da containing a molybdenum prosthetic group, and a small domain of 10 000 Da containing cyt *b*. The small cyt *b* domain can be released from the large domain by tryptic hydrolysis, and is quite homologous to cyt b_5 in terms of amino acid composition and redox properties. In the reaction of this enzyme, sulfite is oxidized to sulfate by the molybdenum cofactor, and the electrons are then transferred to cyt *b*. Cc present in the intermembrane space then transports electrons from cyt *b* of sulfite oxidase to CcO. Flavocytochrome b_2 located in the intermembrane space of yeast mitochondria catalyzes the two-electron oxidation of L-lactate to pyruvate followed by reduction of two molecules of Cc. It is a tetramer of identical subunits, each with a molecular weight of 57 500. The crystal structure[19] revealed that each subunit is composed of two domains, one binding an FMN prothetic group and the second binding cyt *b*. The cyt *b* domain is quite homologous to cyt b_5. Lactate is oxidized by FMN, and the electrons are then transferred to cyt *b*. Cc then transports the electrons from cyt *b* to CcO. The intermembrane space of yeast mitochondria also contains cytochrome *c* peroxidase, which carries out the two-electron reduction of hydrogen peroxide to water accompanied by the oxidation of two molecules of ferrocytochrome *c* (see Section 7; *see* ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***). Cc plays a central role as a mobile shuttle in transporting electrons between the outer membrane, the intermembrane space, and the inner membrane. In addition, release of Cc from the mitochondrial membrane triggers the process of apoptosis, or programmed cell death. A wide variety of different cytochromes are found in other organisms and tissues.

3 STRUCTURE AND MECHANISM OF CYTOCHROME *c*

High-resolution X-ray crystal structures have been determined for cytochrome *c* from many different organisms, including yeast (*S. cerevisiae*, iso-1-cyt *c*),[20] rice,[21] horse,[22] tuna,[23] and bonita.[24] Cc from these organisms contains one heme group bound to the protein matrix by two thioether links from the edge of the porphyrin ring to Cys14 and Cys17. The axial positions of the iron are bound to His18 and Met80. Cc from these organisms contain between 103–111 amino acids and share many of the same structural features (Figure 3). They are globular in shape with slightly less than half of the amino acids organized into five α-helices (3–12, 50–55, 61–69, 70–75, and 88–101). The α-helices are separated by six type II 3_{10} bends (21–24, 32–35, 35–38, 39–42, 43–46, and 75–78) and 4 Ω loops (18–32, 34–43, 40–54, and 70–84) with no β-stranded structures. The heme is almost completely buried in the folded protein with only about 4% exposed to the protein surface. A relatively large number of hydrogen bonds in addition to those contributing the α-helical structures provide added stability to the overall structure. Moore and Pettigrew have reviewed the structural features in detail.[7] The amino acids in van der Waals contact with the buried heme macrocycle provide a very hydrophobic environment for the iron, which plays an important role in controlling the redox potential of the heme and the energetics of electron transfer. Interestingly, there are two propionate groups on the heme that are completely buried inside the protein, and at least one of these is probably deprotonated at pH 7. The X-ray structures indicate that there are several amino acid side chains, which could potentially interact through hydrogen bonds or salt bridges with the propionates.

The surface residues of Cc are divided nearly equally between hydrophobic and hydrophilic types. The charged hydrophilic residues are mainly lysines and these tend to cluster around the exposed heme edge and along the sides as indicated in Figure 5. The segregation of charged residues is not totally exclusive. A few carboxylates are scattered over the periphery of the front surface and some lysines are on the back surface. The overall protein is basic with an isoelectric point of 10 and a net charge of +7 at pH 7. Cytochome *c* undergoes significant but reversible changes in conformation at the extremes in pH. Theorell and Akesson[25] have shown that the oxidized form exists in at least five different conformational states over the range of pH from 0 to 13 and the reduced form exists in at least three different conformations. Some of the conformational changes found at high pH appear to involve changes in coordination of the iron, for example, displacement of Met80. The conformation changes are extremely complex and the interested reader should consult Moore and Pettigrew[7] and the extensive list of references cited.

An important question related to the function of Cc is whether or not there are significant differences in the structures of the oxidized and reduced forms of the protein. Structural differences could lead to energetic barriers to electron transfer in the form of reorganizational energies or conformational changes which could regulate the electron-transfer process. There are many chemical differences between the redox states of Cc but it is not clear that these are of consequence in the biological function of Cc.[7,26] For example, under a number of potentially denaturing conditions the oxidized form appears to be less stable than the reduced form. Ferrocytochrome c appears to be resistant to trypsin

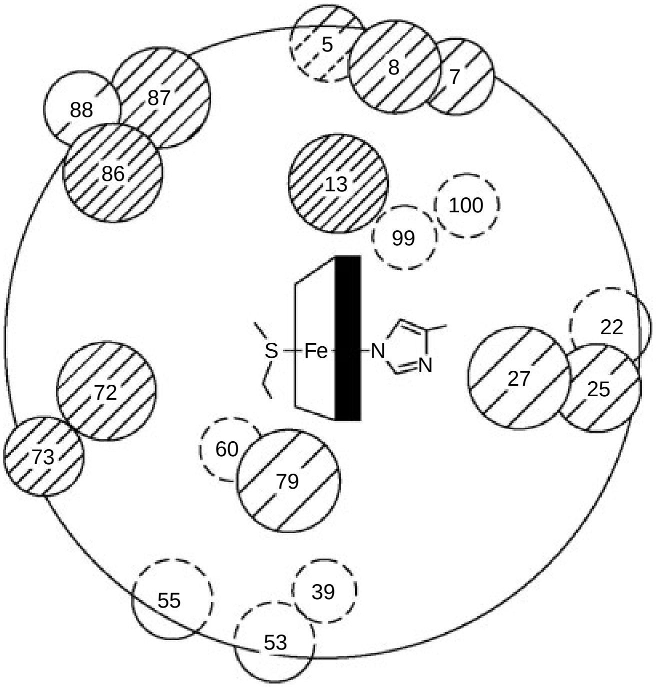

Figure 5 A schematic diagram of horse heart cytochrome *c* viewed from the front of the heme crevice. The approximate positions of the β-carbon atoms of the lysine residues are indicated by *closed* and *dashed* circles for residues located toward the front and back of Cc, respectively. The electrostatic free energy contribution of lysine i, V_i, is indicated by the number of diagonal marks in the circle, with $-0.4\,\mathrm{kJ\,M^{-1}}$ per hatch mark. The binding domain is essentially the same for CcO and cytochrome bc_1

digestion whereas ferricytochrome *c* is not. The binding of small ions and interaction with chromatographic materials appear to be redox-state dependent. Ferricytochrome *c* and ferrocytochrome *c* have different crystal forms and the two cannot be interconverted without damaging the crystals. The X-ray crystal structures indicate that there is little difference in the coordination of the iron between the two redox forms, and the heme is low spin in both oxidation states. Moore and Pettigrew[7] indicate that the differences in iron displacement out of the porphyrin ring plane in mitochondrial Cc are much smaller than those observed in simple porphyrin complexes. Evidence regarding the changes in the remainder of the protein is more ambiguous. X-ray crystallographic studies have indicated that there are no substantial differences in the structures of Fe(III) and Fe(II) forms of horse Cc.[27,28] However, small differences (on the order of an angstrom or less) were noted in the locations of some of the side chains which are consistent with NMR studies. X-ray studies of the bacterial cytochromes *Rhodospirillum rubrum* c_2[29] and *Pseudomonas Aeruginosa* *c*-551[30] show little difference in structure for oxidized and reduced forms.

The mechanism by which Cc transports electrons from the cyt bc_1 complex to CcO is very complicated. An important question posed in the early 1970s is whether Cc binds to cyt bc_1 and CcO at separate sites, or instead has a single binding site for both proteins, and functions as a mobile electron shuttle. It was known that Cc binds to both proteins by means of electrostatic interactions, so the search for binding sites focused on the positively charged domains of Cc. Upon examining the crystal structure, Takano *et al.*[31] proposed that the cyt bc_1 complex might bind to the ‘‘left channel’’ of Cc defined by residues 55 to 75 that form a loop surrounding hydrophobic residues that lead from the surface of the protein to the heme. The eight lysine residues at the periphery of the channel would bind the cyt bc_1 complex electrostatically, while the aromatic residues Tyr74 and Tyr67 would form an electron-transfer pathway. Takano *et al.* also proposed that CcO binds to the ‘‘right channel’’ bounded by residues 1 to 20 and 89 to 101. This channel is also surrounded by lysine residues, and contains the aromatic residues Phe10 and Tyr97 that could transfer electrons from the heme to CcO. In contrast, Salemme *et al.*[32] proposed that both the cyt bc_1 complex and CcO bind to the front of Cc, and that electrons are transferred directly through the exposed edge of the heme. The highly conserved lysine amino groups surrounding the heme crevice of Cc would bind to negatively charged residues on the cyt bc_1 complex and CcO.

Several different laboratories addressed this question experimentally in an extensive series of chemical modification studies to map the binding domain on Cc for the partners. These studies focused on preparing derivatives in which single lysine amino groups were modified to form uncharged or negatively charged groups. Margoliash and coworkers[33,34] prepared 12 different derivatives modified at single lysine residues with the negatively charged 4-carboxy-2,5-dinitrophenyl (CDNP) group, while Millett and coworkers[35–37] prepared 17 derivatives modified with a neutral trifluoracetyl (TFA) or trifluoromethylphenylcarbamoyl (TFC) group. Enzyme kinetic studies[38–40] revealed that modification of any of the lysines immediately surrounding the heme crevice inhibited the binding interaction with both the cyt bc_1 complex and CcO (Figure 5). Using a different approach, Rieder and Bosshard[41] found that these lysine residues were protected from acetylation by complex formation with either the cyt bc_1 complex or CcO. The combined results of these three research groups have demonstrated that the binding domain for both proteins is located at the heme crevice, and that the lysines immediately surrounding the heme crevice help bind the redox partners. Since the binding domains for the cyt bc_1 complex and CcO are the same, Cc must function as a mobile shuttle during electron transport.

Smith *et al.*[42] estimated the contribution V_i that a positively charged amino group on lysine i makes to the total electrostatic free energy of binding by comparing the decrease in binding strength due to modification of lysine i with the neutral TFA or TFC groups, or the negatively charged CDNP group. These V_i values are represented on Figure 5 as the number of hatch marks on the circle for each lysine. Smith *et al.* went on to develop a semi-empirical relationship

representing the electrostatic interaction between Cc and its redox partners by specific complementary charge-pair interactions. This relationship agrees quantitatively with the ionic-strength dependence of the reactions of native Cc with CcO and the cyt bc_1 complex. The interaction with the oxidase involves 8 electrostatic interactions, with interaction energies ranging from $-5.0\,\mathrm{kJ\,mol^{-1}}$ to $-1.3\,\mathrm{kJ\,mol^{-1}}$ (Figure 5). The total electrostatic energy of binding is $-25\,\mathrm{kJ\,mol^{-1}}$ at 50 mM ionic strength. The interaction with the cyt bc_1 complex involves 7 electrostatic interactions, with a total electrostatic energy of binding of $-21\,\mathrm{kJ\,mol^{-1}}$ at 0.2 M ionic strength.

The studies reported above lead to the prediction that the interaction site on CcO consists of a cluster of carboxylate residues. Millett *et al.*[43] found that the water-soluble carbodiimide 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide (EDC) specifically modified five carboxylate groups on subunit II of CcO and inhibited the reaction with Cc. Binding one molecule of Cc to CcO protected Asp112, Glu114, Asp115, and Glu198 from modification by EDC, and prevented the loss in electron-transfer activity. These studies suggest that the negatively charged carboxylate groups on these residues are involved in binding Cc. Glu198 is located between the conserved cysteines 196 and 200 that have been shown to ligand Cu_A.[44] Thus, it is possible that Cu_A is the initial electron acceptor in CcO. Asp112, Glu114, and Asp115 are located in a highly conserved sequence (104–115) containing alternating acidic and aromatic residues that could serve as an electron-transfer pathway from Cc to cyt a or Cu_A. Stonehuerner *et al.*[45] used EDC to identify the binding domain on the cyt bc_1 complex for Cc. EDC selectively labeled carboxylate groups in the sequence 63–81 of cyt c_1, and Cc binding protected these residues from labeling. This highly acidic sequence contains 7 Asp and Glu residues that could be involved in binding Cc. Broger *et al.*[46] have shown that arylazido–lysine 13 Cc is cross-linked to cyt c_1 somewhere in the highly acidic sequence 165–174, suggesting that carboxylate groups in this region are also involved in Cc binding. The highly acidic ''hinge'' protein in the cyt bc_1 complex is also involved in binding Cc.[47]

4 STRUCTURE OF CYTOCHROME b_5

Cytochrome b_5 exists in a soluble form in erythrocytes and in a membrane bound form in microsomes. A soluble derivative of hepatic cyt b_5 with 93 amino acids can be isolated by treatment of microsomes with pancreatic lipase[48] and this form has essentially the same amino acid sequence as the erythrocyte protein.[49] Further treatment of the soluble form with trypsin cleaves two residues from the N-terminal and seven from the carboxylate-terminal and leaves the heme core with only 84 residues. Rat liver cyt b_5 has been prepared by expression in *Eschericha coli* (*E.coli*). The structure[50] of calf liver cyt b_5 obtained by treatment with pancreatic lipase is illustrated in Figure 6. In contrast to Cc, the porphyrin ring in cyt b_5 is not covalently bound to the protein side chains. The heme is held in a hydrophobic pocket by axial coordination to His63 and His39. As in Cc, most of the residues in van der Waals contact with the porphyrin ring contain bulky hydrophobic side chains. The amino acids of cyt b_5 fold around the porphyrin ring forming six short α-helices separated by a number of β bends. A small region of β-pleated sheet structure can be found near the center of the molecule formed by residues 5–7, 74–80, 27–32, 21–25, and 51–54. The porphyrin ring in cyt b_5 is more exposed to the protein surface than that of Cc. Dixon *et al.*[51] calculated an exposed heme to protein surface area ratio of 0.007 and 0.038 for Cc and cyt b_5, respectively. Both hydrophobic and hydrophilic residues can be found on the surface of cyt b_5. Unlike Cc, however, acidic residues are more dominant than basic residues. The distribution of acidic residues is very uneven with 11 of the 18 carboxylates located on the top half of the protein near the exposed heme edge. The dominance of carboxlate groups gives the protein an overall acidic character with a charge at pH 7 of −9.[52]

An interesting feature of the crystal structure of cyt b_5 are the heme propionate groups shown in Figure 6. One of the propionate groups extends into the solvent while the other folds back and is hydrogen bonded to Ser64. In Cc, the porphyrin ring is turned by 90° such that the propionates are not exposed to the solvent. Single crystals of the oxidized form of cyt b_5 can be reduced with sodium dithionite. Upon reduction, crystals turn from red to orange without cracking and remain isomorphous with the oxidized form. The structures of the oxidized and reduced forms are practically identical.

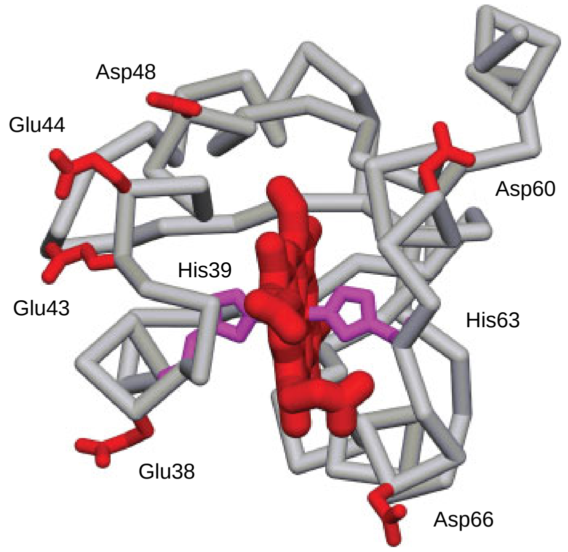

Figure 6 X-ray crystal structure of bovine cytochrome b_5. Acidic residues are red and the heme is red

5 EXPERIMENTAL METHODS FOR STUDYING ELECTRON TRANSFER REACTIONS

The investigation of electron transfer in biological systems over the last two decades can be separated into two general areas: (1) intraprotein electron transfer between metal centers covalently bound to the same protein scaffold and (2) interprotein electron transfer between two separate proteins. The two areas evolved from the realization that many electron-transfer reactions in biological systems appear to take place with large distances separating the metal centers. Thus, the mechanism of long-distance electron transfer became a fundamental component of understanding electron transfer in biological systems. Investigation of intraprotein electron transfer focused initially on artificial systems designed to allow investigators to manipulate the distance between redox centers. Concurrently, many investigators focused on natural systems containing multiple redox centers in the same large protein. The photosynthetic reaction center contains a series of redox centers and is among the most thoroughly investigated.

Photosynthetic reaction centers offer an inherent advantage in the fact that the electron-transfer reactions are activated by light. Thus, very fast laser-based kinetic methods, called laser flash photolysis, can be applied to follow the time course of the reactions. The initial electron transfer step in these systems occurs in approximately 2 ps and is followed by several subsequent steps that are progressively slower. Numerous investigators have focused their attention on these reactions, which are described elsewhere (*see* ***Photosynthesis***).

Three fundamental parameters govern electron transfer: (1) the distance between the redox centers, (2) the difference in the redox potentials of the centers, and (3) the reorganizational barrier, which is related to the difference in the geometries of the oxidized and reduced forms of each of the proteins. Studies of photosynthetic reaction centers have been extremely useful in characterizing the importance of these parameters. In order to further expand this characterization, researchers have developed methods to introduce artificial redox centers into biological systems. The most common strategy involved covalent attachment of ruthenium complexes to specific sites on the surface of small proteins. In other investigations, the iron center of the metalloprotein was changed, commonly to zinc. The results of these studies provided much of our fundamental understanding of the electron-transfer process (*see* ***Long-range Electron Transfer in Biology***).

Surface modification with ruthenium complexes has proven valuable in studies of both interprotein and intraprotein electron transfer in systems that are difficult to study by traditional kinetic tools.[53] The choice of ruthenium complexes in these investigations stems from an extensive photochemistry as well as exceptional thermal stability. The photochemistry provides a means of examining reactions over a time range of nanoseconds to seconds by laser-flash photolysis and the thermal stability allows researchers to covalently bind a wide variety of complexes to proteins with some assurance that the labeled proteins will be stable in subsequent investigations. As a specific example, the use of a ruthenium-labeled cyt b_5 derivative that was designed for the study of both intraprotein- and interprotein electron transfer is described in the following paragraphs.[54,55]

The derivative, Ru-65-cyt b_5, was prepared by the reaction of 4-bromomethyl-4′-methylbipyridine) Ru(bipyridine)$_2^{2+}$ with cyt b_5 that was genetically engineered to place a cysteine at residue 65 of the protein backbone.[54] The reaction involves the elimination of HBr and the formation of a thioether linkage between the 4 methylene carbon of the bipyridine and the cysteine sulfur. The ruthenium complex bound to Cys65 is separated by 12 covalent bonds from His63, which ligates the heme iron as shown in Figure 7. Electron transfer is initiated by exposing Ru-65-cyt b_5 to a short laser flash which excites the resting state, designated as $Ru^{II}Fe^{III}$, to the excited state, $Ru^{II*}Fe^{III}$ (Scheme 1). One of the remarkable properties of these ruthenium complexes is the long excited-state lifetime, typically hundreds of nanoseconds under the conditions of the experiment. The natural decay of the excited state is described by k_d. The excited state Ru(II*) is a strong reducing agent

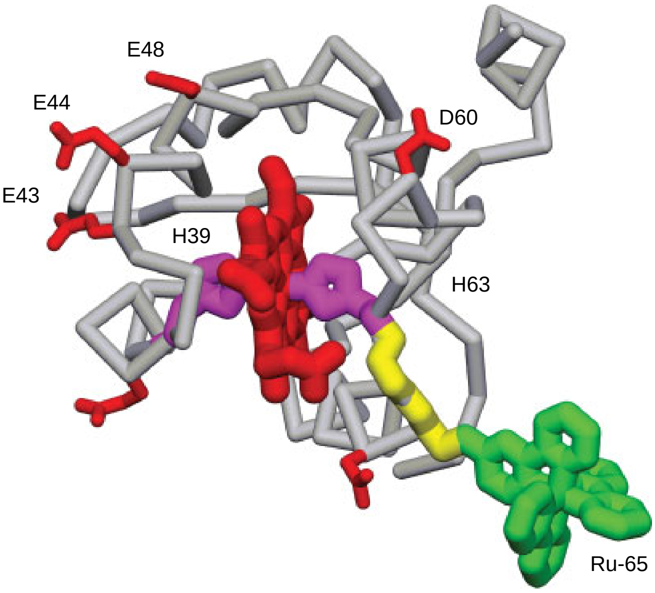

Figure 7 Electron-transfer pathway between ruthenium complex and heme in Ru-65-cyt b_5. The heme group, amino acid residues 63, 64, and 65, and the ruthenium complex are highlighted

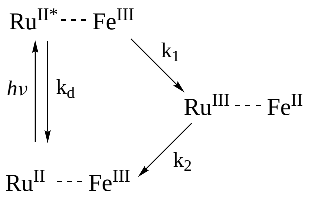

Scheme 1

and rapidly reduces the heme Fe(III) to Fe(II). The resulting ground-state Ru(III) is an extremely strong oxidant and rapidly oxidizes Fe(II) to return the system to the original state. Since the system can be initiated with a laser pulse having a duration of only a few nanoseconds, the time course of the reaction can be followed easily by monitoring the absorbance changes at appropriate wavelengths. The transient absorbance change at 556 nm shows the rapid formation of reduced cyt b_5 followed by a slightly slower reoxidation (Figure 8).[55] The measured rate constants are $k_d = 3 \times 10^6\,s^{-1}$, $k_1 = 12 \times 10^6\,s^{-1}$, and $k_2 = 8.5 \times 10^6\,s^{-1}$. These electron-transfer reactions were further examined using a series of ruthenium complexes with different ligands, which altered the redox potentials over a wide range. A study of the dependence of the rate of reaction on the overall driving force was performed using this strategy.[55] The results were interpreted using the Marcus theory of electron transfer, which in its simplest form is given by equation (1):[56]

$$k_{et} = k_o \exp[-\beta(r - r_o)] \exp\left[\left(-\frac{(\Delta G^{\circ\prime} + \lambda)^2}{4\lambda RT}\right)\right] \qquad (1)$$

where r is the distance between the closest macrocycle atoms in the two redox centers, the van der Waals contact distance $r_o = 3.6$ Å, λ is the reorganization energy, $\Delta G^{\circ\prime}$ is the driving force, $\beta = 1.4\,Å^{-1}$, and the nuclear frequency $k_o = 10^{13}\,s^{-1}$. Dutton and coworkers have found that a wide range of biological electron-transfer systems can be described by this system using the parameters given above.[57] The driving force dependence of the electron-transfer rate constants for Ru-65-cyt b_5 were fitted to equation (1) with r = 13 Å, and $\lambda = 0.94$ eV (Figure 9). The experimental r value is in good agreement with the actual distance between the ruthenium complex and the heme group, while the reorganization energy is in good agreement with the predicted value. Beratan and Onuchic have developed a pathway theory for electron transfer which involves a combination of covalent bond, hydrogen bond, and through-space contributions to the pathway.[58] The kinetic data for Ru-65-cyt b_5 are also in good agreement with this theory, with a pathway consisting of 12 covalent bonds separating the bipyridine ligand of the ruthenium complex and the axial histidine ligand of the heme iron.

The interprotein electron-transfer reactions of Ru-65-cyt b_5 can be studied using a sacrificial electron donor such as aniline to reduce Ru(III) and prevent the back reaction k_2, as described in Scheme 2. Appropriate sacrificial electron donors can also reduce Ru(II*) to Ru(I), which then reduces Fe(III) as shown in the top pathway of Scheme 2. Cyt b_5 is rapidly reduced by either pathway, and is then poised to transfer an electron to another protein. The reaction of cyt b_5 with Cc using this methodology will be described in the next section. Covalent labelling of Cc with ruthenium complexes and subsequent flash photolysis has provided a

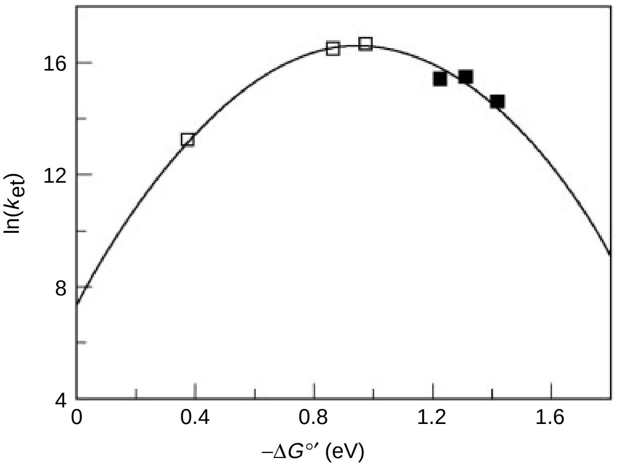

Figure 9 Plot of $\ln k_{et}$ as a function of free energy for electron-transfer reactions of Ru-65-cyt b_5 labeled with different ruthenium polypyridine complexes. The solid line shows the theoretical dependence of equation (1) calculated with a reorganizational energy of 0.94 eV and a distance r of 13 Å. The open boxes are for the reactions involving the excited state, $k_{et} = k_1$, and the filed boxes are for the thermal back reactions, $k_{et} = k_2$, all determined at 22 °C. means of examining the reactions of Cc with CcO, the cyt bc_1 complex, CcP and plastocyanin. More details on these studies are provided in the following sections.

Modification of larger proteins with ruthenium complexes, while possible, have proven difficult. Fortunately, a ruthenium labeled partner such as Cc can be used to rapidly inject or remove an electron from the large protein complex, and thus study internal electron-transfer reactions. In a complementary approach, Nilsson found that the excited state of $Ru(bpy)_3{}^{2+}$ can inject an electron into CcO.[59] The ruthenium complex binds electrostatically to the protein in a location similar to that occupied by Cc. The initial site of electron transfer is the Cu_A site, as it is when Cc is the electron donor. The simplicity of this technique makes it very attractive since it eliminates any modification of the protein which might alter the structure. Sadoski *et al.* showed that significant improvements in the yield of electron transfer could be obtained with ruthenium complexes of higher charge. One specific complex used was the dinuclear complex $[(bpy)_2Ru(qpy)Ru(bpy)_2]^{4+}$ (Figure 10).[60]

6 THE CYTOCHROME b_5–CYTOCHROME *c* REACTION

The reaction between cyt b_5 and Cc has served as a prototype of biological electron-transfer reactions because both proteins are small, well-characterized, and have known X-ray crystal structures. Ferrocytochrome b_5 rapidly reduces ferricytochrome *c* in a reaction that proceeds through a bimolecular complex stabilized by electrostatic interactions. In the first molecular modeling study of an electron-transfer complex, Salemme[61] proposed that the two proteins form a 1:1 complex stabilized by complementary charge-pair interactions between negatively charged carboxylate groups surrounding the heme crevice of cyt b_5 and lysine amino groups surrounding the heme crevice of Cc. The heme groups

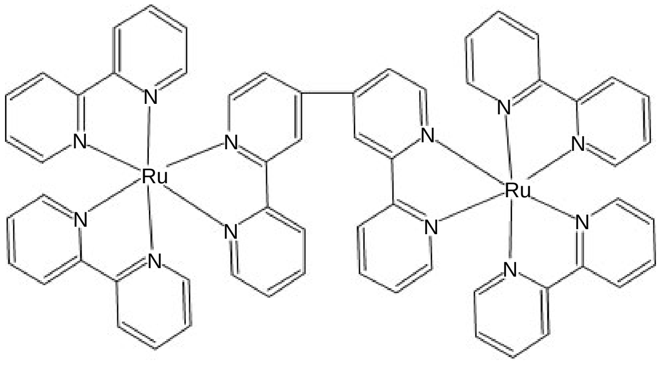

Figure 10 Structure of $[(bpy)_2Ru(qpy)Ru(bpy)_2]^{4+}$

of the two proteins are nearly coplanar in the model, with their edges separated by 8.4 Å. Ng *et al.*[62] found that modification of lysines 13, 25, 27, 72, or 79 surrounding the heme crevice of Cc with TFA or TFC significantly decreased binding to cyt b_5. Rodgers *et al.*[63] found that substitution of Glu48, Asp60, Glu43, or Glu44 on cyt b_5 with glutamine or asparagine residues decreased the binding strength for the complex with Cc by a factor of about 2. A number of other biophysical studies have provided experimental support for Salemme's model[64–68] and indicate that lysines 13, 25, 27, 72, and 79 on Cc form charge-pair interactions with the cyt b_5 carboxylate groups on Asp48, Glu43, Glu44, Asp60, and the most exposed heme propionate group, respectively. NMR and molecular dynamics studies have indicated that the complex is not static as in the original Salemme model, but rather exists in a dynamic equilibrium between several different conformations.[69–71]

The electron-transfer reaction between ferrocytochrome b_5 and ferricytochrome *c* has been studied using a number of different methods. Stopped-flow studies indicated that the reaction is second order above 0.1 M ionic strength, and that the rate constant rapidly decreases with increasing ionic strength.[72] McLendon and Miller used pulse radiolysis to measure a rate constant of $1600 \pm 700\,s^{-1}$ for intracomplex electron transfer at low-ionic strength.[73] The reaction between cyt b_5 and Cc has been extensively studied by Willie *et al.*[54] using the ruthenium-based methodology described in Section 5. The labeled derivative Ru-65–cyt b_5 (Figure 11) was designed specifically to investigate the interprotein electron-transfer reactions of cyt b_5. The position of the ruthenium complex on the surface of Ru-65–cyt b_5 was selected to promote rapid photoinduced electron transfer from ruthenium to the heme group, but not interfere with the binding of redox partners such as Cc (Figure 11). Laser excitation of the Ru-65–cyt b_5–horse Cc complex formed at low-ionic strength resulted in rapid electron transfer from Ru^{II*} to the Ru-65–cyt b_5 heme group, followed by biphasic electron transfer to the Cc heme group with rate constants of $4 \times 10^5\,s^{-1}$ and $3 \times 10^4\,s^{-1}$ (Figure 12). Low-ionic strength favors electrostatic interaction between the proteins and formation of a 1:1 protein–protein complex. At high-ionic strength where the proteins do not form a complex, the reaction is second order and dominated by diffusion rather than electron transfer. Under these conditions, the ruthenium methodology yields the same rate constants as for the reaction between unmodified cyt b_5 and Cc. The overall results are consistent with recent ionic-strength calculations by Sivozhelezov.[74]

Wendoloski *et al.*[71] carried out molecular dynamics studies of the complex between cyt b_5 and Cc, and reported that complex formation altered the position of the side chain on Cc residue Phe82 to a new position between the two heme groups. This led to the proposal that the aromatic ring on Phe82 may act as an electron-transfer bridge between the heme groups of cyt b_5 and Cc. However, Willie *et al.* found that substitution of Phe 82 with Tyr, Gly, Leu, or Ile did not change the rate

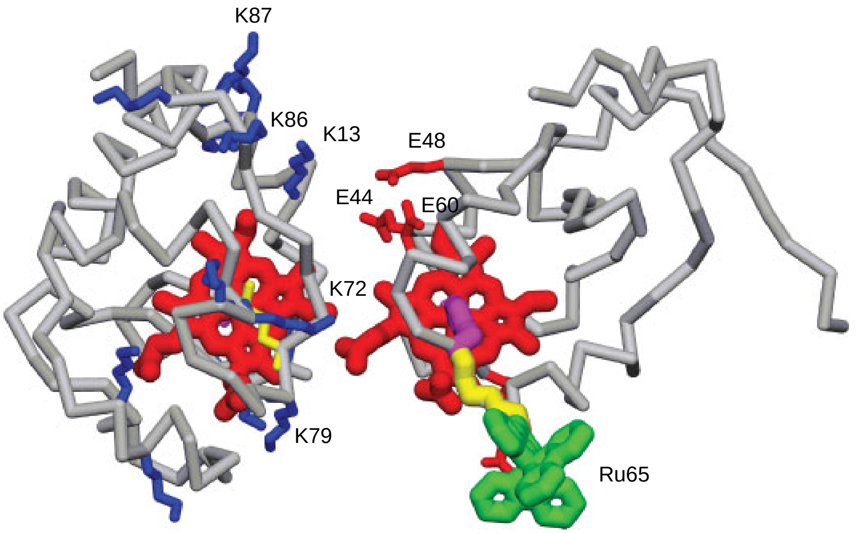

Figure 11 Molecular model of the complex between Ru-65-cyt b_5 and Cc. The geometry of the complex is the same as that of the complex involving native cytochrome b_5 proposed by Salemme. The heme groups (red), and the ruthenium complex (green) are highlighted. The atoms forming an electron-transfer pathway between the ruthenium complex and the heme group of Ru-65-cyt b_5 are colored yellow. The lysine and arginine residues are blue, while aspartate and glutamate residues are red[54]

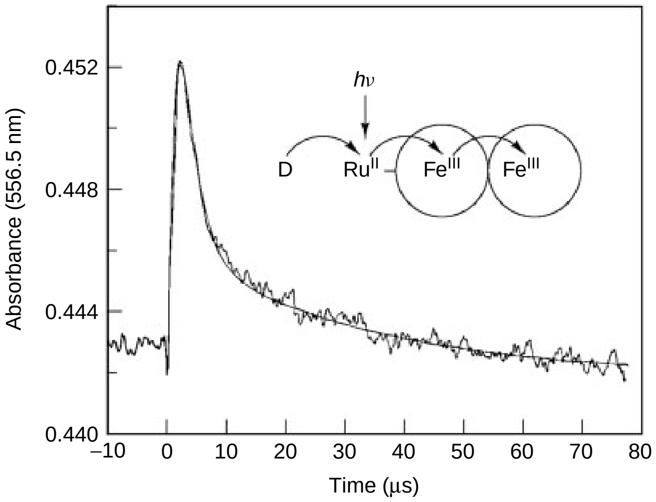

Figure 12 Transient absorption profile recorded at 556.5 nm for electron transfer in a solution containing 20 μM Ru-65-cyt b_5, 26 μM Cc, 1 mM sodium phosphate, pH 7, and 10 mM aniline. The transient was fit to a biexponential function with $k_f = 4.0 \times 10^5\ s^{-1}$ and $k_s = 3.4 \times 10^4\ s^{-1}$. (Reprinted with permission from Ref. 54. © 1992 American Chemical Society)

constant for electron transfer from cyt b_5 to Cc by more than a factor of two.[75] These results demonstrate that an aromatic side chain is not needed at Phe 82 for rapid electron transfer with Cc. The biphasic kinetics observed for the reaction of Ru-65–cyt b_5 with Cc at low-ionic strength indicate that there are at least two different conformational forms of the complex. This is consistent with previous studies indicating that the cyt b_5–Cc complex may exist in dynamic equilibrium between several different forms.[69–71] As the ionic strength increases, the fast-phase rate constant decreases and the slow-phase rate constant increases until a single phase is present at 50 mM ionic strength. This behavior indicates that the two different conformations of the complex interconvert more rapidly with increasing ionic strength.

7 CYTOCHROME *c*–CYTOCHROME *c* PEROXIDASE REACTION

The cytochrome *c*–cytochrome *c* peroxidase system has become an important paradigm for investigating fundamental questions about interprotein electron transfer. Extensive structural data are available for Cc isolated from many different organisms, while the X-ray crystal structure of yeast CcP has been determined for both the resting ferric form of the enzyme, CcP, and the hydrogen peroxide oxidized form Compound I (CMPI)[76,77] (*see* ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***). Moreover, Pelletier and Kraut have determined the crystal structure of the 1:1 complex between yeast iso-1-cytochrome *c* (yCc) and CcP.[78] In the first step of the reaction, hydrogen peroxide oxidizes ferric CcP to CMPI ($Fe^{IV} = O,R^{\bullet+}$), which contains an oxyferryl heme $Fe^{IV} = O$ and an indolyl radical cation, $R^{\bullet+}$, located on Trp191.[79,80] CMPI is then sequentially reduced to CMPII and CcP in two one-electron steps involving ferrocytochrome *c*. Two forms of the singly oxidized state CMPII have been identified, CMPII($Fe^{IV} = O,R$) containing the oxyferryl heme and CMPII($Fe^{III},R^{\bullet+}$) containing the radical cation.[81] A number of important questions about the

reaction mechanism will be addressed here. First, does Cc react initially with $Fe^{IV} = O$ on CMPI($Fe^{IV} = O, R^{\bullet+}$) to form CMPII($Fe^{III}, R^{\bullet+}$), or instead with the radical cation to form CMPII($Fe^{IV} = O$,R). Second, what are the true rate constants for electron transfer from Cc to the radical cation and the oxyferryl heme. Third, what binding domain(s) and pathways are used by Cc for electron transfer to the radical cation and the oxyferryl heme. Fourth, what is the mechanism for complete reduction of CMPI by two molecules of Cc under physiological conditions.

A new yeast Ru-Cc derivative, Ru-39-Cc, was designed to study the reaction mechanism with CcP (Figure 13).

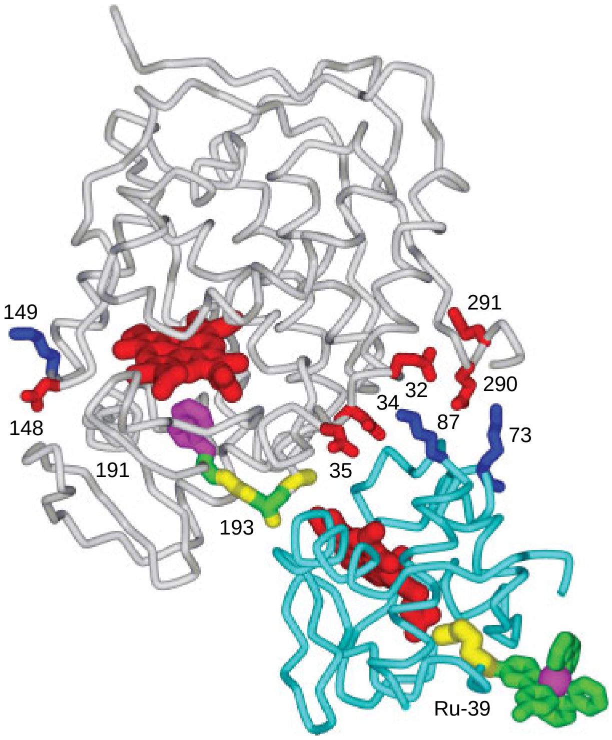

Figure 13 X-ray crystal structure of the CcP-yCc complex.[78] The heme groups are colored red, the Trp191 indole group is purple, the Trp191 backbone and Ala193 are green, Gly192 and Ala 194 are yellow, and Ru39 is green. Cc residues 39–41 between Ru-39 and heme c are colored yellow. The side chains of CcP residues E32, D34, E35, E290, E291, and yCc residues K73 and K87 are labeled. The low-affinity Cc binding site is proposed to be located near D148 and K149, which are labeled

The sulfhydryl group at Cys39 on the back surface of yeast H39C,C102T iso-1-Cc was labeled with Ru(bpy)$_2$(4-bromomethyl-4′methyl-2.2′-bipyridine) to give Ru-39-Cc.[82] Both the binding constant at low-ionic strength and second-order rate constant at high-ionic strength for the reaction of Ru-39-Cc with CcP are the same as for native yCc.[83] These results indicate that the ruthenium group on the backside of Ru-39-Cc does not affect the interaction with CcP. Electron transfer from Ru(II*) to the heme group in Ru-39-Cc occurred with a rate constant of $5 \times 10^5\ s^{-1}$. There is good electronic coupling between the ruthenium complex and the heme group involving 13 covalent bonds and one hydrogen bond (Figure 13). The driving force of the reaction, 1.1 eV, is close to the reorganization energy of 0.74–1.0 eV, and thus the rate constant is close to the maximum value (cf. Figure 9).

When a 1:1 Ru-39-Cc:CMPI complex was excited with a single laser flash at low-ionic strength, the excited state Ru(II*) rapidly reduced heme c Fe(III), followed by electron transfer from heme c Fe(II) to the Trp191 radical cation in CMPI with rate constant $k_{eta} = 2.0 \times 10^6\ s^{-1}$ (Figure 13; Scheme 3).[83] Excitation with a second laser flash resulted in electron transfer from heme c Fe^{II} to the oxyferryl heme in CMPII($Fe^{IV} = O$,R) with rate constant $k_{etb} = 5000\ s^{-1}$. These studies indicate that the Trp191 radical cation is the initial site of reduction in CMPI, rather than the oxyferryl heme. Stopped-flow studies have confirmed that native yeast and horse Cc also initially reduce the Trp191 radical cation in CMPI under a variety of ionic strength and pH conditions.[84]

On the basis of their crystal structure of the complex between yeast iso-1-Cc (yCc) and CcP, Pelletier and Kraut have proposed an electron-transfer pathway that extends from the exposed heme methyl group of Cc through CcP residues Ala194, Ala193, and Gly192 to the indole group of Trp191 (Figure 13). In order to determine whether the reaction domain used in solution is the same as found in the crystal structure, the reaction of Ru-39-Cc with a series of CcP mutants with altered surface residues was examined (Table 1). These studies indicate that the reactions of Ru-39-Cc with both the radical cation and the oxyferryl heme in solution use the binding domain identified in the crystal structure (Table 1, Figure 13).[83] The rate constants k_{eta} and k_{etb} were each decreased 3- to 4-fold by the mutations D34N, E290N, and A193F, while the dissociation constant K_d of the complex

$$c^{II} + (R^{\bullet+}, Fe^{IV}{=}O) \underset{k_d}{\overset{k_f}{\rightleftharpoons}} c^{II}{:}(R^{\bullet+}, Fe^{IV}{=}O) \xrightarrow{k_{eta}} c^{III}{:}(R, Fe^{IV}{=}O) \underset{k_f}{\overset{k_d}{\rightleftharpoons}} c^{III} + (R, Fe^{IV}{=}O)$$

$$c^{II} + (R, Fe^{IV}{=}O) \underset{k_d}{\overset{k_f}{\rightleftharpoons}} c^{II}{:}(R, Fe^{IV}{=}O) \xrightarrow{k_{etb}} c^{III}{:}(R, Fe^{III}) \underset{k_f}{\overset{k_d}{\rightleftharpoons}} c^{III} + (R, Fe^{III})$$

Scheme 3

Table 1 Effect of CcP mutants on reaction with Ru-39-Cc. k_{eta} and k_{etb} were measured at 5 mM and K_d at 100 mM ionic strength[83]

Mutant	$k_{eta} \times 10^{-6}\,s^{-1}$	$k_{etb} \times 10^{-3}\,s^{-1}$	K_d (μM)
CcP	2.0	5.0	0.6

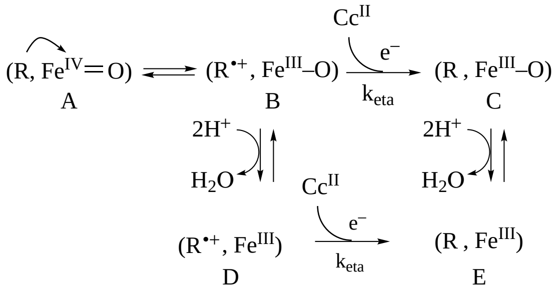
between Ru-39-Cc and CMPI was increased by 10- to 20-fold (Table 2). The negatively charged carboxylates on Asp34 and Glu-290 interact electrostatically with the positively charged yCc lysines 87 and 73, respectively, in the crystalline complex (Figure 13). The methyl group of Ala193 is in van der Waals contact with the heme CBC methyl group at the center of the crystalline binding domain. Since the value of k_{eta} is independent of viscosity and temperature, it is the true rate constant for electron transfer from the Cc heme to the Trp191 radical cation and not rate-limited by conformational gating.[85] The experimental rate constant k_{eta} can thus be compared with predictions of the Marcus theory based on the crystal structure. The distance between the heme group in yCc and the Trp191 indole ring atom in CcP is 16.0 Å in the crystal structure. Since k_{eta} is independent of temperature, it is reasonable to assume that the driving force $-\Delta G^{\circ\prime}$ equals the reorganization energy λ. A theoretical rate constant of $k_{et} = 3 \times 10^5\,s^{-1}$ is calculated using equation (1). This theoretical estimate is in reasonable agreement with the experimental value of $k_{eta} = 2 \times 10^6\,s^{-1}$. The best pathway between heme *c* and the Trp191 indolyl radical cation consists of 11 covalent bonds and a van der Waals contact of 4.1 Å between the heme CBC methyl group and the Ala193 methyl group.

The reduction of CMPII($Fe^{IV} = O$, R) has been found to involve rapid internal electron transfer leading to formation of the radical cation in CMPII(Fe^{III}, $R^{\bullet+}$), which is then reduced by yCc^{II} in the high-affinity binding site (Scheme 4).[87]



Scheme 4

The steps A → B → D in Scheme 4 have a rate constant of $1100\,s^{-1}$, which is rate limited by proton transfer to the oxygen atom on the iron. At low concentrations of solution Cc^{II}, reduction of CMPII($Fe^{IV} = O$, R) involves steps A → B → D → E with second-order rate constant k_b.[83] However, at saturating concentrations of Cc^{II} the reduction of CMPII($Fe^{IV} = O$, R) involves the steps A → B → C → E with rate constant $k_{etb} = 5000\,s^{-1}$.[83] This suggests that proton transfer is faster in the C → E step than in the B → D step due to electrostatic repulsion by the radical cation. Mutating Trp191 to Phe decreased the rate of reduction of the oxyferryl heme by yCc^{II} more than 10 000-fold, showing the essential role of the Trp191 radical cation.[88] Both steps in the complete reduction of CMPI therefore involve electron transfer from Cc^{II} to the Trp191 radical cation using the binding site and pathway identified in the crystal structure.

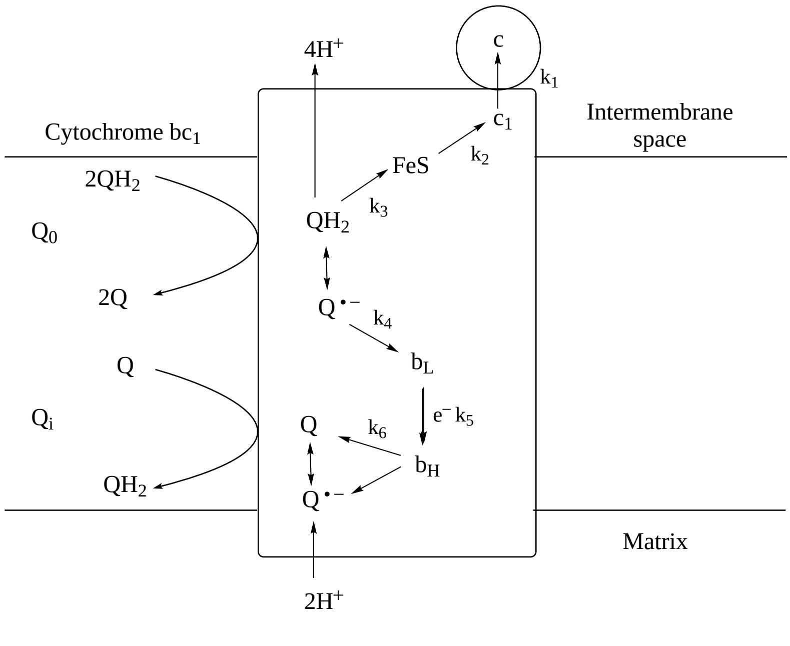
A second molecule of yCc binds to a low-affinity site on the 1:1 yCc:CcP complex to form a 2:1 complex at low-ionic strength. yCc^{II} binding to the low-affinity site significantly increases the rate constant for dissociation of yCc^{III} from the high-affinity site at low-ionic strength, an example of substrate-assisted product dissociation. Both ruthenium photoreduction and stopped-flow experiments have shown that the low-affinity Cc binding site is not significantly active in direct electron transfer to either the Trp191 radical cation or the oxyferryl heme.[84,89] It is therefore surprising that the excited state of zinc-porphyrin horse Cc, ^{3}Zn-hCc, was found to be active in electron transfer to the ferric heme from the low-affinity site on CcP, but is nearly inactive from the high-affinity site.[90] The reason for this striking difference in reaction pathways is that the Trp191 indole cannot be oxidized to the radical cation by the reductive ^{3}Zn porphyrin, and thus cannot be a redox intermediate in the reaction. The distance between the ^{3}Zn-hCc in the high-affinity site and the CcP heme (26.5 Å metal-to-metal) is too large for efficient electron transfer. ^{3}Zn-hCc binds to the second, low-affinity site close to Asp148 with a metal-to-metal distance of 22–25 Å,[91] which allows a faster rate of electron transfer than from the high-affinity site. These results illustrate that the pathway for electron transfer can depend critically on the reaction mechanism. Electron transfer from ^{3}Zn-hCc to the CcP ferric heme is a pure electron-transfer process that should obey the Marcus relation. In

contrast, electron transfer from yCc to the oxyferryl heme is a complex process involving proton transfer to the oxygen atom and release of water, and requiring the use of the Trp191 radical cation as a redox intermediate.

The mechanism for complete reduction of CMPI by two molecules of Cc^{II} involves two complex formation and dissociation steps and two intracomplex electron-transfer steps (Scheme 3). The formation and dissociation rate constants k_f and k_d of the high-affinity complex between yC*c* and CMPI were measured over a wide range of ionic strength using a ruthenium photoreduction technique.[85] The dissociation constant k_d increases from $<5\,s^{-1}$ at low-ionic strength to $4000\,s^{-1}$ at 150 mM ionic strength, while k_f decreases from $>3 \times 10^9\,M^{-1}\,s^{-1}$ at low-ionic strength to $1.3 \times 10^9\,M^{-1}\,s^{-1}$ at 150 mM ionic strength. The rate constants in Scheme 3 are $k_f = 1.3 \times 10^9\,M^{-1}\,s^{-1}$, $k_d = 4000\,s^{-1}$, $k_{eta} = 1.0 \times 10^6\,s^{-1}$, and $k_{etb} = 3000\,s^{-1}$ at physiological ionic strength, estimated to be 150 mM. The rate-limiting step in the overall reaction is product dissociation below 150 mM ionic strength, and substrate complex formation at higher-ionic strength. At physiological ionic strength, the interaction between yC*c* and C*c*P is optimized to facilitate both rapid substrate complex formation and product complex dissociation.

8 CYTOCHROME *c*–CYTOCHROME *bc*$_1$ REACTION

The cytochrome *bc*$_1$ complex (cyt bc_1) is an integral membrane protein in the electron-transport chains of mitochondria and many respiratory and photosynthetic prokaryotes.[10] The complex contains two b cytochromes (b_L and b_H) located on a single transmembrane polypeptide chain, and cyt c_1 and the 2Fe2S protein located on the cytoplasmic side of the membrane. Each cyt *b* iron is ligated by two histidine nitrogen atoms. Cyt c_1 has a relatively large hydrophilic domain located on the cytoplasmic surface of the membrane, and is anchored to the membrane by a single hydrophobic α-helix at the C-terminus. The redox potentials of cyt b_L, cyt b_H, cyt c_1, and the 2Fe2S center are −80 mV, +50 mV, +280 mV, and +280 mV, respectively. Electron transfer through the complex involves a Q-cycle mechanism in which four protons are translocated to the positive (P) side of the membrane per two electrons transferred from ubiquinol to Cc (Scheme 5).[10] The reaction is initiated at the Q_o site where an electron is transferred from ubiquinol to the 2Fe2S center, and then to cyt c_1 and cyt c. The resulting semiquinone in the Q_o site transfers an electron to cyt b_L and then to cyt b_H and ubiquinone in the Q_i site. The resulting ubisemiquinone remains bound in the Q_i site until it accepts a second electron from cyt b_{562} to form ubiquinol. The Rieske iron–sulfur protein has been found in different conformations in different crystal forms of the complex, and in the presence of Q_o-site inhibitors (Figure 14).[11–14] The Rieske iron–sulfur protein is in the ‘‘*b state*’’ conformation with 2Fe2S proximal to the cyt b_L heme in the presence of the Q_o-site inhibitor stigmatellin. In the absence of the inhibitor, the 2Fe2S protein is in the ‘‘c_1 *state*’’ conformation with 2Fe2S close to cyt c_1 in bovine $P6_522$ crystals, but is conformationally mobile in bovine $I4_122$ crystals.[11–13] A shuttle mechanism has been proposed in which the Rieske protein changes conformation from the *b* state, where oxidized 2Fe2S accepts an electron



Scheme 5

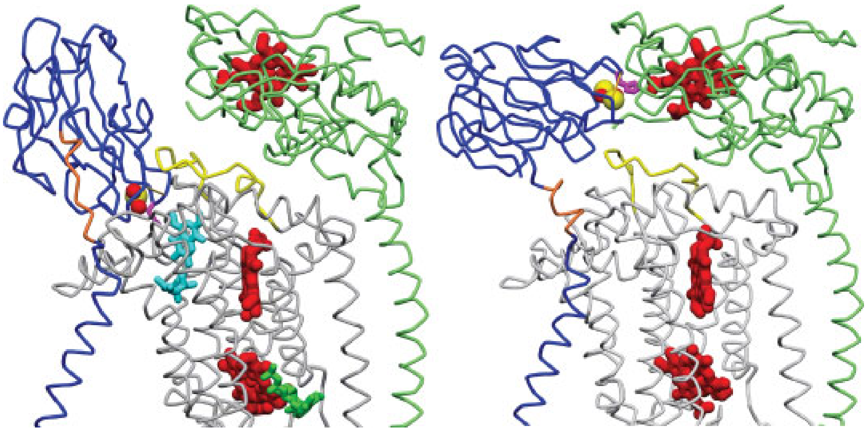


Figure 14 X-ray crystal structures of cytochrome bc_1 from chicken in the presence of stigmatellin and antimycin (b state), and in the beef $P6_522$ crystals (c_1 state).[12,13] The Rieske, cyt c_1, and cyt b subunits are colored blue, green, and grey, respectively. The hemes, the 2Fe2S center, stigmatellin, and antimycin are colored red, red/yellow, cyan, and green, respectively. The Rieske neck region residues 66–72 are colored orange, the ef loop is yellow, and His161 is colored purple

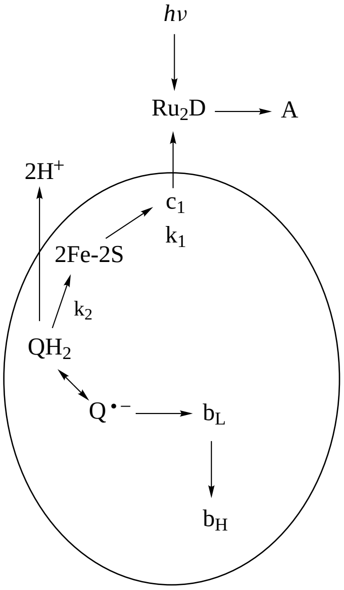
from ubiquinol in the Q_o site, to the c_1 state where reduced 2Fe2S transfers an electron to cyt c_1.[11–13]

Electron transfer within the cyt bc_1 complex has been studied using the binuclear ruthenium complex $[Ru(bpy)_2]_2(qpy)^{4+}$ (Figure 10), which binds with high affinity to the negatively charged binding domain on the surface of cyt c_1 as a surrogate for Cc.[92] Photoexcitation of $[Ru(bpy)_2]_2(qpy)$ to the metal-to-ligand charge transfer state, $[Ru(bpy)_2]_2(qpy)^*$, results in oxidation of cyt c_1 within 1 µs in the presence of a sacrificial electron acceptor as shown in Scheme 6. The reduction of photooxidized cyt c_1 in bovine cyt bc_1 has a fast phase with a rate constant of $k_1 = 16\,000\ s^{-1}$ due to electron transfer from 2Fe2S to cyt c_1, and a slow phase with a rate constant of $k_2 = 250\ s^{-1}$ due to electron transfer from QH_2 to 2Fe2S and cyt c_1. This is followed by rapid electron transfer from the semiquinone in the Q_o site to cyt b_L and cyt b_H (Scheme 6). The corresponding rate constants in *R. sphaeroides* cyt bc_1 are $k_1 = 80\,000\ s^{-1}$ and $k_2 = 1000\ s^{-1}$. Experiments exploring the effects of temperature, pH, and driving force demonstrated that the electron-transfer reaction from the 2Fe2S center to cyt c_1 is not rate-limited by true electron transfer, but rather by dynamic fluctuations in the conformation of the Rieske protein between the b state and the c_1 state.[93] In the c_1 state, the iron–sulfur ligand His161 forms a hydrogen bond with the heme c_1 propionate oxygen (Figure 14). This provides a direct pathway for electron transfer from the 2Fe2S center to heme c_1 with an edge-to-edge distance of 7.8 Å. The rate constant calculated from the Marcus equation (1) is $3 \times 10^7\ s^{-1}$, which is considerably faster than the observed value of $16\,000\ s^{-1}$ for the bovine enzyme or $80\,000\ s^{-1}$ for the *sphaeroides* enzyme. The experimental rate constant k_1 thus provides a true measure of the rate of the conformational change from the b state to the c_1 state. Additional support for the mobile-shuttle mechanism has been obtained from cross-linking and mutational studies that immobilize the 2Fe2S protein or alter the conformation of the neck region.[94]

Electron transfer from quinol in the Q_o site to the iron–sulfur center has a relatively small rate constant ($1500\ s^{-1}$ in *R. sphaeroides* cyt bc_1) and a large activation energy. The activation barrier for this process has been shown to occur after formation of a complex between quinol and the oxidized 2Fe2S center that is stabilized by a hydrogen bond between the deprotonated 2Fe2S ligand His161 and quinol.[95]



Scheme 6

Electron transfer takes place over a distance of 7 Å from quinol through the bridging ligand His161 to 2Fe2S, and is coupled to proton transfer from the quinol to His161. The slow-rate constant and high-activation energy of this process are due to the proton-coupled electron transfer mechanism.[95] A major unresolved question about the Q-cycle mechanism is how QH_2 in the Q_o site can deliver two electrons sequentially to the high- and low-potential chains, even though thermodynamics would favor delivery of both electrons to the high-potential chain. Crofts *et al.* have suggested that following electron transfer to 2Fe2S, the resulting semiquinone rotates towards cyt b_L, favoring electron transfer to cyt b_L and preventing electron transfer to 2Fe2S.[96] The recent discovery that two quinol molecules reside in the Q_o site may complicate this mechanism, however.[97] It is also possible that the conformational dynamics of the 2Fe2S protein may play a role in preventing electron transfer from the semiquinone in the Q_o site to 2Fe2S. Recent studies on the effect of the Q_o-site inhibitor famoxadone on the conformational dynamics of the iron–sulfur protein are of interest in this regard. Famoxadone binding to the Q_o site of bovine cyt bc_1 was found to decrease the rate constant of the conformation change from the b state to the c_1 state from $16\,000\,s^{-1}$ to $1500\,s^{-1}$.[98] X-ray crystallography studies revealed that famoxadone binding leads to significant conformational changes in three domains on the surface of cyt b, including the *ef* loop which is part of the ISP-docking site (Figure 14).[99] The *ef* loop may play a role in relaying famoxadone-induced conformational changes in the Q_o pocket to the ISP-docking site to decrease the rate of release of the ISP. The linkage between the conformation of the Q_o site and the dynamics of the ISP movement could be a key to how the enzyme promotes the transfer of the first electron from QH_2 to 2Fe-2S, but inhibits the transfer of the second electron from semiquinone to 2Fe-2S.

The electron-transfer reaction from the cyt bc_1 complex to Cc involves three steps: formation of a 1:1 reactant complex between reduced cyt bc_1 and Cc^{3+}, intracomplex electron transfer from cyt c_1^{2+} to Cc^{3+}, and release of Cc^{2+}. The interaction between Cc and cyt bc_1 should stabilize the reactant complex in an optimal orientation for rapid electron transfer, and also allow both rapid reactant complex formation and product complex dissociation. The reaction rate measured by steady state and stopped-flow kinetics decreases with increasing ionic strength, indicating that electrostatic interactions are important to the reaction.[100] Chemical modification studies have indicated that six lysine amino groups surrounding the heme crevice of Cc are involved in the interaction with cyt bc_1.[38,40] Chemical modification and cross-linking studies have indicated that acidic residues on bovine cyt c_1 and subunit 8 are involved in binding Cc.[45–47] The X-ray crystal structures show that the cyt c_1 heme edge on the cytoplasmic surface is surrounded by acidic residues that could form the docking site with Cc.[11–14] Most importantly, the X-ray crystal structure of the complex between yeast Cc and yeast cyt bc_1 has recently been determined to 2.97 Å resolution (Figure 15).[101] Surprisingly, the complex is stabilized largely by nonpolar interactions, including a planar-stacking interaction between yCc Arg13 and Phe230 of cyt c_1. Complementary charged residues are located around the periphery of the binding domain, but only two are close enough to make direct polar interactions. The distance between the edges of the heme *c* and heme c_1 groups is only 9.4 Å, giving an estimated rate constant for electron transfer of 1×10^6 to $8 \times 10^6\,s^{-1}$.

The second-order reaction between Cc and cyt c_1 has been studied by stopped-flow spectroscopy at high-ionic strength, but the reaction becomes too fast to resolve by this technique as the ionic strength is decreased below 200 mM.[100] A new yeast Ru_z-39-Cc derivative was designed to measure intracomplex electron transfer with the cyt bc_1 complex in the physiological direction.[102] The ruthenium complex attached to Cys39 on the surface opposite from the heme crevice of Cc does not affect the interaction with cyt bc_1 (Figure 15). The new $Ru(bpz)_2(dmb)$ complex has a large reduction potential for the Ru(II*)/Ru(I) transition, and is optimized for photooxidation of the reduced heme *c*. Laser excitation of the reduced Ru_z-39-Cc derivative resulted in electron transfer from heme *c* Fe(II) to Ru(II*) with a rate constant of $1.5 \times 10^6\,s^{-1}$ to form heme c Fe(III) and Ru(I). Atmospheric oxygen rapidly oxidized Ru(I), preventing the back reaction. The yield of photooxidized heme *c* is 20% in a single flash, which is quite large for this type of derivative. When a 1:1 complex between yeast Ru_z-39-Cc and yeast cyt bc_1 was photoexcited at low-ionic strength, intracomplex electron transfer from cyt c_1^{2+} to photooxidized heme c^{3+} occurred with a rate constant of $14\,000 \pm 3000\,s^{-1}$. In the crystal structure of the yCc:cyt bc_1 complex, the heme *c* and heme c_1 groups are in close proximity with a distance of 17.4 Å between the two iron atoms, and an edge-to-edge distance between the two porphyrin heterocycles of 9.4 Å.[101] With this distance and a reorganization energy λ of 1.0 V, the rate constant estimated from equation (1) is $1.8 \times 10^5\,s^{-1}$. Although the theoretical value is larger than the experimental value of $1.4 \times 10^4\,s^{-1}$, the theory has been applied most extensively to intraprotein electron transfer, with relatively few applications to intracomplex electron transfer between two proteins. There is a through-space jump of 4.5 Å between the two hemes in the crystal structure, which could significantly decrease the rate constant.

As the ionic strength is increased to 200 mM, the fast intracomplex phase of electron transfer disappears indicating complex dissociation, and a slow phase appears due to the bimolecular reaction of solution Ru_z-39-Cc with cyt bc_1. The second-order rate constant decreases with increasing ionic strength above 250 mM, consistent with a reaction between oppositely charged proteins. There is only one electrostatic charge-pair interaction in the binding domain of the yCc:ybc_1 crystallographic complex. However, there are five lysine amino groups on yCc and five carboxylate groups on cyt bc_1 surrounding the interaction domain, which could guide

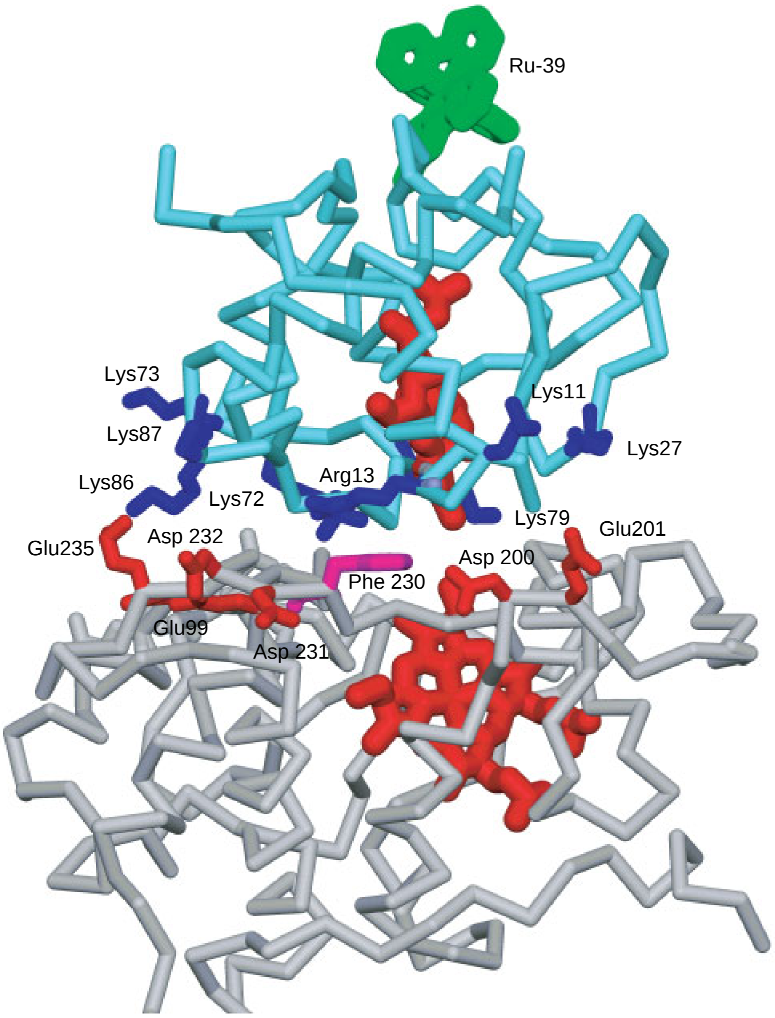


Figure 15 X-ray crystal structure of the complex between yeast cyt bc_1 and yCc.[101] Cyt c_1 is colored grey, yCc is light blue, the heme groups are red, acidic residues on cyt c_1 are red, basic residues on yCc are blue, and Phe230 is purple. The ruthenium complex on Cys39 is green

Cc to the correct binding site during the final stages of the complex formation process (Figure 15).

9 CYTOCHROME *c*–CYTOCHROME *c* OXIDASE REACTION

Cytochrome *c* oxidase (CcO), the terminal member of the mitochondrial electron-transport chain, transfers electrons from Cc to molecular oxygen and pumps protons across the mitochondrial membrane. The determination of the X-ray crystal structures of CcO from both bovine mitochondria and *P. denitrificans* has made it possible to address questions about the mechanism of electron transfer and proton pumping at the molecular level.[15,16] The enzyme from bovine mitochondria has 13 subunits, while *Paracoccus* enzyme has 4 subunits. CcO contains four redox-active metal centers, Cu_A, located in subunit II, and heme a, heme a_3, and Cu_B, located in subunit I. Cu_A consists of two copper atoms bridged by the sulfur atoms of two cysteine residues. Efficient electron transfer from Cc to CcO requires that the binding interaction between the two proteins facilitate rapid formation of a reactant complex with CcO, stabilize the optimal orientation of the complex for rapid electron transfer to the initial acceptor in CcO, and allow rapid dissociation of the product complex to release oxidized Cc. The steady state reaction is limited by product dissociation at low-ionic strength, reaches an optimum at intermediate ionic strength, and is strongly inhibited at high-ionic strength, indicating the importance of electrostatic interactions between the two proteins.[33–36] Chemical modification studies have shown that six lysine amino groups surrounding the heme crevice of Cc interact electrostatically with CcO.[33–37] Steady state and stopped-flow kinetics studies have provided insight into the reaction between Cc and CcO, but did not allow resolution of intracomplex electron transfer. The Ru-39-Cc derivative

was designed to measure intracomplex electron transfer to the initial acceptor in CcO, as well as the rate constants for complex formation and dissociation.[82] When a 1:1 complex between Ru-39-Cc and beef CcO was photoexcited at low-ionic strength, the following electron-transfer sequence was observed: Ru(II*) → hemec^{3+} → Cu_A^{2+} → heme a^{3+} with rate constants of $k_1 = 5 \times 10^5\,s^{-1}$, $k_a = 6 \times 10^4\,s^{-1}$, and $k_b = 1.8 \times 10^4\,s^{-1}$, according to Scheme 7 (Figure 16).[82] The initial electron acceptor in CcO was thus identified to be Cu_A. When the ionic strength was increased from 40 mM to 100 mM, the fast phase decreased in amplitude due to dissociation of the 1:1 complex, and a slow phase appeared because of the intermolecular reaction between free Ru-39-Cc and CcO. The rate constants for complex formation and dissociation were also determined using the ruthenium photoreduction technique. The complete reaction at physiological ionic strength (100 mM) involves substrate complex formation between Cc^{2+} and CcO with rate constant $k_f = 1.8 \times 10^8\,M^{-1}\,s^{-1}$, intracomplex electron transfer from Cc^{2+} to Cu_A^{2+} with rate constant $k_a = 6 \times 10^4\,s^{-1}$, and product complex dissociation with rate constant $k_d = 8 \times 10^3\,s^{-1}$ (Scheme 7).[82]

The X-ray crystal structures of bovine and *P. denitrificans* CcO reveal a cluster of acidic residues on subunit II near the binuclear Cu_A center.[15,16] The highly conserved aromatic residue, Trp143, at the center of this acidic cluster is in van der Waals contact with the Cu_A center and could be involved in electron transfer with Cc. In order to investigate the location of the binding domain for Cc, a series of *R. sphaeroides* CcO mutants was prepared in which acidic residues were replaced with neutral Asn or Gln residues (Figure 17, Table 2).[86] When the 1:1 complex between Ru-55-Cc and wild-type CcO is photoexcited at low-ionic strength, electron transfer from heme c to Cu_A occurs with an intracomplex rate constant of $k_a = 4 \times 10^4\,s^{-1}$, followed by electron transfer from Cu_A to heme a with a rate constant of $k_b = 9 \times 10^4\,s^{-1}$. The rate constant k_a is decreased to 700 s^{-1} by the D214N mutation, indicating a significant change in the binding orientation of Ru-55-Cc. The value of k_a was decreased by 2 to 4-fold by the E157Q, E148Q, and D195N mutations. The dissociation constant K_D was significantly decreased by the D214N, E157Q, E148Q, and D195N mutations, indicating that they affect both binding strength and orientation. The k_a, K_D, and k_{2nd} values were not significantly affected by the D151N/E152Q and D188N/E189Q double mutants, indicating that these residues

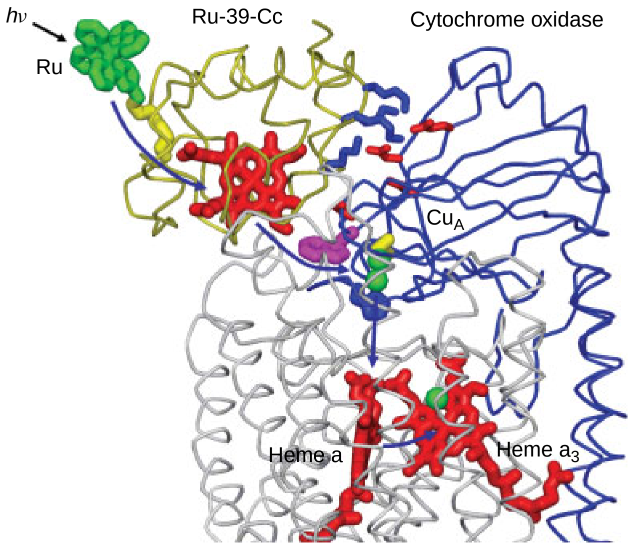

Figure 16 Complex between Ru-39-Cc and CcO. Ru-39-Cc is bound to CcO in the configuration determined by Roberts and Pique.[103] The Cc backbone is colored yellow, CcO subunit I is grey, and CcO subunit II is blue. Subunit II Trp143, Met263, and His260 are colored purple, yellow, and blue, respectively. Cc lysines 8, 13, 72, 86, and 87 are colored blue, while subunit II Glu148, Asp151, Glu157, Asp195, and Asp214 are colored red

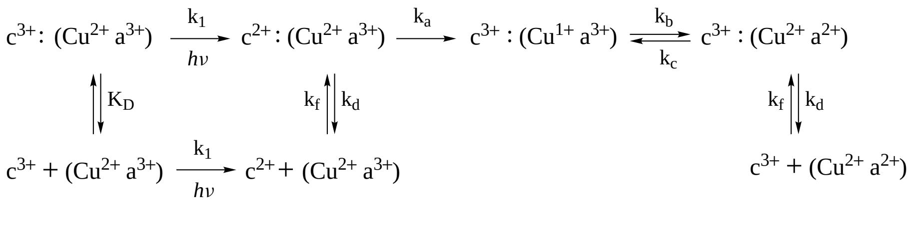
are outside the binding domain. The aromatic residue Trp143 was mutated to Phe or Ala to investigate its role in mediating electron transfer from the heme group of Cc to Cu_A. The rate constant k_a was decreased 450-fold and 1200-fold by the mutations W143F and W143A, respectively.[86] It is proposed that these mutations cause a substantial disruption in the pathway for electron transfer rather than simply leading to a change in the orientation of the complex.

The mutational studies indicate that Cc binds to a highly conserved acidic domain on the surface of subunit II involving the negatively charged carboxylates on residues Asp214, Glu157, Glu148, and Asp195. The positively charged lysines 8, 13, 72, 86, and 87 surrounding the heme crevice of Cc have been shown to be involved in the interaction with CcO using a chemical modification approach. A theoretical model for the complex between Cc and CcO determined by Roberts and Pique is consistent with the kinetic studies (Figure 17).[103] The interaction consists of a central hydrophobic domain, surrounded by complementary



Scheme 7

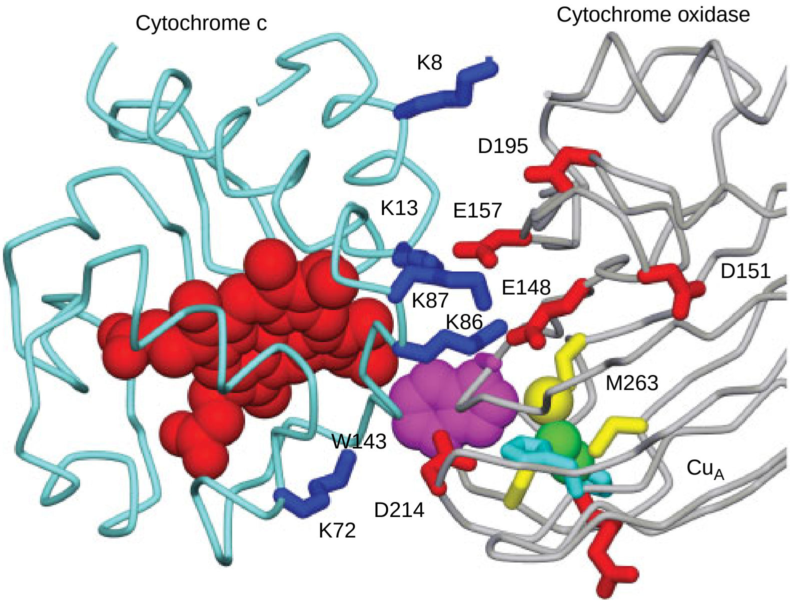


Figure 17 Model for the high-affinity complex between horse Cc and CcO determined by Roberts and Pique.[103] The backbone of horse Cc and CcO subunit II are shown with the side chains of selected lysines and acidic residues colored blue and red, respectively. The residue numbers on subunit II are for *Rhodobacter sphaeroides CcO*. The Cc heme and subunit II Trp143 and Met 263 sulfur atom are represented by CPK models. The Cu_A coppers are represented by green CPK models

electrostatic interactions between Cc lysines 8, 13, 86/87, 72, and CcO Asp195, Glu157, Glu148, and Asp214, respectively. At the center of the hydrophobic domain, the indole ring of Trp143 is in van der Waals contact with the heme CBC methyl group. The edge-to-edge distance between the heme c macrocycle and the Met263 Cu_A ligand is 12.5 Å in the Cc:CcO model complex. A theoretical electron-transfer rate constant of $6 \times 10^4\,s^{-1}$ is calculated from the Marcus equation (1), assuming $r = 12.5$ Å, $\lambda = 0.65$ eV and $\Delta G^{\circ\prime} = -0.03$ eV. This theoretical value is in good agreement with the experimental value of $k_{et} = 6 \times 10^4\,s^{-1}$ for the reaction between Ru-39-Cc and Cu_A. Since the indole ring of Trp143 is in van der Waals contact with both the Cc heme and the Cu_A ligand Met263, there is good electronic coupling between redox centers (Figure 17).

In the novel binuclear Cu_A center of CcO, the two copper atoms are bridged by the sulfur atoms of Cys252 and Cys256. The outer copper atom is also liganded by His217 and Met263 while the inner copper is liganded by His260 and the backbone carbonyl of Glu254. Two *R. sphaeroides* CcO mutants, M263L and H260N, were examined to investigate the mechanism of electron transfer from Cc to Cu_A and heme a.[104] Met263 ligates the copper that is closest to Cc, while His260 ligates the copper that is linked by a hydrogen-bond network to heme a. Two copper atoms are retained at the Cu_A center of these mutants, but the redox potential of Cu_A was increased by 120 mV for the M263L mutant and 90 mV for the H260N mutant. The mixed valence Cu(1.5)···Cu(1.5) state of the wild-type Cu_A center is converted to a state in which the two copper atoms are no longer equivalent. The rate constant for intracomplex electron transfer from heme c to Cu_A is decreased from $40\,000\,s^{-1}$ to $16\,000\,s^{-1}$ by the M263L mutation, and to $11\,000\,s^{-1}$ by the H260N mutation. The rate constants for electron transfer between Cu_A to heme a are $k_b = 4000\,s^{-1}$ and $k_c = 66\,000\,s^{-1}$ for M263L CcO and $k_b = 45\,s^{-1}$ and $k_c = 180\,s^{-1}$ for H260N, compared to $k_b = 90\,000\,s^{-1}$ and $k_c = 17\,000\,s^{-1}$ for wild-type CcO. The effects of the M263L mutation on the kinetics can be explained by the increase in redox potential of the Cu_A center. However, the large decrease in the rate constants for electron transfer between Cu_A and heme a in the H260N mutant must be due to a disruption in the structure between the two centers. The pathway for electron transfer from Cu_A to heme a is thought to involve a hydrogen-bond network through the Cu_A ligand His260, the peptide backbone, and the highly conserved subunit I residue Arg482 to the heme a propionates. Disruption of this pathway by the H260N mutation leads to the large decrease in the rate constants for electron transfer between Cu_A and heme a.

1 INTRODUCTION

Oxygenase enzymes are important components of oxygen biological chemistry that sustains all aerobic life. Oxygen is formed in the four-electron oxidation of two water molecules catalyzed by the photosystem II oxygen-evolving system in plants and photosynthetic microorganisms (*see* ***Manganese: The Oxygen-evolving Complex & Models***). Once inside cells, oxygen is transported by iron- (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***) and copper-containing proteins (*see* ***Copper Proteins with Dinuclear Active Sites***) to subcellular compartments and utilized in a myriad of biological functions. The importance of oxygen stems from the thermodynamically favorable nature of reactions that involve reduction and cleavage of the O–O bond (Figure 1) (*see* ***Dioxygen & Related Ligands***). In the mitochondria, cytochrome *c* oxidase catalyzes the highly favorable reduction of oxygen to water ($E^{\circ\prime} = +0.82$ V) and couples this electron-transfer reaction to proton translocation across a membrane (*see* ***Cytochrome Oxidase***). The resultant proton gradient is utilized for the synthesis of ATP – the energy source for aerobic organisms. The two-electron reduction of oxygen to hydrogen peroxide ($E^{\circ\prime} = +0.30$ V) provides the thermodynamic driving force for oxidase enzymes to oxidize many biological molecules.

Apart from water, all reduced oxygen species (Figure 1) are highly reactive. Superoxide ($O_2^{\bullet-}$), peroxide and especially the hydroxyl radical ($HO^{\bullet}$), cause cellular damage by oxidizing peptides, lipids, and nucleic acids. These reactive oxygen species (ROS) are side products in many reactions inside cells, for example, hydrogen peroxide from oxidase activity. Aerobic organisms have evolved highly active and specific enzymes for ROS removal. The disproportionation of superoxide to oxygen and peroxide is catalyzed by superoxide dismutase (SOD) (*see* ***Copper Proteins with Type 2 Sites***; ***Manganese Proteins with Mono- & Dinuclear Sites***; ***Nickel Enzymes & Cofactors***). Hydrogen peroxide is removed by peroxidases and catalases (*see* ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***). These enzymes are amongst the most active and efficient biological catalysts.

$$\text{Superoxide dismutase} \quad 2O_2^{\bullet-} \longrightarrow O_2 + O_2^{2-} \quad (1)$$

$$\text{Peroxidase} \quad H_2O_2 + 2AH \longrightarrow 2H_2O + 2A \quad (2)$$

$$\text{Catalase} \quad 2H_2O_2 \longrightarrow 2H_2O + O_2 \quad (3)$$

In the disproportionation of superoxide (equation 1) and hydrogen peroxide (equation 3), the reactant is both the electron donor and electron acceptor, while peroxidases (equation 2) require an external source of electrons. Some organisms have evolved to exploit this property of peroxidases for both the synthesis and oxidative degradation of organic compounds. Higher organisms have actually harnessed the destructive power of ROS in the immune defense system.

1.1 Oxygen is Kinetically Trapped

The reduction of oxygen to water is a highly favorable reaction. When oxygen was first released into the Earth's atmosphere, it was an ecological catastrophe because early organisms lived on the chemistry of lower oxidation state species such as Fe^{2+} and S^{2-}, in an anaerobic world. These vital elements were rapidly oxidized at neutral pHs and suddenly became unavailable. Today anaerobic organisms only survive in special niches that have low levels of oxygen. In an aerobic atmosphere, carbon- and hydrogen-containing compounds that are present in all living things, are thermodynamically unstable to oxidation to carbon dioxide and water. However, the direct oxidation of organic compounds by oxygen is kinetically slow: We live in a metastable world and coexist with oxygen in a kinetic trap.

Molecular oxygen is a kinetically slow oxidant because of its electronic structure, which may be described as $(\sigma 1s)^2(\sigma^*1s)^2(\sigma 2s)^2(\sigma^*2s)^2(\sigma 2p_z)^2(\pi 2p_{x,y})^4(\pi^*2p_x)^1(\pi^*2p_y)^1$ (*see* ***Dioxygen & Related Ligands***). The bond order is two and the highest occupied molecular orbital is the doubly degenerate antibonding π^* orbital. The two π^* electrons have parallel spins, and O_2 is a diradical with a triplet ground state, ${}^3\Sigma_g{}^-$. The first excited state, with both π^* electrons in one orbital, is a singlet (${}^1\Delta_g{}^+$) 23 kcal mol^{-1} above the ground state. In the second excited state, the two electrons are in separate π^* orbitals but their spins are paired, resulting in a singlet state (${}^1\Sigma_g{}^-$) that is a further 14 kcal mol^{-1} above the ${}^1\Delta_g{}^+$ state.

The triplet ground state of oxygen is the principal barrier to direct attack of organic compounds. Essentially all stable

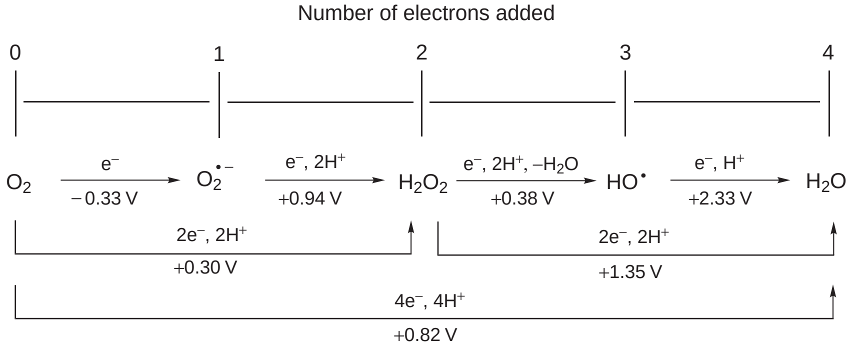

Figure 1 The electrode potentials for the stepwise reduction of oxygen to water. E°′ values are at pH 7.0, 298 K, 1 atm O_2 and unit activity for other components

organic molecules have singlet ground states, and the products of oxidation by oxygen are also singlets. The direct reaction between a triplet molecule (O_2) and a singlet molecule to give a singlet product is spin-forbidden. The reaction to give a triplet product is spin-allowed but requires preactivation of the organic molecule to an excited state, resulting in a high activation barrier. The reaction between singlet O_2 and a singlet organic molecule is spin-allowed. However, the lowest energy singlet state of O_2 is 23 kcal mol^{-1} above the ground state and thus presents a high activation barrier to the reaction. Singlet oxygen can be generated photochemically in the presence of a sensitizer molecule. However, these reactions often give different products from those catalyzed by chemical and biological catalysts.

The high kinetic barrier to reactions with triplet O_2 is overcome in biological systems by the use of transition metals (mainly iron and copper) and electron-rich organic groups. Transition metals readily undergo redox reactions and direct reduction of oxygen is possible, but metal centers in metalloenzymes can bind oxygen. The Fe(II) centers in heme and nonheme iron proteins are high spin ($S = 2$) and the binding of triplet O_2 ($S = 1$) is fast because it is not spin-inhibited. In oxygen transport metalloproteins such as hemoglobin (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***) and hemocyanin (*see* ***Copper Proteins with Dinuclear Active Sites***), there is no activation of the metal-bound O_2 molecule. In enzymes, further electron transfer or chemical steps lead to activation and cleavage of the O–O bond and the formation of reactive intermediates that can attack bound substrates. Highly electron-rich organic molecules can also undergo direct reaction with O_2. Compounds such as flavins have singlet ground states but can readily form stable cation radicals. The isoalloxazine double bond in a reduced flavin molecule is electron rich because it has three electron-releasing nitrogen substituents (Figure 2). It readily reduces oxygen to superoxide because the flavin radical cation is resonance-stabilized. These two ions recombine to form a flavin hydroperoxide that can decompose to form hydrogen peroxide or, in the case of flavin monooxygenases, oxidize a bound substrate.

1.2 Oxygen Activation by Oxygenases

Oxygenases activate O_2 to oxidize organic molecules. Mason[1] and Hayashi[2] were the first to observe oxygenase activity by ^{18}O labeling experiments. The term ‘oxygenase’ was introduced by Hayashi.[3] Monooxygenases cleave O_2 to give one molecule of water while inserting the other oxygen atom into the substrate (equation 4, where X is the substrate) while dioxygenases insert both oxygen atoms (equation 5).

$$\text{Monooxygenases} \quad X + O_2 + 2e^- + 2H^+ \longrightarrow XO + H_2O \quad (4)$$

$$\text{Dioxygenases} \quad X + O_2 \longrightarrow X(O)_2 \quad (5)$$

Oxygenases contain transition metals, mainly iron (heme and nonheme), copper, and manganese. Organic prosthetic groups (e.g. flavins) are also found in monooxygenases. These enzymes oxidize a very broad range of organic compounds. Dioxygenases are particularly important in the biodegradation of aromatic compounds by microorganisms. The aromatic ring is oxidized by a nonheme iron dioxygenase to the dihydrodiol that is re-aromatized to the catechol. Diol dioxygenases, another class of nonheme iron dioxygenases, then cleave the ring, leading ultimately to mineralization of the organic compound (*see* ***Iron Proteins with Mononuclear Active Sites***).

Monooxygenases usually utilize an external source of electrons (equation 4). However, nonheme iron monooxygenases can also activate oxygen by transferring one oxygen atom to a cofactor. A common cofactor is 2-oxo-glutarate (2-OG), which is converted to succinate in the reaction (Figure 3). 2-OG dependent enzymes are involved in antibiotic biosynthesis and also include the newly discovered oxygen-sensing enzyme hypoxia inducible factor (HIF).[4–7] Since the cofactor is also oxygenated, such enzymes could be classified as dioxygenases.

2 CYTOCHROME P450 ENZYMES ARE HEME MONOOXYGENASES

2.1 History of the Cytochrome P450 (CYP) Superfamily

In 1958, Klingenberg[8] and Garfinkel[9] independently reported liver microsomal pigments that showed an unprecedented absorption maximum at 450 nm upon carbon monoxide binding. Omura and Sato showed that these pigments were heme-containing proteins and designated them 'cytochrome P450'.[10,11] P450 enzymes are *b*-type cytochromes, with the iron bound to protoporphyrin IX (Figure 4) (*see* ***Iron Porphyrin Chemistry***) and the porphyrin ring substituents are not covalently bonded to the polypeptide. In *c*-type cytochromes a cysteine thiol group is added across the double bond of each of the porphyrin vinyl groups (*see* ***Iron: Heme Proteins & Electron Transport***). Mason proposed that the unusual spectrum of P450 enzymes arose from thiolate coordination to the heme iron.[12] The importance of cytochrome P450 enzymes became evident when Estabrook and coworkers showed that these microsomal enzymes are monooxygenases that catalyze the hydroxylation of steroids and other organic compounds.[13] As more and more P450 enzymes were discovered, it was found that all eukaryotic enzymes were associated with either the inner mitochondrial or the endoplasmic reticulum membranes, while the vast majority of microbial enzymes were cytosolic and soluble.

Early attempts to solubilize membrane-bound P450 enzymes resulted in loss of activity and shift of the characteristic 450 nm absorption band of the Fe^{II}-CO form to 420 nm. This inactive form was designated 'cytochrome P420'.[11] Liver microsomal P450 enzymes were eventually solubilized in their active forms by Coon and coworkers,[14] and the field of P450 research grew rapidly. New P450 enzymes, often induced by xenobiotics, were isolated from mammals, fungi, plants, and, later, humans. In the late 1960s, Gunsalus and coworkers isolated the soluble enzyme $P450_{cam}$ from the soil bacterium *Pseudomonas putida*.[15–17] The availability of large quantities of this stable and soluble enzyme, and its physiological electron transport cofactor proteins putidaredoxin reductase and putidaredoxin, made possible detailed spectroscopic and mechanistic investigations into P450 catalysis. $P450_{cam}$ was also the first P450 enzyme to be structurally characterized.[18]

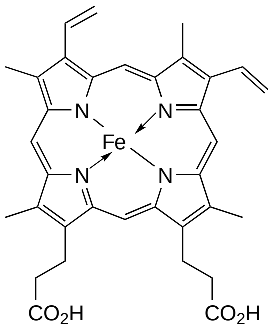

Figure 4 Iron protoporphyrin IX (heme *b*), the prosthetic group of P450 enzymes

As more genes encoding P450 enzymes were sequenced, nomenclature of the P450 superfamily was systematized.[19] The CYP (P450) superfamily was grouped by amino acid sequence identity into families (1, 2, 3 . . .), subfamilies (A, B, C . . .) and individual enzymes (1, 2, 3 . . .). Hence, current names include CYP1A2, CYP3A4, CYP2E1, CYP102A2, and so on (see http://drnelson.utmem.edu/CytochromeP450.html). The increasing availability of genome sequences shows that P450 enzymes are found in almost all organisms. Only certain bacteria, such as *Escherichia coli* and *Lactobacillus*, do not synthesize P450s. As of January 2004, there are over 3000 distinct P450 sequences in the data banks. There are about 53 human P450 enzymes, the worm *C. elegans* has 80, fruit fly 83, the plant *A. thaliana* 286, rice 500, but yeast has only 3.

2.2 Physiological Significance

Some P450 enzymes are constitutively expressed and play vital roles in the biosynthesis of endogenous compounds such as steroids and other hormones (e.g. nitric oxide) in mammals,[20] and secondary metabolites in plants.[21] In microorganisms the substrate hydroxylation activity of P450 enzymes enables the organism to grow on chemically inert compounds such as alkanes as the sole carbon and energy source.[22,23] P450 enzymes are also involved in the synthesis of important medicinal antibiotics in microorganisms.[24] Many P450 enzymes are induced by xenobiotics and perform vital functions in detoxification pathways.[25,26] Hydrophobic and chemically inert exogenous compounds are oxidized to more soluble, polar derivatives that are either excreted directly or conjugated to sugars for transport and excretion.[20] This xenobiotic-removal function casts P450 enzymes in a central role in drug metabolism and pharmacokinetics. Indeed P450 enzymes in the human body metabolize over 50% of all pharmaceuticals. P450 enzymes also convert some drugs, for example, losartan, to their active forms, or derivatives that are more active than the parent compound. The circulating concentration and hence efficacy of a medicinal compound may vary between individuals depending on the constitutive expression levels of different P450 isoforms, the inducibility of different P450 enzymes, and gene polymorphism.

The increased reactivity of substrate oxidation products also means that P450 enzymes can transform otherwise inert compounds into reactive derivatives which may be toxic or carcinogenic.[26] Thus at an early stage of development, candidate pharmaceutical compounds are subjected to oxidation by a variety of heterologously expressed human P450 enzymes and the products screened for toxicity. The *N*-hydroxylation of nitrosoamines and aromatic amines give metabolites that are toxic and can react with DNA. Procarcinogens such as polycyclic aromatic hydrocarbons (e.g. benzanthracene and benzo[*a*]pyrene) and aflataxin B are converted to carcinogens by P450 enzymes. The active carcinogens that modify DNA are the highly electrophilic epoxides and diol-epoxides (Figure 5). In addition, other oxidation products, especially phenol and hydroquinone derivatives, readily undergo redox cycling to generate ROS such as superoxide and peroxide which cause damage to cells.

2.3 Electron Transport in P450 Enzyme Systems

2.3.1 Classification of P450 Enzymes

The two electrons required for the P450 monooxygenase reaction (equation 4) are normally derived from NADH or NADPH and transferred to the P450 enzyme one-at-a-time by

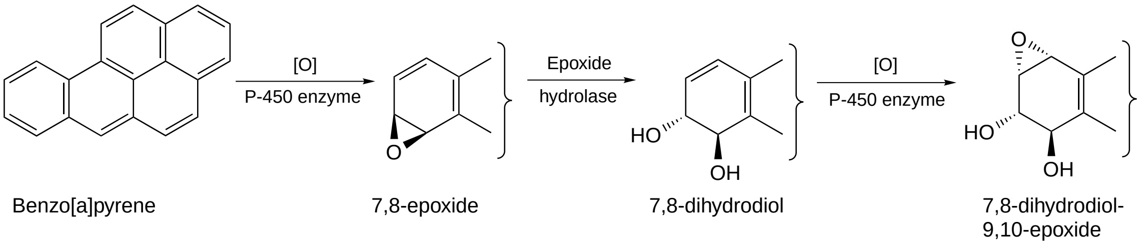

Figure 5 Activation of the procarcinogen benzo[*a*]pyrene by P450 enzymes. The diol-epoxide is the active carcinogen that modifies nucleic acids

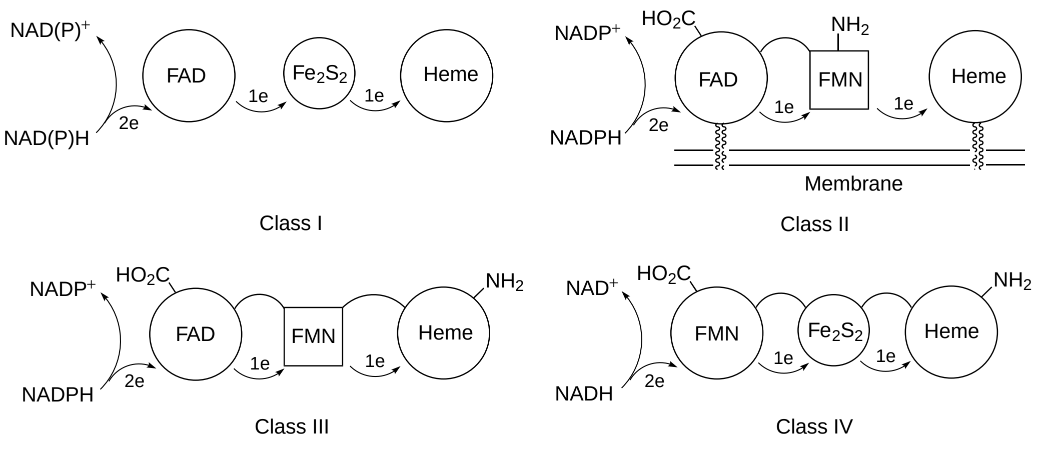

Figure 6 The four classes of P450 enzymes distinguished by the nature of their electron transport chains

an electron-transfer protein. Since NAD(P)H is a two-electron reductant, this is a noncomplementary electron-transfer reaction like those found with inorganic complexes. The electron-transfer proteins play the role of a catalyst, analogous to $Ta_6Cl_{12}^{2+}$ in the reduction of Fe^{3+} by Sn^{2+}.

There are four classes of P450 enzymes that are distinguished by the organization of their electron transport chains (Figure 6). NAD(P)H delivers a hydride (2 electrons) to a flavin group. Class I P450 systems, which include mitochondrial and most bacterial P450 enzymes, utilize three-component electron transport chains where a flavin adenine dinucleotide (FAD)-containing reductase transfers an electron to an Fe–S protein which then delivers the electron to the P450 monooxygenase. Class II P450 enzymes are membrane-bound microsomal systems comprised of two proteins. A NADPH-cytochrome P450 reductase, with FAD and FMN groups in separate domains, acts as the electron-transfer shuttle. The FAD group accepts two electrons from NADPH which are transferred to the P450 enzyme via the FMN group. Hence the FMN group performs the role of Fe–S redox centers of Class I systems. The first example of a Class III P450 enzyme was $P450_{BM\text{-}3}$ (CYP102A1) from *Bacillus megaterium*. Like their Class II counterparts, Class III systems also have a reductase protein containing FAD and FMN groups in separate domains, but this reductase is fused to the C-terminal of the P450 monooxygenase enzyme. Class III P450s are therefore fused Class II systems and catalytically self-sufficient. More Class III bacterial enzymes are being discovered, and eukaryotic counterparts are also known.[27] The first example of a Class IV enzyme was reported in 2002.[28] Like Class III enzymes, P450RhF from *Rhodococcus* is also self-sufficient. However, the reductase domain contains a flavin mononucleotide (FMN) group which accepts electrons from NADH and transfers them to the P450 enzyme via a Fe_2S_2 group in a separate domain (Figure 6).[29] This Class IV enzyme is essentially a fused Class I system except that FMN is the initial electron acceptor instead of FAD.

2.3.2 *Structure of P450 Electron-transfer Proteins*

The crystal structure of NADPH-cytochrome P450 reductase (CPR), the common electron-transfer protein of Class II eukaryotic P450 systems, was reported in 1997.[30] This was followed by the structures of adrenodoxin reductase (AdR)[31] and adrenodoxin (Adx),[32] the two electron-transfer proteins of the Class I mitochondrial P450 system. The crystal structure of a cross-linked AdR-Adx complex has also been reported.[33,34] Putidaredoxin reductase (PdR) and putidaredoxin (Pd) of the $P450_{cam}$ system have also been structurally characterized.[35,36]

The structure of CPR is significant because this membrane-bound protein mediates electron transfer from NADPH to *all* microsomal P450 enzymes. A soluble form of CPR was generated by limited protease digestion and crystallized. The structure consists of a N-terminal FMN domain linked to the C-terminal FAD domain via a hinge domain (Figure 7). The protein crystallized with the isoalloxazine rings of the flavin cofactors from the different domains in close contact (4 Å), which facilitates electron transfer (*see* ***Long-range Electron Transfer in Biology***). A surface region near the FMN cofactor was suggested to be the recognition site for the binding of P450 enzymes. However, at the present time, there is little experimental data on the recognition and binding interactions between CPR and microsomal P450 enzymes. It is possible that the hinge domain in CPR allows the FMN domain to move away from the FAD domain and bind to P450 monooxygenases.

The crystal structure of the cross-linked AdR-Adx complex (Figure 8) showed that there were changes in the structure of AdR, but not of Adx, upon complex formation.[33,34] The Fe_2S_2 ferredoxin Adx is known to undergo a redox-dependent conformation change that is required for electron transfer (*see* ***Iron–Sulfur Proteins***).[32,37] The structure of Adx in the complex suggests that this is possible in the protein-protein complex. It had been noted from the structures of the separate proteins that the charge distributions of AdR and Adx are highly asymmetric, resulting in large dipoles for the proteins that may facilitate protein-protein recognition and binding. This was observed in the complex where the cluster of basic residues on the surface of AdR formed salt bridge contacts with surface acidic residues on Adx. The closest approach of the AdR isoalloxazine ring to the Adx Fe_2S_2 group was 10 Å, which facilitates electron transfer between the cofactors.

The structure of PdR (Figure 9) is significantly different from that of AdR although both proteins are related to disulfide reductases and other flavin-dependent enzymes. The

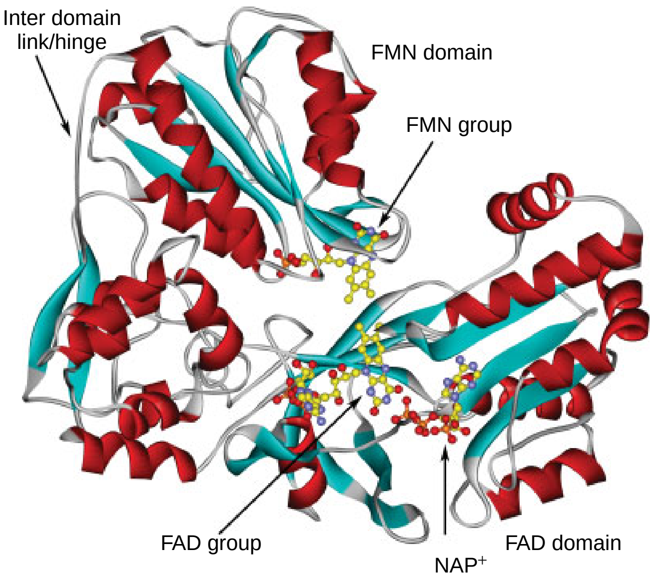

Figure 7 The crystal structure of NADPH-cytochrome P450 reductase (CPR). The FAD and FMN domains are linked by a hinge domain

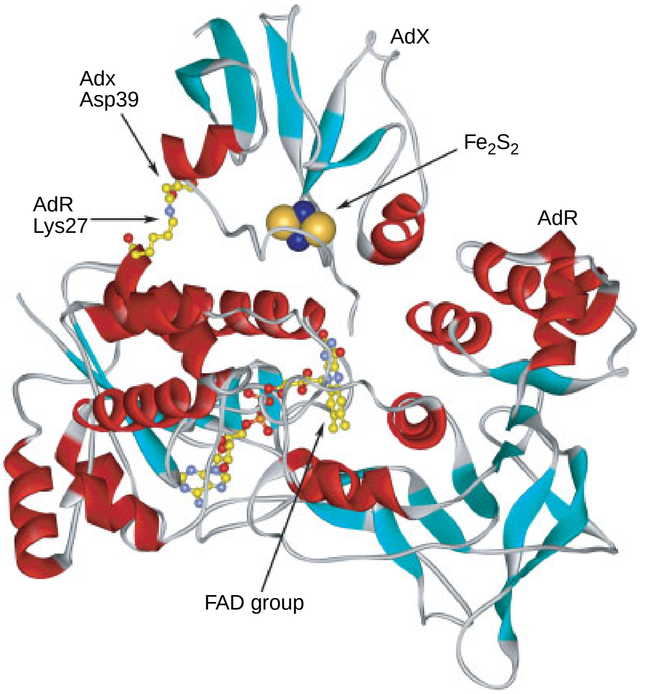

Figure 8 The structures of the FAD-containing adrenodoxin reductase (AdR) and the Fe_2S_2 ferredoxin adrenodoxin (Adx) cross-linked by the side chains of Lys27 of AdR and Asp39 of Adx. The distance of closest approach of the two redox centers is ~10 Å

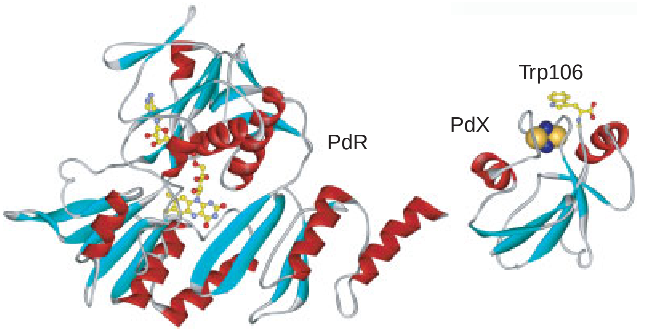

Figure 9 The structure of PdR and Pdx, the electron-transfer proteins of the $P450_{cam}$ system. The PdR molecule is viewed from the *si* side of the flavin from which Pdx is proposed to approach and accept electrons from PdR. The Fe_2S_2 center of Pdx is close to the protein surface, and the C-terminal Trp-106 residue is important for electron transfer

C-terminal FAD-binding domains of the two proteins are different in size and have different secondary structure elements (Figures 8 and 9). The highly asymmetric charge distribution of AdR was absent from PdR, which has a much lower dipole moment. The reductant NADH approaches and binds on the *re* side of the FAD in PdR, indicating that Pdx should bind on the *si* side. Unlike for AdR, the *si* side surface of PdR is much less hydrophilic, suggesting that the PdR/Pdx interaction predominantly involved polar contacts. The structure of Pdx is consistent with these observations. Although Adx and Pdx share the same overall ferredoxin fold, Pdx (Figure 9) is conformationally rigid; it does not have an asymmetric charge distribution; and the immediate vicinity of the Fe_2S_2 redox center is largely neutral. It appears that polar residues on the surface of Pdx are involved in molecular recognition with the *si* side surface of PdR. The different charge distributions, conformational dynamics, and protein recognition interactions observed in these structures have resolved the long-standing puzzle of the poor cross reactivity between these two Class I P450 systems.

2.4 Structure of P450 Enzymes

The first structurally characterized P450 enzyme was $P450_{cam}$ (CYP101) from *Pseudomonas putida*.[18,38] This was followed by the crystal structures of $P450_{BM\text{-}3}$ (CYP102A1) from *Bacillus megaterium*,[39,40] $P450_{terp}$ (CYP108) from a *Pseudomonad*,[41] and $P450_{eryF}$ (CYP107A1) from *Saccharopolyspora erythraea*.[42,43] The structures of other bacterial P450 enzymes have been determined, including the sterol demethylase CYP51 and CYP121 from *Mycobacterium tuberculosis*,[44,45] CYP154A1 and CYP154C1 from *Streptomyces coelicolor*,[46,47] CYP119 from the thermophilic bacterium *Sulfolobus solfataricus*,[48,49] CYP175A1 from another thermophile *Thermus thermophilus*, P450oxyB and P450oxyC from the vancomycin-synthesizing *Amycolatopsis orientalis*,[50,51] and $P450_{epoK}$ which is involved in epothioline synthesis in *Sorangium cellulosum*.[52]

Since bacterial enzymes are soluble and often readily crystallized, we can expect the crystal structures of many more prokaryotic P450 enzymes to be determined in the future. Eukaryotic P450 enzymes are membrane-bound and much more difficult to crystallize. Johnson and coworkers have replaced the N-terminal membrane anchor residues with short hydrophilic peptides and also used mutagenesis to reduce the extent of protein aggregation.[53] Using this method, rabbit CYP2C5 and human CYP2C9 and CYP2B4 have been crystallized and structurally characterized.[54,55]

All of the structures of P450 enzymes show a common overall fold (the P450 fold) and similar secondary structure elements.[56–59] The P450 fold has a helix-rich domain and another domain mainly comprised of β-sheets. The heme is located at the boundary between these two domains and the substrate-binding pocket is defined by residues from both domains. The primary sequences and structures of P450 enzymes show a well-conserved series of helices A–L. The I and L helices contact the heme on the distal and proximal sides, respectively. The B, C, and I helices have extensive contacts with the substrate, and residues in the F and G helices also contribute to substrate binding. However, the structures of P450 enzymes, in particular the crucial substrate-binding pocket on the distal side of the heme, differ dramatically in detail. These differences arise from slightly different lengths

and arrangement of helices and β-sheets, and also different packing of the two major domains in the structure.

The $P450_{cam}$ structure does not show any opening from the heme prosthetic group to the protein surface. Substrate entry must therefore rely on transient conformational fluctuations to open a substrate access channel. Other enzymes do have well-defined substrate access channels, for example, $P450_{BM\text{-}3}$ (CYP102A1) and CYP51,[39,44] or have very open structures with large clefts leading directly from the protein surface to the heme, for example, CYP154C1 and CYP2B4.[46,55] CYP2B4 crystallizes as a dimer with an open cleft that runs from the surface of the protein to the heme. In the absence of a substrate the cleft is partially filled by residues from the other molecule of the dimer, with the imidazole side chain from one residue coordinated to the heme.

2.4.1 *Structure of $P450_{cam}$ (CYP101)*

Although first reported nearly twenty years ago, the structural features and inferences drawn from the structure of $P450_{cam}$ remain the basis of much of the current understanding of P450 catalysis, and will do so in future efforts on detailed mechanistic investigations. The structure of $P450_{cam}$ with camphor bound within its active site is shown in Figure 10.[18] The protein is a trigonal prism with triangular sides of ~60 Å and a thickness of ca. 30 Å. In this 'normal' view of the P450 structure, the helix-rich domain is on the right while the more β-sheet domain is in the top left quadrant. The heme is sandwiched between the two domains and roughly parallel to the triangular faces. The iron is five-coordinate and out of the porphyrin plane towards the proximal cysteine thiolate ligand.

Of the secondary structural elements, helices I and L contact the heme. The L helix provides the proximal Cys-357 ligand to the heme iron, and contains the highly conserved P450 signature sequence FGHGXHXCLG used to identify CYP genes in genomes. The I helix on the distal side is the longest in the molecule and spans the whole structure. It contains two highly conserved residues Asp-251 and Thr-252. There is a characteristic kink in the helix (Figure 11) as a result of a H-bond between the backbone carbonyl of G248 and the alcohol side chain of T252; in a normal helix the hydrogen bond is formed with the amide NH of T252. This kink creates a small pocket or groove which was proposed to be important for oxygen binding. Supporting evidence comes from the structure of the ferrous-carbon monoxide form of the enzyme, in which the oxygen of the CO ligand pointed into this groove.[60] Three ordered water molecules (WAT 523, 566, 687) are found in the vicinity of this groove (Figure 11) and these, together with the D251 and T252 side chains, are believed to be involved in the relay that shuttles protons to the heme-bound O_2 for O–O bond cleavage (see Section 2.5.2).

On the proximal side of the heme, the amide NH protons of L358, G359 and Q360 form H-bonds with the C357 proximal thiolate ligand. Since the Cys-Leu-Gly motif is part of the highly conserved P450 signature sequence, this set of H-bonds occurs in all P450 enzymes and they play crucial roles in moderating the electronic structure and redox properties of the heme. The proximal side of the heme is close to the protein surface (shortest distance ~10 Å), and it is most likely that the physiological electron-transfer protein will deliver the electron from this side of the enzyme. The proximal surface of $P450_{cam}$ has a number of basic residues that are conserved across the CYP superfamily. The presence of such residues, in particular R72, R112, K344 and R392 in $P450_{cam}$,[61,62] suggests that basic residues on the proximal surface of P450 enzymes interact with surface acidic residues on the electron-transfer protein.[30,63]

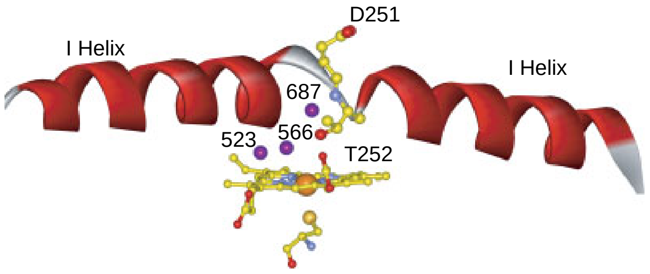

Figure 11 The oxygen-binding groove in the I helix formed by the characteristic kink in the helix. The side chains of Asp-251 and Thr-252, and the three ordered water molecules 523, 566 and 687, are proposed to be involved in oxygen binding and proton shuttling

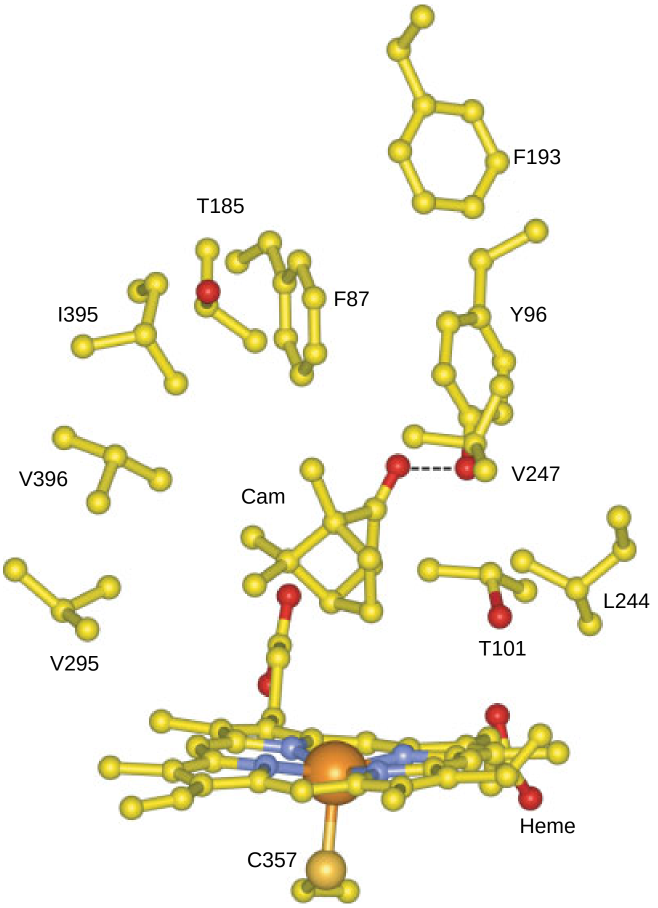

Figure 12 The active structure of $P450_{cam}$ with bound camphor. The amino acid side chains that define the substrate pocket and contact the substrate are shown. The dotted line indicates the hydrogen bond between the camphor carbonyl and the phenol side chain of Tyr-96

The active-site structure of $P450_{cam}$ with bound camphor is shown in Figure 12. There are numerous noncovalent contacts between substrate and protein, and the camphor carbonyl is H-bonded to the phenol side chain of Y96 – the most prominent hydrophilic active-site residue.[18] The contacts between camphor and F87, L244, V247, V295, and V396 contribute to the strength of binding and, together with the H-bond to Y96, hold the orientation of the molecule so that the camphor C-5 is placed ∼4.5 Å from the heme iron and the Cys-S/Fe/C-5 angle is close to 180°. The importance of the camphor-Y96 H-bond has been demonstrated by mutagenesis studies.[64] Sligar also noted that the active-site residues are arranged approximately in tiers above the heme. Tier 1 contains T101, L244, V295, while F87, Y96, F98, V247, I395 and V396 are in Tier 2, and T185 is in tier 3 and appears to serve as a cap on the active site. This Tier model offers a useful framework for discussing the effect of amino acid substitutions on protein substrate recognition and catalytic activity.[65]

Based on multiple sequence alignments, Gotoh has identified six substrate recognition sites (SRS) in P450 sequence space.[66] When mapped onto the $P450_{cam}$ structure (Figures 10 and 12), SRS 1 is in the B′–C loop (around F87, Y96 and T101), SRS 2 and 3 are on the F and G helices (around T185 and F193), SRS 4 is in the distal I helix (around L244 and V247), SRS 5 is between helix K and β strand 1–4 (around V295), while SRS 6 is in β strand 4–2 (around I395 and V396). These SRS regions can be identified in the sequences of P450 enzymes but comparison of the available structures indicates that the locations of these sites in 3-D space are not well conserved.[56–59] Helix movement and different packing of secondary elements as well as changes in the domain contacts can result in varied active-site architecture.

2.4.2 *Structure of $P450_{BM\text{-}3}$ (CYP102A1) and CYP2C9*

The structure of the heme domain of $P450_{BM\text{-}3}$ with a fatty acid substrate bound shows the characteristic P450 fold and the kink in the distal I helix,[40] and E267 and T268 are equivalent to D251 and T252 in $P450_{cam}$. Two features in the structure are particularly relevant to the present discussion. Firstly $P450_{BM\text{-}3}$ has a well-defined substrate access channel that extends from the surface residues R47 and Y51 at the channel entrance down through to the heme (Figure 13). Secondly, unlike the $P450_{cam}$ structure in which camphor is poised over the heme iron for oxidation at C-5, the terminal carbons of the fatty acid substrate are prevented from approaching the heme iron by the F87 side chain in $P450_{BM\text{-}3}$. Hence there must be a conformational change during catalysis, perhaps associated with an electron-transfer step, to flip the F87 side chain out of the way to allow the substrate carbons to approach the heme iron.

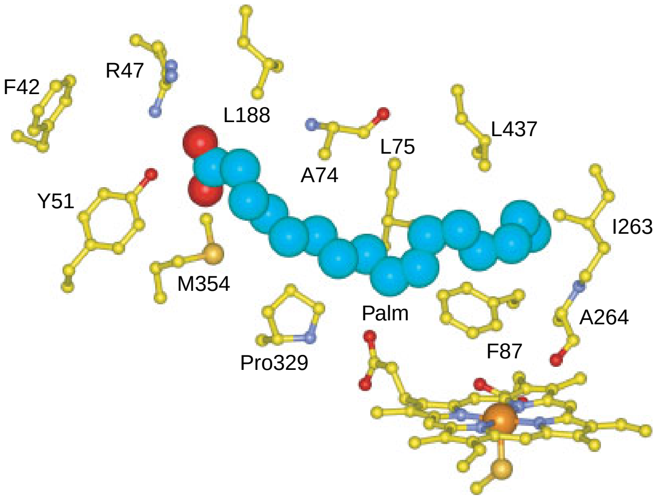

Figure 13 The active-site structure of $P450_{BM\text{-}3}$ with palmitoleic acid bound to the substrate pocket. The fatty acid substrate extends along the substrate access channel to the surface of the protein. The side chains lining the channel are also shown

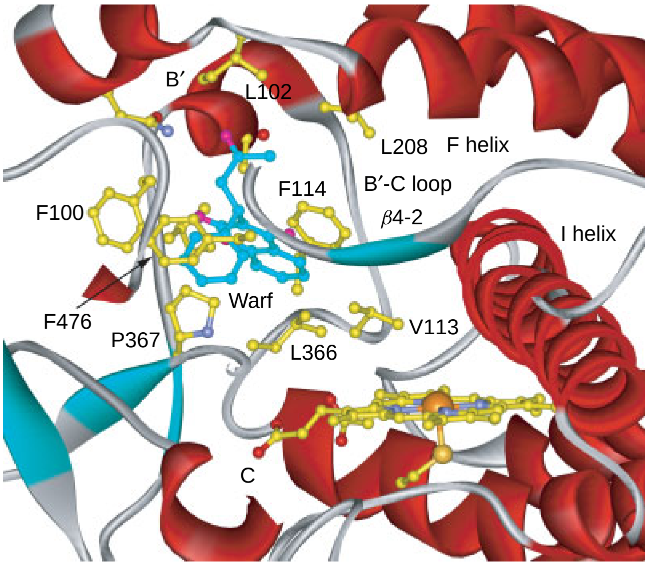

Figure 14 The structure of human CYP2C9 with warfarin (in blue) bound within the active site. There is a large pocket over the heme defined by the B′–C loop, the F and I helices, and the β4–2 strand

The structure of CYP2C9, a drug metabolizing human P450 enzyme, with warfarin bound within its active site, is shown in Figure 14.[54] Although the CYP2C9 enzyme is closely related to CYP2C5, another structurally characterized P450 enzyme, their structures are very different. One important observation from the CYP2C9 structure is that the active site is very large and can accommodate more than one substrate. Warfarin is bound to the enzyme by numerous noncovalent and polar contacts with protein side chains. This binding orientation is nonproductive because warfarin is too far away from the heme for efficient oxidation. In addition, even with a large three-ring compound such as warfarin bound, there is space to accommodate another, equally large molecule in the active site. There is a large pocket defined by residues in the B′–C loop (including V113 and F114, Figure 14), the F and I helices, and the β4–2 strand. This second pocket extends over the heme, and a substrate bound here may be preferentially oxidized by the enzyme. The presence of multiple potential substrate-binding pockets is a model for drug-drug interactions where one drug can affect the efficacy and toxicity of another simultaneously administered drug.

2.5 Catalytic Cycle and Intermediates of P450 Enzymes

2.5.1 The P450 Catalytic Cycle

The generally proposed P450 catalytic cycle is shown in Figure 15. The overall features of the mechanism have not changed since the early 1970s.[67] However, recent work showed that the nature of the intermediates and rate-limiting step can differ among enzymes, and that protein structure and dynamics play important roles. An overview of the catalytic cycle is provided in this section. More detailed discussions on the intermediates, rate-limiting step and mechanism of aliphatic C–H bond oxidation then follow. The mechanism of aromatic C–H bond oxidation, alkene epoxidation, and atypical activity of P450 enzymes are discussed in Section 2.6.

The resting state **I** of P450 enzymes has a ferric heme, commonly with a water molecule acting as the sixth ligand to the heme iron. The iron center is low spin and out of the porphyrin plane, towards the cysteine thiolate ligand. The heme reduction potential is around −300 mV (vs. NHE). In Step **1** of the catalytic cycle the substrate binds to the active site, on the distal side of the heme and near the iron center. This step is generally accompanied by the expulsion of active-site water molecules, including the heme iron sixth ligand. The five-coordinate iron in the substrate-bound form **II** remains below the porphyrin plane and the heme usually shifts towards the high-spin state. The heme reduction potential of **II** is around −170 mV. Step **2** is the transfer of the first electron by the associated electron-transfer protein to generate the ferrous-deoxy form **III**. This high-spin ferrous center binds oxygen (Step **3**) and forms the low-spin, diamagnetic oxy-P450 **IV** which has a reduction potential ~0 mV. This $Fe^{II}(Por)\cdot(O_2)$ complex (see Section 2.5.2) is unstable to auto-oxidation which regenerates **II** and releases superoxide ($O_2^{\bullet -}$), with a typical half-life of minutes at ambient temperatures.[68–70] In Step **4**, the electron-transfer protein delivers the second electron required for oxygen activation. A ferric-peroxo species (**V**) is formed which is protonated to give the ferric-hydroperoxo intermediate (**VI**). In mammalian P450 systems, cytochrome b_5 (reduction potential ca. −50 mV) can also be the source of the second electron.

The intermediates beyond **VI** have not been observed, and their molecular and electronic structures remain controversial. Clearly a highly reactive species is generated and water is a by-product of the overall reaction. Certain 'oxygen atom' donors can replace the two electrons and O_2 required for the normal catalytic activity of P450 enzymes. These oxygen surrogates include hydrogen peroxide, alkyl hydroperoxides (ROOH), peroxyacids (RCO_3H), chlorite (ClO_2^-), periodate (IO_4^-) and iodosylbenzene (PhIO).[71–75] In this 'peroxide shunt' (Step **13**), the substrate-bound form of the enzyme **II** is converted to the active species **VII**. The ferric heme in peroxidases and catalases reacts with hydrogen peroxide to give a high-valent intermediate called Compound I, which has been characterized in detail as an oxy-ferryl (Fe^{IV}=O) porphyrin π-cation radical (*see* ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***). From indirect evidence, and by analogy with peroxidases, it is generally proposed that the ferric-hydroperoxo intermediate **VI** is protonated at the noniron bound oxygen atom (Step **6**), leading to O–O bond cleavage and release of a water molecule. At this stage, the P450 catalytic cycle can be considered formally as the two-electron reduction and heterolytic cleavage of O_2 to give water

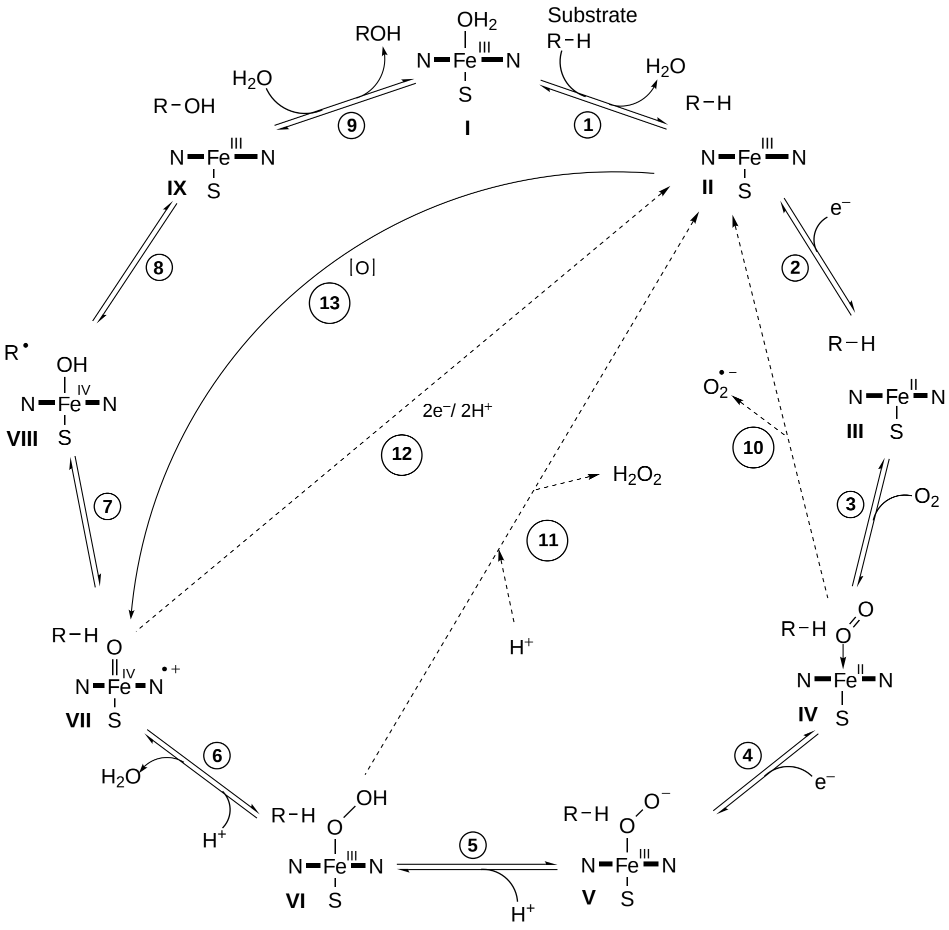

Figure 15 The P450 catalytic cycle including uncoupling side reactions (Steps **10**, **11** and **12**) and the peroxide shunt (Step **13**)

and an oxygen atom (equation 6).

$$O_2 + 2e^- + 2H^+ \longrightarrow H_2O + O \qquad (6)$$

Since the resting state of the enzyme is Fe^{III}, and an oxygen atom requires two electrons to complete its octet, O–O bond cleavage in **VI** and the bonding of an oxygen atom to the heme iron leads to a species which is two oxidizing equivalents above ferric, formally $Fe^{V}{=}O$ or $(Fe{=}O)^{3+}$. The electronic structure of this ferryl intermediate **VII** is not known, but it is commonly depicted as a $Fe^{IV}{=}O$ porphyrin π-cation radical (P450 Compound I, by analogy with peroxidases and catalases). In Step **7**, this reactive intermediate attacks the substrate; it can abstract a hydrogen atom or an electron from the substrate, or indeed form a σ-complex with the substrate via a C–O bond (see Section 2.6). Hydrogen atom abstraction gives a Fe^{IV}–OH species **VIII** and a substrate radical that is held within the active site. These two radicals collapse (Step **8**) to give the alcohol product and return the heme to a ferric state **IX**. The two-step hydrogen abstraction/radical collapse pathway is called the radical rebound mechanism.[76] In the final step of the cycle (Step **9**), the product dissociates from the enzyme. The crystal structure of $P450_{cam}$ with 5-*exo*-hydroxycamphor bound within the active site showed that the alcohol oxygen of this camphor oxidation product is ligated to the ferric heme iron.[77] Since all substrate oxidation products contain an oxygen atom with lone pairs of electrons that can coordinate to the heme, it is not known if P450 enzymes fully return to the true resting state **I** (as shown in Figure 15), or the substrate could displace the product directly from the active site so that the cycle will proceed directly from **IX** to **II**.

2.5.2 *Nature of Intermediates in the P450 Catalytic Cycle*

Spectroscopic techniques played a major role in characterizing the resting state and intermediates of P450 enzymes before the first crystal structure of a P450 enzyme became available. These techniques included UV-visible absorption, EPR, NMR, MCD, resonance Raman, Mössbauer and EXAFS spectroscopy.[78–80] Recent application of these techniques to transient intermediates generated by stopped-flow and rapid quench methods, and reactions at cryogenic temperatures, have provided important new insights into the structure of intermediates in the P450 catalytic cycle.

The Resting State I. The heme iron is six-coordinate and located out of the porphyrin plane in the substrate-free, low-spin ferric resting state of almost all P450 enzymes. Contradictory arguments have been put forward to account for the low-spin state. The active site of substrate-free $P450_{cam}$ is filled with a cluster of six hydrogen-bonded water molecules.[38] $P450_{cam}$ with adamantane and other camphor analogs bound within the active site are high spin and yet one water remains ligated to the heme iron.[81] It was suggested that substrate-free $P450_{cam}$ was low spin because H-bonding within the water cluster imparted substantial hydroxide (stronger ligand) character to the water ligand. Semiempirical calculations suggested that the isolated Cys–heme–OH_2 complex is high spin, and the protein electrostatic field plays a major role in stabilizing the low-spin state.[82] Studies on porphyrin model compounds also suggested that a water ligand on its own is not sufficient to drive the heme low spin.[83,84] However, when the porphyrin substituent groups are modified to form two H-bonds to the water ligand, the heme iron becomes low spin.[85] The water ligand can also be made hydroxide-like by H-bonding interactions with the protein.[51] It appears that hydroxide-like character of the water ligand is a general requirement for a low-spin resting state. The high-spin resting states of some mammalian P450s[86] may indicate a less hydroxide-like ligand, or a five-coordinate heme iron.

Hydrogen bonding on the proximal side of the heme has emerged as an important factor in determining the properties of P450 enzymes. The thiolate sulfur of the proximal C357 in $P450_{cam}$ forms H-bonds with the amide NH of L358, G359 and Q360.[18] These H-bonding interactions are conserved in other P450 enzymes.[39,42,57] Poulos suggested that proximal H-bonding may stabilize the Fe–S bond and control the heme redox potential.[56] Studies on iron porphyrin model complexes with H-bonds to the proximal RS^- ligand clearly showed that such interactions caused significant positive shifts of the reduction potential and affected the monooxygenase activity.[87–90] Mutagenesis studies have highlighted the role of proximal ligand H-bonding in $P450_{cam}$.[91,92] The L358P, Q360L, and Q360P mutations shifted the heme reduction potential by 35–70 mV to more negative values as well as affecting the $Fe(O_2)$ interaction and kinetics of O–O bond heterolysis. Spectroscopic data indicated that the Q360 mutations mainly altered the Fe–S σ-interaction while the L358P mutation increased S→Fe π-donation. The activity of the Q360 mutants was comparable to the wild type but the L358P mutant showed higher activity for the oxidation of nonnatural substrates such as styrene. NMR studies showed that L358 and Q360 are involved in electron transfer, and that the L358P mutation induced structural changes similar to those induced by putidaredoxin binding.[93,94] Therefore proximal ligand H-bonding not only increases the heme reduction potential to promote electron transfer but also affects the O–O bond activation and substrate oxidation steps.

Deoxy-ferrous P450 III. Detailed spectroscopic studies had shown that the heme in deoxy-ferrous P450 is high spin.[79,80] The crystal structure of deoxy-ferrous $P450_{cam}$ closely resembled that of the ferric form (Figures 10–12), with the iron out of the porphyrin plane.[95]

Oxy-P450 IV. Oxygen binds rapidly to high-spin deoxy-ferrous P450 **III** to give the oxy-P450 species **IV**. Despite extensive studies, the electronic structure of oxy-ferrous heme complexes is not definitely understood. It is well documented that such species can be considered to have two extreme forms: ferrous-oxygen (Fe^{2+}–O_2) and ferric-superoxide (Fe^{3+}–$O_2^{\bullet-}$). The chemical properties of these proteins are consistent with both structures, for example, displacement of the bound oxygen by CO indicates a Fe^{2+}–O_2 structure while substitution by anions such as CN^- and N_3^- to form Fe^{3+}–X, and auto-oxidation to form ferriheme and $O_2^{\bullet-}$, are more readily accounted for by the Fe^{3+}–$O_2^{\bullet-}$ structure. Oxy-heme proteins are diamagnetic. In the Fe^{2+}–O_2 form, the ligand field splitting induced by O_2 binding must be sufficient to drive the d^6 Fe^{2+} center low spin. This occurs because O_2 is a good π-acceptor. On the other hand, even if the ligand field splitting is high in the Fe^{3+}–$O_2^{\bullet-}$ form, there will be an unpaired electron on the d^5 Fe^{3+} center and another on the superoxide anion. These two spins must be strongly coupled by antiferromagnetic coupling to give a diamagnetic state. Whether the Fe^{2+}–O_2 or Fe^{3+}–$O_2^{\bullet-}$ structure is adopted depends on the extent to which an electron is transferred from Fe^{2+} to O_2, which in turn depends on the extent of π-back donation from the iron center. Oxy-heme species are best considered as $Fe^{(2+\delta)+}$–$O_2^{\delta-}$ where δ indicates partial transfer of an electron from Fe^{2+} to O_2. The O–O stretching frequency is indicative of the O–O bond order and hence the extent of back-donation. Resonance Raman spectroscopy detected the O–O stretch for oxy-$P450_{cam}$ **IV** at 1140 cm^{-1},[96] which is 20 cm^{-1} lower than the value found for oxy-hemoglobin and consistent with the anionic thiolato coordination in P450 enzymes compared to the neutral imidazole nitrogen ligand in globins. Hence oxy-$P450_{cam}$ is closer to the Fe^{3+}–$O_2^{\bullet-}$ limit than oxy-globins.

The crystal structure of oxy-$P450_{cam}$ **IV** with bound camphor showed that O_2 is bound end-on (η^1) to the heme iron with the distal oxygen atom pointing towards the side chain of T252.[95] The Fe–O distance was 1.8 Å. Camphor was displaced slightly from its position in the ferric form of the enzyme to create space for O_2 binding but the C-5 of camphor was in van der Waals contact with the proximal oxygen atom. The iron center moved from below the porphyrin plane in the ferric (**II**) and deoxy-ferrous (**III**) forms into the porphyrin plane.

There were changes in the protein and water structure in the oxygen-binding groove between G248 and T252 which may be important in O–O bond activation. Two new water molecules were found in the oxygen-binding groove of oxy-ferrous $P450_{cam}$. The presence of these water molecules induced conformational changes to D251 and T252. One

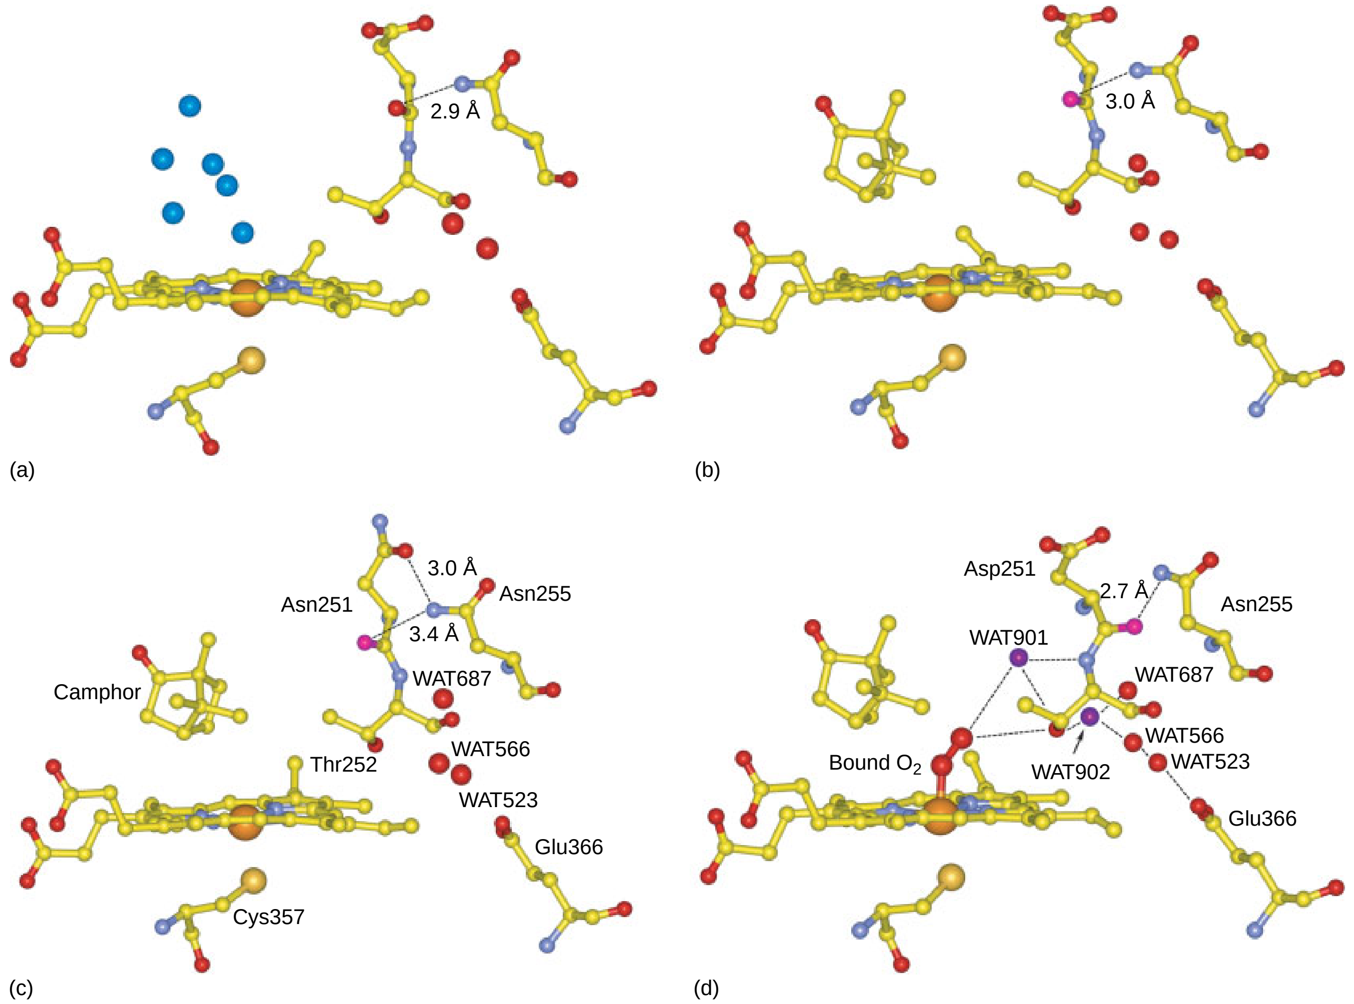

Figure 16 The protein structural dynamics of $P450_{cam}$ up to the O_2 binding step. (a) The structure of substrate-free ferric $P450_{cam}$ showing the cluster of six-water molecules (dark blue) in the substrate-binding pocket and the two waters in the O_2-binding groove in the kink within the I helix. (b) The structure of ferric $P450_{cam}$ with bound camphor; the six-water cluster has been displaced and a new water molecule (WAT687) enters the O_2-binding groove to complete the chain of three water molecules that ends at Glu366. Note the side chains of D251, T252 and N255. (c) The structure of the D251N mutant showing the altered side chain conformation and the H-bond between the N251 carbonyl and side chain NH_2 of N255. (d) The structure of oxy-$P450_{cam}$ with bound camphor. Two new water molecules (901 and 902) are found in the oxy-$P450_{cam}$ structure. The bound O_2 is hydrogen-bonded to WAT901 and the T252 side chain. The flipped conformation of the D251 main chain carbonyl, stabilized by a hydrogen bond to the N255 side chain, creates space to accommodate WAT901. This driving force is not available in the D251N mutant because the N255 side chain is hydrogen-bonded to the N251 side chain

water molecule (WAT901, Figure 16d) formed H-bonds to the distal oxygen atom of the heme-bound O_2, the amide NH and hydroxyl side chain of T252, and other protein groups. The distal oxygen of the bound O_2 also formed a H-bond to the T252 hydroxyl side chain. The other new water molecule (WAT902) formed H-bonds to the hydroxyl side chain of T252, WAT901, WAT687 and other protein groups. Waters 901, 902, 687, 566 and 523 extend in a chain anchored by a H-bond between WAT523 and the carboxylate side chain of E366.

The characteristic kink in the distal I helix of most P450 enzymes was believed to perform the function of an oxygen-binding groove, but the structure of oxy-$P450_{cam}$ suggested that its role may be to accommodate an extra water molecule that forms a H-bond to stabilize O_2 binding. T252 is highly conserved amongst P450 enzymes. Replacement of threonine with serine or an artificial amino acid residue with a methoxy group in place of the alcohol had little effect on the activity,[97] but the T252A mutant showed slow O–O bond cleavage and increased peroxide formation.[98] These activity data, and the structure of oxy-$P450_{cam}$, indicate that the role of T252 is to provide an oxygen atom that can participate in H-bonding in proton delivery for O–O bond cleavage.[95,97]

The requirement of two protons for O–O bond cleavage and the appearance of two new water molecules in oxy-$P450_{cam}$ may be a coincidence. Certainly the chain of water

molecules (Figure 16d) does not lead to the protein surface to allow proton delivery. However, the oxy-heme complex has two H-bonds to the distal oxygen and appears to be well set for proton delivery and O–O bond cleavage after the second electron is transferred. The mechanism of proton delivery is not known, but WAT901 and 902 are very likely to be involved and the side chain of D251 is known to play an important role (Figure 16d). The D251N mutation decreased the O–O bond cleavage rate by two orders of magnitude but there was no increased loss of peroxide.[99,100] The crystal structure of the D251N mutant showed that the N251 side chain carbonyl formed a H-bond with the side chain NH_2 of N255 (Figure 16c),[100] while in the wild-type structure the D251 side chain carboxylate is H-bonded to the K178 side chain. The structure of oxy-$P450_{cam}$ showed that the N255 side chain NH_2 was required for H-bonding to the *backbone* carbonyl oxygen of D251 to flip this carbonyl group and create space for the catalytically important new water molecule WAT901.[95] The H-bond between the *side chain* carbonyl of N251 and the N255 side chain NH_2 blocks this critical conformation change, thus slowing proton delivery. Finally the 'closed' nature of the chain of water molecules in oxy-$P450_{cam}$ also suggests that further protein conformational changes, and perhaps the entry of more water molecules, are required to shuttle protons to the water cluster after the second electron transfer.

The Ferric-peroxo (V) and Ferric-hydroperoxo (VI) Intermediates. Stopped-flow studies have not detected any intermediates after the second electron transfer (Step **4**). Sligar, Hoffman, and coworkers have studied the cryoreduction (77 K) of oxy-$P450_{cam}$ by solvated electrons generated by irradiation with a ^{60}Co source. EPR studies showed that the ferric-hydroperoxo species (Fe^{III}–O–OH) **VI** was the first observed product, suggesting fast protonation (Step **5**) of the ferric-peroxo form **V**.[101] Consistent with this suggestion was the observation that cryoreduction of the active-site mutant D251N, in which the proton delivery pathway has been disrupted,[100] gave the ferric-peroxo species **V** at 77 K and this was transformed to the hydroperoxo form **VI** upon annealing at higher temperatures.[102] The sequence of reactions can be summarized as follows: (i) oxy-P450 **IV** has the 'ferric-superoxo' electronic configuration and is stabilized by H-bonding, (ii) the second electron is transferred and becomes localized on the O–O moiety to form the ferric-peroxo species **V**, (iii) the developing negative charge on the distal oxygen is rapidly neutralized by rearrangement of the H-bonding to transfer a proton and give the ferric-hydroperoxo form **VI** in a process that requires the carboxylate side chain of the 251 residue.

No further chemical input is necessary for substrate oxidation to occur once the second electron is transferred. Quantum mechanical calculations have provided insights into the protonation and O–O bond cleavage steps. Density function theory (DFT) calculations on the ferric-peroxo form of $P450_{eryF}$ indicated fast protonation at the distal oxygen by a chain of two water molecules that extended to a serine side chain. The second protonation step, which leads to O–O bond cleavage, was found to be essentially activationless.[103] Once the two protons are transferred, formation of the ferryl species was very facile. Interestingly, the calculations also suggested that a single water molecule was not sufficient to protonate the peroxo group.

The Ferryl Compound I Intermediate VII. Cryoreduction of oxy-$P450_{cam}$ with bound camphor in a crystal resulted in partial reaction and disorder, and definitive refinement was not possible. Thawing the crystal gave the product of camphor oxidation.[95] Spectroscopic investigations on cryoreduced oxy-$P450_{cam}$ did not detect the Compound I intermediate **VII**.[102] Annealing of ferric-hydroperoxo $P450_{cam}$ (**VI**) from 77 K to within a narrow temperature range (180–200 K) gave ferric $P450_{cam}$ with the product of camphor oxidation, 5-*exo*-hydroxycamphor, bound to the heme iron. The data suggest that the Compound I intermediate **VII** is sufficiently reactive that it rapidly attacks camphor to form the product even at 200 K. It was also shown that, while D251 was required for the first protonation of **V** to give **VI**, T252 was critical for the second protonation to give the active intermediate **VII**. Thus the T252A mutation did not interfere with the rapid delivery of the first proton to form **VI**, even at 77 K, but the mutant did not give any product of camphor oxidation upon thawing.

The peroxide shunt has been used to by-pass the electron-stransfer steps and generate the ferryl intermediate directly from ferric P450s. Transient signals have been observed in stopped-flow experiments when ferric $P450_{cam}$ with camphor or other substrates bound was treated with hydrogen peroxide or *m*-chloroperbenzoic acid.[104,105] Similar results have been reported for CYP119 from *Sulfolobus solfataricus*.[106] However, these spectroscopic intermediates have not been definitively assigned to a ferryl species. The product of the reaction between substrate-free ferric $P450_{cam}$ and peracetic acid has been rapidly freeze-quenched and examined by EPR and Mössbauer spectroscopy.[107,108] It was concluded that the reaction gave a $Fe^{IV}{=}O$ ($S = 1$) species together with a protein-based radical, that is, an analogue to peroxidase Compound II which contains a noncoupled protein radical. This oxidizing equivalent located on the protein is lost to the catalytic reaction of the enzyme. Further EPR and mutagenesis studies showed that the protein radical was based on the phenol side chains of Y75 or Y96. However, when both these residues were replaced with the more inert phenylalanine, the radical signal disappeared without a new signal from the expected porphyrin radical.

DFT calculations on the electronic structure of P450 Compound I models with HS^-, MeS^-, or cysteinate as the proximal ligand and no substituents on the porphyrin ring show that a number of spin states are close in energy.[109,110] The protein medium (in the form of the dielectric constant) and the proximal NH–S hydrogen bonding interactions both have significant effects. Calculations on the bare 'P450 Compound

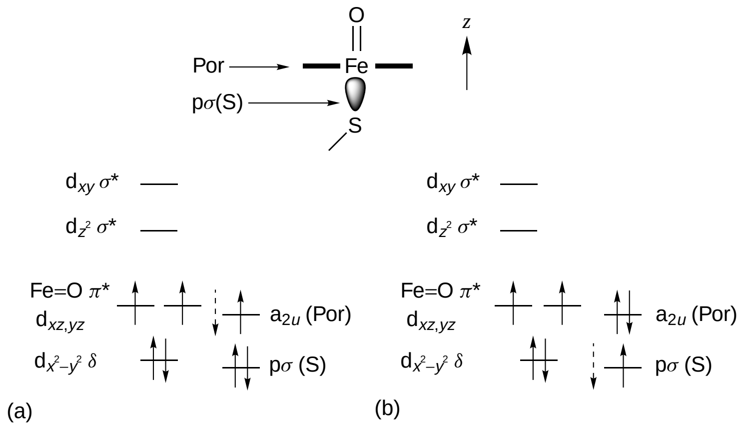

Figure 17 The electronic structure of the P450 Compound I intermediate from density function theory (DFT) calculations. The two unpaired electrons on the Fe(IV) center are in the 3d π^* orbitals while the other unpaired electron may be in the porphyrin a_{2u} π^* orbital (a) or sulfur pσ orbital (b). The solid arrows in the a_{2u} or pσ orbital show the electron spin parallel to those in the 3d π^* orbital (quartet state) while the dotted arrows indicate the doublet state

I' (**VII**) in a vacuum show that it has two unpaired electrons in the degenerate d_{xz},d_{yz} set of Fe=O π^* orbitals, with the other two 3d electrons of the Fe(IV) center in the $d_{x^2-y^2}$ orbital (Figure 17).[111–116] The other unpaired electron is spread over the porphyrin and proximal sulfur ligand, but largely localized on the sulfur (Figure 17b).[112] In effect, the thiolate has been oxidized to the radical. The Fe–S bond is long (~2.6 Å) and the iron sits above the heme plane. Slightly different calculations suggest that the unpaired electron on sulfur is in a pπ orbital.[114,115,117,118]

Introducing the proximal NH–S bonding found in the crystal structure, and applying a low dielectric constant for the medium, shortened the Fe–S distance, pulled the iron into the porphyrin plane, and most importantly shifted the radical from the proximal sulfur to a porphyrin π^* orbital (Figure 17a).[119,120] Hence, increasing the polarity around the proximal sulfur ligand stabilized the ionic $-S^-$ over the radical –S· form, and ensured that the other oxidizing equivalent was more localized on the porphyrin π-system. More sophisticated hybrid quantum mechanics-molecular mechanics (QM-MM) calculations further cemented this trend towards a shorter Fe–S bond and greater spin density on the porphyrin, and also indicated that the unpaired electron (oxidizing equivalent) is most likely to be in a porphyrin a_{2u} orbital.[109,121] Some spin density was also found on the heme propionate group which formed a salt bridge to an arginine side chain, suggesting that the heme periphery groups and the protein environment modulate the electronic structure of the P450 Compound I intermediate.[109] Significantly, the Fe=O dπ^* orbitals containing the two unpaired electrons on iron interact weakly with the porphyrin a_{2u} orbital containing the third unpaired electron. Hence, the P450 Compound I could have doublet or quartet electronic states $^2A_{2u}$ or $^4A_{2u}$, and the exact partition between these two states will vary from one enzyme to another because the electronic structure is sensitive to the micro-architecture of the heme pocket. DFT calculations have given contradictory predictions on the lowest energy spin state from slightly different levels of theory,[109,121,122] suggesting that the Compound I doublet and quartet states are very close in energy.

2.5.3 Mechanism of C–H Bond Oxidation

The Radical or Oxygen Rebound Mechanism. The mechanism of C–H bond oxidation by the P450 Compound I intermediate has been debated for over twenty years.[71,80,110,123] A simple concerted mechanism (Figure 18) has been disproved by large intramolecular kinetic isotope effects ($k_H/k_D > 10$),[124] scrambling of stereochemistry,[124–126] and substrate rearrangements.[76,124,125,127–129] Deuterium labeling studies in norbornane oxidation by liver microsomal P450 enzymes showed scrambling of stereochemistry.[124] Similar labeling at C-5 of camphor showed that the hydrogen in the 5-*exo*-hydroxycamphor product could come from the exo or endo face but only the exo alcohol was formed.[125] In 1976, Groves and McClusky put forward a nonconcerted mechanism for C–H bond activation by P450 Compound I that accounted for the isotope effects and rearrangement.[76,113] The first step is the abstraction of a hydrogen atom by the ferryl oxygen to give a Fe^{IV}–OH species (**VIII**) and a carbon-based substrate radical that remains bound within the active site (Figure 18). This radical can then recombine with the iron-bound hydroxyl group, abstracting a hydroxyl radical to form the alcohol product and returning the other electron in the Fe^{IV}–OH bond to the iron center. This stepwise pathway has been called the radical rebound (or oxygen rebound) mechanism. The oxygen lone pair of the alcohol product can act as a ligand to the Fe^{III} center (Figure 18). However, radical reactions in solution normally result in scrambling of stereochemistry. The high stereoselectivity and stereospecificity observed in

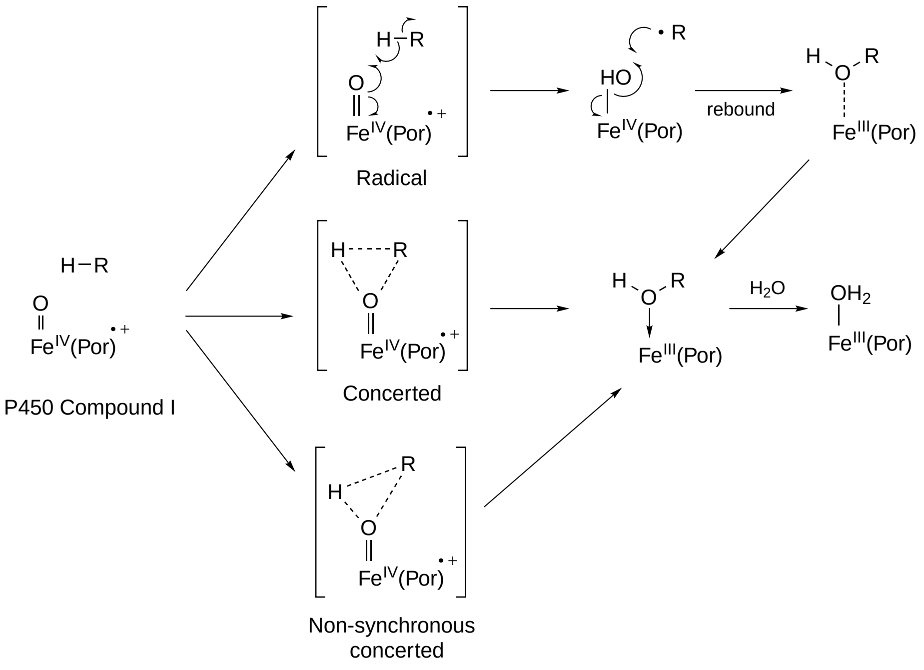

Figure 18 The concerted, nonsynchronous concerted, and radical (oxygen) rebound mechanisms of C–H bond oxidation by the P450 Compound I intermediate

many P450 reactions[83,130,131] suggest that either the radical is short-lived or that substrate motion within the active site is limited. Since some P450 enzymes can oxidize large as well as small molecules it seems that, at least in some cases, the substrate will be mobile and therefore it is likely that the substrate radical will have a short lifetime.

Ortiz de Montellano and Stearns were the first to use a radical clock substrate such as bicyclo[2,1,0]pentane to time the radical rebound reaction.[132] Radical clock substrates contain strained ring systems which undergo rapid ring-opening reactions once the radical is generated (Figure 19). If the rate constants of the ring-opening reactions are known, the ratio of rearranged and unrearranged products from a reaction

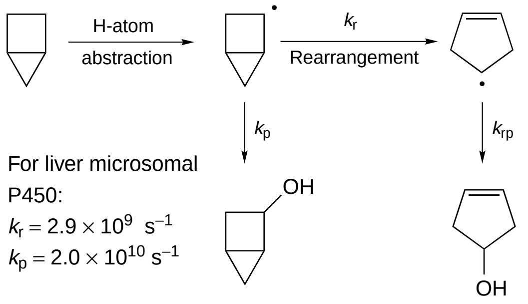

Figure 19 Structure of bicyclo[2,1,0]pentane and its use as a radical clock for C–H bond oxidation catalyzed by P450 enzymes. The radical intermediate can undergo the rebound step with the Fe^{IV}–OH species before and after ring-opening rearrangement

allows the lifetime of the radical intermediate to be calculated. A radical lifetime of 50 ps was determined for the oxidation of bicyclo[2,1,0]pentane by microsomal P450.

Newcomb and coworkers used ultrafast radical clock substrates which are also able to detect carbocationic intermediates (Figure 20) to time the radicals in P450 reactions.[133] The apparent radical lifetimes of 70–200 fs were far too short for reaction intermediates and much more like the lifetimes of transition states.[134–137] A non-synchronous concerted mechanism was proposed to introduce some concerted nature to the rebound mechanism.[135] In this nonsynchronous mechanism the transition state is high asymmetric, with C–H bond breaking and O–H bond formation being much more advanced than C–O bond formation (Figure 18). Some substrates also gave products arising from rearrangement of carbocation intermediates,[136,138,139] which led to the suggestion that two oxidizing species are involved: a Compound I iron-oxo species (**VII**) that inserts an oxygen atom without a radical intermediate and the ferric-hydroperoxo intermediate (**VI**) that inserts HO^+ to form a carbocation intermediate.[133,138,139]

The possibility of the ferric-hydroperoxo species **VI** being the active C–H bond oxidizing intermediate has been investigated. Mutagenesis of T303 in CYP2E1 disrupts proton delivery for O–O bond cleavage, allowing **VI** to accumulate. Allylic C–H bond oxidation of alkenes was found to be slow but the rate of epoxidation was increased.[136] The T252A mutant of $P450_{cam}$ catalyzed the epoxidation of styrene but there was no C–H bond oxidation of the benzene ring, nor

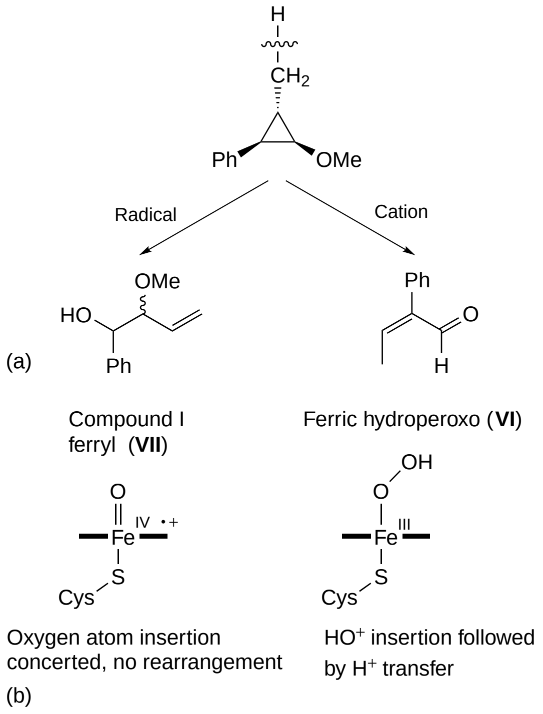

Figure 20 (a) An ultrafast radical clock substrate capable of distinguishing between radical and carbocation intermediates (b) The proposed two-oxidant pathway of C–H bond oxidation by P450 enzymes in which Compound I follows a concerted mechanism with no intermediate while the ferric-hydroperoxo attacks substrates by insertion of HO^+ leading to carbocation intermediates which rearrange to give the alcohol product

was the mutant able to catalyze camphor oxidation.[140] Studies on porphyrin model compounds also showed that the ferric-hydroperoxo species catalyzed slow alkene epoxidation.[141,142] DFT calculations suggest that a hydroperoxo species is at best a slow oxidant for C–H bonds.[122,143] Detailed spectroscopic investigations of intermediates in camphor oxidation at cryogenic temperatures clearly established that the proton abstracted from camphor C-5 became the product hydroxyl proton.[102] Thus, it appears that the ferric-hydroperoxo intermediate **VI** can oxidize alkenes but it is not sufficiently oxidizing to attack C–H bonds.

Based on DFT calculations, Shaik and coworkers proposed a 'two-state reactivity' process.[110,113,116,120,143] The doublet and quartet states of P450 Compound I (see Figure 17) have virtually identical reactivity but follow very different pathways. The low-spin doublet state leads to a substrate radical transition state with no barrier to the rebound step, whereas the high-spin quartet state generates a radical with a significant barrier to rebound. In this model, predominance of the low-spin pathway explains the apparently short ($\sim$100 fs) radical lifetimes in some radical clock experiments, while the high-spin pathway accounts for the finite radical lifetimes in others. The calculations further suggested that the doublet state did not generate cationic character in the substrate intermediate while the quartet state allowed the build up of significant positive charge on the substrate and is the potential cationic pathway. Since these two states of Compound I are very close in energy, minor changes in the heme environment could change the partition between these pathways, leading to different proportions of products arising from radical/cationic intermediates. Hybrid QM-MM calculations have, however, indicated that the quartet state is the more reactive and the doublet state may not be necessary.[109,122]

Groves made the interesting observation that the oxidation of clock substrates with only methylene C–H bonds (e.g. bicyclo[2,1,0]pentane or the [4,1,0] molecule norcarane) showed finite radical lifetimes and gave only trace amounts of cation rearrangement products.[131] The proportion of cation rearrangement products increased for the oxidation of primary C–H bonds of methyl groups in some ultrafast radical clock substrates (see Figure 20). This partition between radical and cationic pathways was suggested to be the result of competition between radical rebound to form products and electron-transfer oxidation of the radical by the Fe^{IV}–OH intermediate (**VIII**). Such competition had been described for electron transfer from primary alkyl radicals to an Fe^{III}(phen) oxidant against trapping of the radical by a bromine atom.[144,145] The rate of electron transfer was sensitive to the redox potentials of both the iron and alkyl radical centers, and shown to be ca. 10^8 $M^{-1}s^{-1}$ for secondary alkyl radicals. Electron-transfer oxidation of the radical should be faster for the more oxidizing Fe^{IV} species in P450 catalysis and may compete with the rebound rate of ca. 10^{10} s^{-1}. Other important factors are the distance between the substrate C–H bond and the Fe=O oxygen of Compound I, and the mobility of the substrate and radical intermediate within the active site. Primary C–H bonds in a methyl group are less sterically encumbered and can approach closer to the Compound I ferryl oxygen. Both the rebound and electron-transfer oxidation of the substrate radical could be accelerated compared to those for secondary C–H bonds, and hence there may be little to no radical rearrangement (faster rebound) but the proportion of cationic products may be increased (faster electron-transfer oxidation).

The mechanisms of enzymatic aliphatic C–H bond oxidation remain one of the most interesting and challenging areas in chemical biology. Since the proposal of the radical rebound mechanism by Groves and McClusky in 1976,[76] catalysis research has delved further into the intricate detail of the structure of the Compound I species and its reaction with C–H bonds. The protein environment and dynamics have been shown to have subtle but important effects on the redox potential, electronic structure, and reactivity of the heme iron. Nature has evolved mechanisms to exert delicate control over iron bioinorganic chemistry, electron transfer, and to choreograph the binding and movement of substrate and water molecules in the active site at all steps of the P450 catalytic cycle.

2.5.4 *Rate-limiting Steps in the P450 Catalytic Cycle*

Of the nine steps in the generalized cycle shown in Figure 15, some are obviously fast reactions but essentially any of the other steps could be rate limiting for the overall cycle. The binding of substrate (Step **1**) and O_2 (Step **3**) are probably very fast and diffusion-controlled for all P450 enzymes. The second-order rate constant of O_2 binding to $P450_{cam}$ has been determined to be ca. 10^8 M^{-1} s^{-1},[123] and for camphor binding, 2.5×10^7 M^{-1} s^{-1}.[146] At a substrate concentration of 100 μM the camphor binding rate is 2 500 s^{-1}, or 150 000 min^{-1}. By comparison, the fastest steady state substrate oxidation rate observed to date for a P450 enzyme is 20 000 min^{-1} for arachidonic acid oxidation by $P450_{BM\text{-}3}$.[147]

It is notable that many P450 enzymes do not have obvious substrate access channels.[56,57] However, the diffusion-controlled nature of substrate binding indicates that the structural and conformational changes required for substrate entry to most P450 enzymes must be very fast.[123,148] Structural studies on $P450_{cam}$ have shown that, in the absence of a substrate, residues such as F87, F193 and I395 (see Figure 12) which are close to the protein surface, are very mobile and could be part of a cluster of residues that open up to allow substrate entry.[38] The structures of $P450_{cam}$ with a number of large inhibitors bound within the active site all showed dramatic movements of protein backbone and side chains, and yet the enzyme was stable.[149–151] These observations clearly show that the 'P450 fold' can tolerate large changes in the structure, including those transient fluctuations required for entry of substrates into the active site.

For nearly thirty years, the paradigm of P450 catalysis was that the rate-limiting step of the catalytic cycle was the first electron transfer (Step **2** in Figure 15), and that this was gated by substrate binding (Step **1**) and the associated changes in heme spin state.[123,152,153] This paradigm is firmly established for the bacterial enzymes $P450_{cam}$ and $P450_{BM\text{-}3}$. The $P450_{cam}$ heme reduction potential shifts from −300 mV in the absence of substrate to −170 mV when camphor binds to the enzyme.[152,154] A similar positive shift of the heme potential by 140 mV upon substrate binding has also been reported for $P450_{BM\text{-}3}$.[153] For the $P450_{cam}$ system, the reduction potential of the electron-transfer protein putidaredoxin (Pdx) is −235 mV.[155] The proposal was that, in the absence of substrate, reduction of the P450 enzyme by the electron-transfer protein is thermodynamically unfavorable and therefore slow. When substrate binds to the active site, the heme reduction potential rises and the reaction is thermodynamically favorable and fast. Substrate binding serves as a regulatory step or 'gate' so that NADH is not wasted in futile cycling which puts metabolic stress on the organism.

In the absence of substrate, the heme iron of $P450_{cam}$ is six-coordinate and low spin. Camphor binding expels all water molecules from the $P450_{cam}$ active site, and the iron becomes five-coordinate and high spin.[152,156] A linear free-energy relationship has been observed between the $P450_{cam}$ spin state equilibrium and heme redox potential.[157] The presence of the sixth ligand is expected to stabilize the higher oxidation state of the heme iron and increase the ligand field strength, which accounts for the lower reduction potential and the low-spin iron center in substrate-free $P450_{cam}$. Loss of this ligand upon substrate binding changes the heme spin state and reduction potential and switches on the catalytic cycle. The first electron-transfer step is rate limiting for the overall reaction. This simple and elegant scheme is very attractive and had been the paradigm for nearly 30 years. Early work on microsomal P450s supported gating by substrate binding,[158–160] but further work showed that the concentration of the electron-transfer reductase CPR in microsomes or systems reconstituted in lipids might be too low for fast electron-transfer kinetics to be observed.[161,162] Detailed analysis of the rates of electron transfer and steady state turnover for many human P450s showed that the rate-limiting step occurs after the electron-transfer reactions.[162,163]

Substrate binding does not induce changes to the heme spin state and redox properties for all P450 enzymes. Some mammalian P450s have high-spin heme in the absence of substrate but the heme reduction potential remains low,[86,164,165] while others do not show a shift to high-spin heme or an increase in the potential but fast electron transfer is still possible.[162,164,166] The bacterial enzyme $P450_{cin}$ does not show a change in heme redox potential when cineol binds to the active site and initiates the catalytic cycle.[167] Studies on the oxidation of nonnatural substrate by $P450_{cam}$ and $P450_{BM\text{-}3}$ mutants also gave many examples of the breakdown of the correlation between substrate binding, heme spin state and electron-transfer kinetics.[168–170] The accumulated data show that (a) changes in heme spin state and reduction potential upon substrate binding is not a general property of P450 enzymes, (b) the heme spin state is not always linked to the reduction potential or the catalytic activity, and (c) the first electron transfer is rate-limiting for most (if not all) bacterial enzymes but for many mammalian enzymes the rate-limiting step occurs after electron transfer.

When the first electron transfer is rate limiting, it has been suggested that the thermodynamic argument for gating by substrate binding overlooked the effect of O_2 binding.[171] The reduction potential of the P450 enzymes (equation 7) are measured under anaerobic conditions. Under turnover conditions, O_2 is present and rapidly binds to the heme Fe(II) center (equation 8).

$$P450_{cam}Fe^{III} + Pdx^{Red} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} P450_{cam}Fe^{II} + Pdx^{Ox} \tag{7}$$

$$P450_{cam}Fe^{II} + O_2 \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} P450_{cam}Fe^{II}(O_2) \tag{8}$$

The effect of O_2 binding is to stabilize the Fe^{II} state of the heme, and the reduction potential will increase by approximately 60 mV per decade increase in O_2 concentration for both the substrate-free and substrate-bound forms. At the

ambient concentration of O_2 in the cytoplasm ($\sim$ mM), the reduction potential is likely to be increased sufficiently for the reduction of the substrate-free form of P450 enzymes to become thermodynamically favorable. Since k_2 (equation 8) is large, the turnover rate of the cycle will be determined by k_1. In semiclassical Marcus theory,[172] the rate of electron transfer can be expressed as:

$$k_{\text{et}} \propto (H_{\text{AB}})^2 \exp\left(-\frac{(\lambda + \Delta G^\circ)^2}{4\lambda k_{\text{B}} T}\right) \quad (9)$$

where H_{AB} is the donor–acceptor coupling matrix element, ΔG° is the free-energy change or driving force for the reaction and λ is the reorganization energy, the sum of both inner (changes in metal–ligand bonding) and outer (solvents and other structural changes) sphere components (*see* ***Long-range Electron Transfer in Biology***). For P450 enzymes, the change in heme reduction potentials indicate that the reduction of the substrate-free form of the enzyme is ca. 140 mV less favorable compared to the substrate-bound form if the reorganization energies were the same for both reactions. When the substrate-free form is reduced, the transition from a six- to five-coordinate iron center will introduce a large inner-sphere reorganization barrier (λ_{inn}) to electron transfer because the Fe^{III}–OH_2 bond has to be weakened before electron transfer can occur. When camphor binds to the active site, both the ferric and ferrous forms have five-coordinate heme iron, λ_{inn} is much smaller and electron transfer is greatly accelerated.

The magnitude of λ_{inn} will be as high as 1 eV when a metal–ligand bond has to be broken during electron transfer. In general, the total reorganization energy ($\lambda_{\text{inn}} + \lambda_{\text{out}}$) will be of the order of 0.3–1.3 eV, which is 5 to 10 times the difference in ΔG° between substrate-bound and substrate-free forms of $P450_{\text{cam}}$ and other P450 enzymes. The reorganization energy may dominate over the redox potential in the activation energy for electron transfer in equation (9). In addition to changes in the primary coordination sphere of the heme iron, protein conformation changes, such as altered hydrogen bonding, may also contribute to λ.

The importance of donor–acceptor coupling strength (H_{AB}) is often ignored. Electron transfer is facilitated by coupling or overlap of the donor (reductant) and acceptor (oxidant) wavefunctions. This overlap can occur directly or via specific groups in the intervening medium (*see* ***Long-range Electron Transfer in Biology***).[173–176] In general, donor–acceptor coupling, and hence the electron-transfer rate, decreases with distance or if a good pathway through the medium (peptide) is absent. Delocalized prosthetic groups (such as flavins) with more extended wavefunctions can give faster electron transfer. The electron-transfer distance can also vary between different P450 systems. The potential significance of these factors will become clearer when catalytically competent electron-transfer complexes are characterized in the future.

2.5.5 Uncoupling Reactions

Substrate-specific P450 enzymes oxidize their natural substrate with 100% yield based on NAD(P)H consumed, for example, camphor oxidation by $P450_{\text{cam}}$, fatty acid oxidation by $P450_{\text{BM-3}}$, and in sterol biosynthesis. Each molecule of NAD(P)H leads to the activation of one molecule of O_2 and the formation of one molecule of product. The catalytic reaction follows the cycle from Steps **1**–**9** in Figure 15, with no deviations. These reactions are said to be tightly coupled. However, P450 enzymes do show slightly relaxed substrate specificity, and the oxidation of nonnatural substrates often proceeds with low product yields, sometimes as low as 1%. This is particularly common for P450 enzymes responsible for xenobiotic oxidation. In such reactions the excess reducing equivalents are channeled away from product formation and form hydrogen peroxide and water.

There are three branch points in the P450 catalytic cycle.[65,123] As noted above, oxy-ferrous P450 is unstable to auto-oxidation to form superoxide. During the catalytic cycle, if the second electron transfer is slow or the Fe–O_2 interaction weakened, superoxide dissociation (Step **10**, Figure 15) will compete with substrate oxidation. Superoxide then disproportionates nonenzymatically to O_2 and H_2O_2. In some cases, superoxide can be detected as a direct product during turnover. One mechanism of increased superoxide dissociation is movement of the substrate within the active site, which causes steric interaction with the bound O_2. It is notable that the structure of oxy-$P450_{\text{cam}}$ shows the camphor substrate contacting the heme-bound oxygen atom.[95] Clearly, a substrate not bound as specifically as camphor can sterically hinder O_2 binding, and substrate mobility will result in collisions between substrate and the bound O_2.

Another mechanism of H_2O_2 formation is dissociation of the hydroperoxo ligand (Step **11**, Figure 15) from the ferric-hydroperoxo intermediate **VI**. The Fe^{III}–OOH interaction can be weakened by steric hindrance with a substrate bound too close to the heme iron and during movements of a mobile substrate, or by protonation of the heme-bound oxygen atom.[65,81] The neutral H_2O_2 molecule is a much weaker ligand than the anionic hydroperoxide (HO_2^-). Protonation could occur if the substrate does not exclude all water molecules from the active site, and water molecules get access to the proximal oxygen in **VI**. However, DFT calculations showed that an isolated water molecule is not sufficiently acidic to protonate the hydroperoxo group.[103] It is likely that an acidic protein side chain is also involved (see Section 2.5.2).[177]

The third uncoupling pathway, or branch point, occurs at the Compound I species **VII**. If the substrate is bound too far away from the Compound I oxygen, or if the functional group closest to this oxygen is inert to oxidation, the lifetime of **VII** will be increased and electron-transfer reduction of **VII** to **II** can become the dominant reaction. The overall result is the use of two molecules of NAD(P)H to reduce O_2 to two water molecules. This is the reaction catalyzed by oxidases and this oxidase uncoupling pathway has been

observed with perfluorohexane and microsomal P450,[178] and 5,5-difluorocamphor with $P450_{cam}$.[179] Mutagenesis studies on $P450_{cam}$ also showed that the oxidase pathway dominates uncoupling if a substrate is manipulated to bind far away from the heme.[65]

2.6 Typical and Atypical Activity of P450 Enzymes

The primary (or typical) activity of P450 enzymes is the oxidation of C–H bonds by the $(FeO)^{3+}$ ferryl (Compound I) intermediate. Alkene epoxidation is also a common reaction. However the highly electrophilic nature of the ferryl species opens up other oxidative reactions such as desaturation, dealkylation, ipso attack, C–C bond cleavage, isomerization, and one-electron oxidation.[180] Other intermediate species in the P450 catalytic cycle can also catalyze chemical transformations. Deoxy-ferrous P450 **III** can act as a reducing agent and the distal oxygen atom of the ferric-hydroperoxo intermediate **IV** can act as a nucleophile. A collection of typical and atypical reactions catalyzed by P450 enzymes is shown in Figure 21.

Alkene Oxidation. The insertion of an oxygen atom into the π bond of an alkene to form an epoxide is a technologically important reaction because optically pure epoxides are valuable intermediates in synthesis. Although at first sight the mechanism might be considered a straightforward concerted insertion of the ferryl oxygen, the product profiles suggest otherwise. Alkene oxidation can give rearrangement products such as aldehydes and ketones, and terminal alkenes can give rise to *N*-alkylation of the porphyrin ring, leading to enzyme inactivation. These side reactions are not observed when P450 enzymes are treated with the epoxide products, which suggests a stepwise mechanism via radical or carbonium ion intermediates generated by electron-transfer oxidation or direct electrophilic attack by the ferryl oxygen (Figure 22). Rearrangement of a substrate cation radical leads to the allylic alcohol, and this pathway can be distinguished from direct allylic C–H bond oxidation by the kinetic isotope effect. The carbonium ion intermediate can rearrange to give an aldehyde or ketone, or it can attack the porphyrin ring nitrogen.

Arene Oxidation and the NIH Shift. P450 enzymes catalyze the oxidation of aromatic compounds to give phenols, dihydrodiols, and rearrangement products that can be rationalized with an arene oxide intermediate. A common process in aromatic oxidation is the 'NIH shift'.[181,182] This is a rearrangement reaction in which a ring substituent undergoes a 1,2-migration to the adjacent ring carbon to give an *ortho*-substituted phenol, or is displaced by the incoming hydroxo group (Figure 23). The NIH shift and the formation of dihydrodiol products via hydrolysis by epoxide hydrolase are strong evidence for epoxide intermediates. Earlier work assumed a concerted mechanism of oxygen atom insertion into the arene ring. However, evidence for a concerted mechanism is not unequivocal. Guengerich has

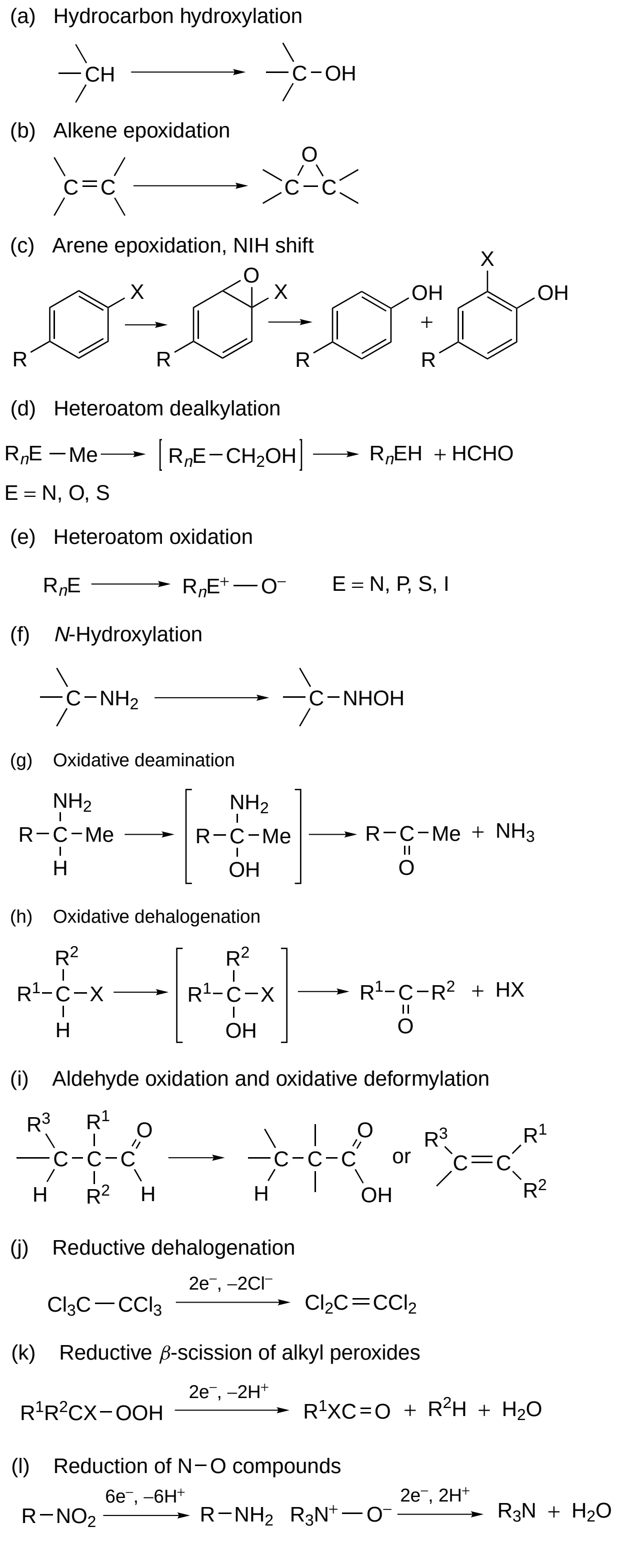

Figure 21 Summary of the diverse reactions catalyzed by P450 enzymes

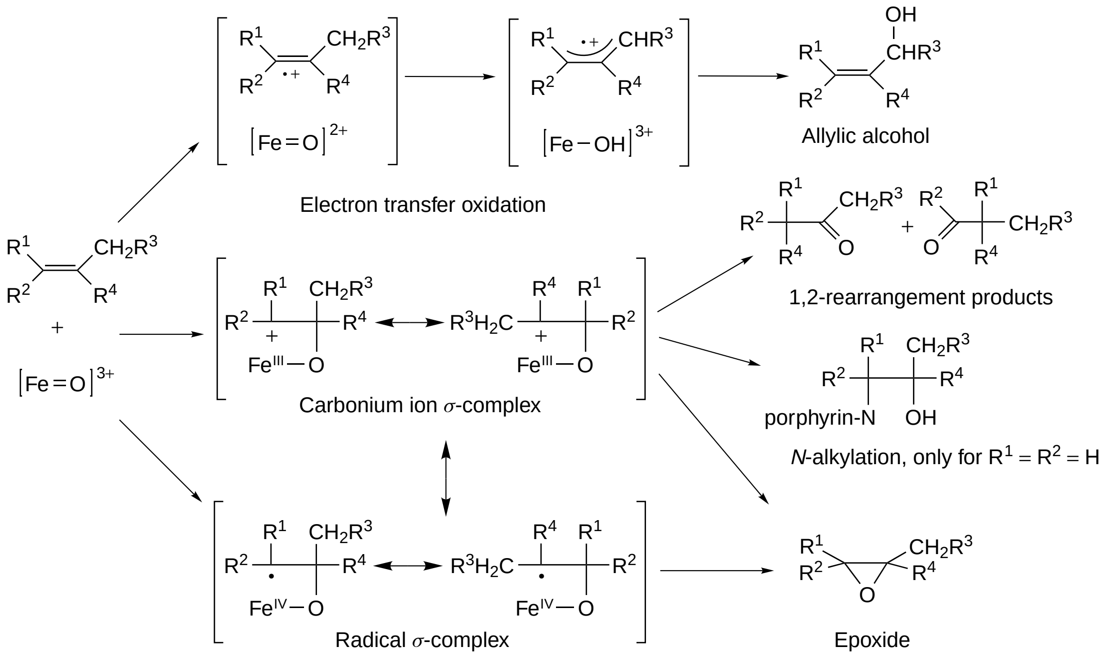

Figure 22 The carbocation and radical mechanisms and potential side reactions of alkene oxidation by P450 enzymes

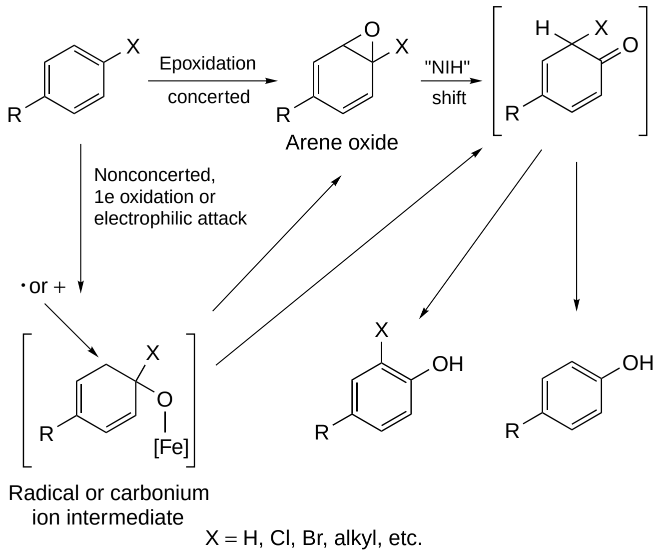

Figure 23 The pathways of arene oxidation and the NIH shift

suggested nonconcerted pathways via radical and carbonium ion σ-complexes, as well as electron-transfer oxidation.[183] The exact mechanism will depend on the substrate and the orientation in which it is bound within the enzyme active site. With the larger polyaromatic compounds, and as the number of electron-releasing substituents increases, the electron-transfer oxidation pathway may become dominant. Indeed, a stable polymethoxybenzene cation radical has been observed in P450-catalyzed oxidation.[184] The concerted pathway may dominate if the substrate is bound close to the ferryl oxygen.

Oxygenation and Dealkylation of Heteroatom-containing Compounds. There are two common reactions for P450-catalyzed oxidation of compounds containing heteroatoms. Firstly compounds with N, P, S and I centers can be oxygenated, for example, amine to the *N*-oxide $R_3N^+–O^-$, but P450 Compound I (**VII**) does not oxygenate F, Cl, and O. Secondly, all compounds with a $–CH_2R$ substituent undergo oxidative dealkylation, releasing the alkyl group as the aldehyde (Figure 21). This dealkylation activity is identical to oxidative deamination and dehalogenation, and follows a common pathway of apparent hydroxylation of the α-carbon to form an unstable intermediate, for example, a halohydrin, thioacetal and carbinolamine, that break down with cleavage of the carbon-heteroatom bond.

Guengerich has proposed a unified mechanism based on radical intermediates for this class of reactions (Figure 24).[183] For the oxygenation reaction, direct transfer of the ferryl oxygen atom to the heteroatom is unlikely in view of the bond strengths and electron density distributions. Instead, the Compound I intermediate oxidizes the heteroatom to a radical cation which attacks the $Fe^{IV}=O$ species to form the heteroatom-oxygen bond (Figure 24a). The dealkylation reaction can be considered formally to proceed via direct C–H bond hydroxylation followed by breakdown of the intermediate. This is likely when the heteroatom is oxygen, fluorine, and chlorine because the ferryl species cannot oxidize these heteroatoms. Thus *O*-dealkylation of 7-ethoxycoumarin

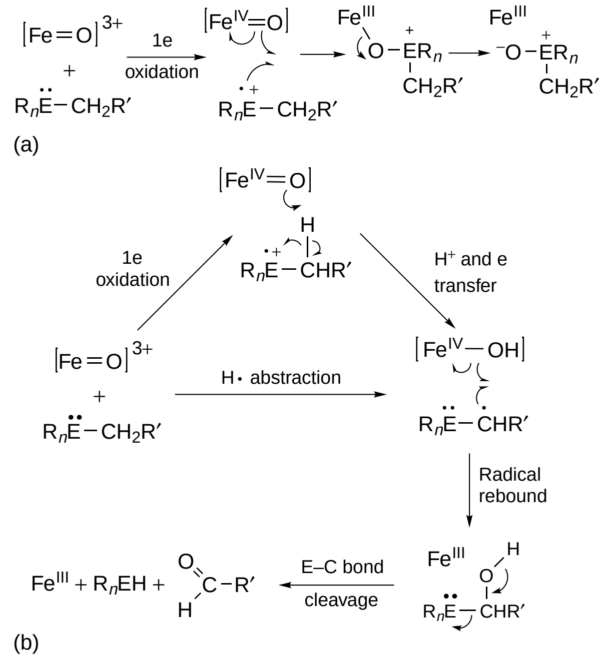

Figure 24 The mechanism of oxidation of heteroatom-containing compounds by P450 enzymes (a) The one-electron oxidation mechanism of heteroatom oxygenation (b) The one-electron and hydrogen atom abstraction mechanisms of heteroatom dealkylation

shows a large kinetic isotope effect ($k_H/k_D \approx 13$), indicative of a hydroxylation mechanism (Figure 24b). With amines, sulfides, and iodides, which have readily oxidized lone pairs of electrons, a stepwise pathway akin to that of heteroatom oxygenation is preferred. One-electron oxidation by the Compound I intermediate gives $Fe^{IV}{=}O$ and a heteroatom cation radical which renders the α-hydrogens more acidic. The $Fe^{IV} = O$ oxygen then abstracts a proton from the α-carbon. As negative charge develops on the α-carbon, an electron is transferred to the cationic heteroatom, resulting in a radical centered on the α-carbon. This intermediate is indistinguishable from that generated via hydrogen atom abstraction by the ferryl intermediate, and similarly undergoes a rebound reaction with the Fe^{IV}–OH species to form the α-hydroxylated intermediate from which the aldehyde is released (Figure 24b). Evidence in support of the stepwise mechanism includes (a) the low kinetic isotope effects ($k_H/k_D = 1.3-3.0$) for the oxidative dealkylation of amines which are similar to isotope effects observed for nonenzymatic electrochemical oxidation,[185] (b) cyclopropylamines give ring-opening products and are mechanism-based inhibitors of P450 enzymes,[186,187] (c) the linear free-energy relationship observed with *para*-substituted *N*,*N*-dimethylanilines,[188,189] (d) preferential demethylation of *N*-methyl,*N*-ethylaniline which showed the importance of the cationic heteroatom radical over the reactivity of the C–H bond,[190] (e) the oxidation of 4-alkyl,1,4-dihydropyridine releases the alkyl group as the radical which attacks the porphyrin.[191,192]

The different mechanisms for oxidizing heteroatom-containing compounds have two main branch points. Firstly, the P450 ferryl intermediate can abstract a hydrogen atom or oxidize the heteroatom. For highly electronegative atoms such as F, O and Cl, the hydroxylation pathway dominates. For more readily oxidized atoms such as N and S, the mechanism shifts to the one-electron pathway. If the amine nitrogen is acetylated, the lone pair is lower in energy and the hydroxylation pathway can compete, and accordingly the kinetic isotope effect is increased.[193] The second branch point is at the $Fe^{IV}{=}O$/cation-radical pair. An E–O bond is formed if no α-hydrogen is present, or if the α-hydrogen is less acidic because the heteroatom cation is not very electron withdrawing. Hence aromatic and other amines without α-hydrogens are *N*-hydroxylated (to N–OH) or oxygenated (to N^+–O^-), while amines with α-hydrogens are dealkylated. On the other hand sulfur-containing compounds are oxygenated even when α-hydrogens are present, for example, dimethylsulfide is oxidized to dimethyl sulfoxide.

Aldehyde Oxidation, Oxidative Deformylation and Other C–C Bond Cleavage Reactions. Aldehyde oxidation was studied intensely because the 'ferryl mechanism' does not account for the last step of steroid demethylation in the biosynthesis of estrogens from androgens, that is, the aromatase reaction (Figure 25a). Akhtar proposed that the distal oxygen of the ferric-hydroperoxo intermediate **VI** is sufficiently nucleophilic to attack the aldehyde group.[194–197] The resulting peroxyhemiacetal intermediate can rearrange by an ionic or radical mechanism (Figure 25b), leading to abstraction of a β-hydrogen to form a C=C double bond and loss of formic acid. Strong evidence for the mechanism comes from the observation that hydrogen peroxide and alkyl hydroperoxides can support the reaction with the ferric resting state of the P450 aromatase but not compounds such as iodosylbenzene that provide a single 'oxygen atom'.[197,198] A related reaction in the steroid biosynthesis pathway is the side chain cleavage of 17-α-hydroxypregnenolone in which an acetyl group is removed and the β-hydrogen is abstracted from an alcohol group, leading to the ketone instead of an alkene (Figure 25c).

The alkyl cleavage reactions proceed via sequential oxidation to the alcohol and then aldehyde or ketone, followed by oxidative C–C bond cleavage. The oxidation of alcohols to aldehydes and ketones can proceed via hydroxylation to the hemiacetal which spontaneously dehydrates to give the product (Figure 26a). A slightly different mechanism of alcohol oxidation has been proposed to operate in the final step of the cholesterol side chain cleavage reaction to form pregnenolone (Figure 26b).[199] The reaction proceeds with two initial C–H bond oxidation steps to form the glycol. In the final step, the ferryl intermediate abstracts a hydrogen atom from one of the alcohol groups. The glycol C–C bond is cleaved homolytically when the alkoxyl radical forms the aldehyde, and the resultant carbon-based radical is oxidized

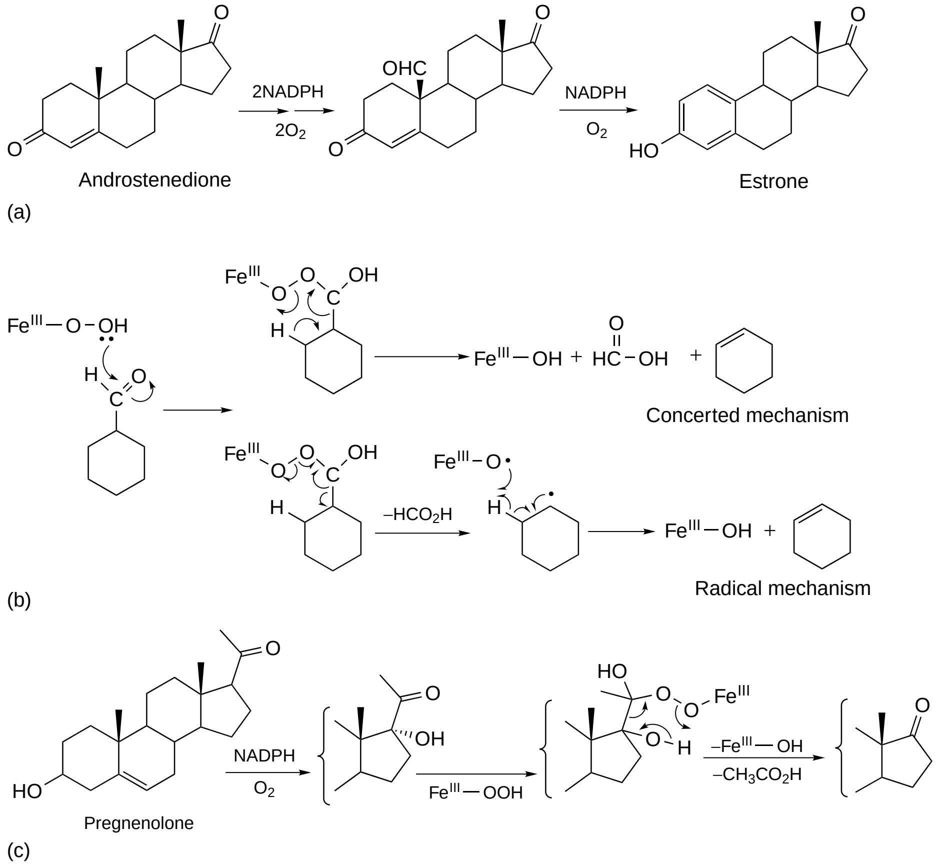

Figure 25 (a) The aromatase activity of P450 enzymes in which androstenedione is converted to estrone via oxidative deformylation (b) The concerted and radical mechanism of deformylation via breakdown of a peroxohemiacetal intermediate formed by nucleophilic attack of the ferric-hydroperoxo intermediate on the aldehyde (c) Abstraction of a β alcohol hydrogen leads to the formation of a ketone rather than a ring C=C double bond

by the Fe^{IV}–OH species to the cation which is deprotonated to form the second aldehyde.

Reductions. P450 enzymes primarily catalyze oxidation reactions using the ferryl and ferric-hydroperoxo intermediates. However, the heme Fe^{III}/Fe^{II} reduction potential is ca. −300 mV in the absence of substrate, and ca. −170 mV if the sixth ligand water is displaced by a bound substrate. If a bound molecule has sufficiently high electron affinity, electron-transfer reduction by the Fe^{II} state can occur. This reaction will be promoted by stabilization of the developing negative charge on the substrate by active-site residues, and retarded by the presence of oxygen which binds rapidly and tightly to the ferrous heme. Nevertheless if the oxygen tension is low or if oxygen binding is weakened, for example, by steric hindrance with a substrate that binds close to the heme iron, substrate reduction can occur even under conditions that are not strictly anaerobic.

Some reduction reactions catalyzed by P450 enzymes are listed in Figure 21. The starting materials are often oxidizing agents and contain electronegative atoms that can accommodate the developing negative charge. The reductive dehalogenation of haloalkanes has been studied extensively because of the potential applications in bioremediation.[200–203] Mammalian P450 enzymes have been reported to catalyze the reductive dehalogenation of polyhalogenated aromatics.[204] The mechanism of hexachloroethane reductive dehalogenation to give tetrachloroethene is shown in Figure 27. Both electron-transfer steps are followed by loss of chloride and the π-bond is formed when the second electron is transferred. The rate-limiting step is the first electron transfer, and the rate increases with the extent of chlorination. Theoretical calculations showed a correlation between the rate of reaction and the electron affinity of the chloroethene.[205]

3 INDOLEAMINE 2,3-DIOXYGENASE

3.1 History, Properties and Physiological Significance

In 1937, Kotake and Ito found that D-Trp-fed rabbits excreted *N*-formyl-D-kynurenine. Later Hayaishi and

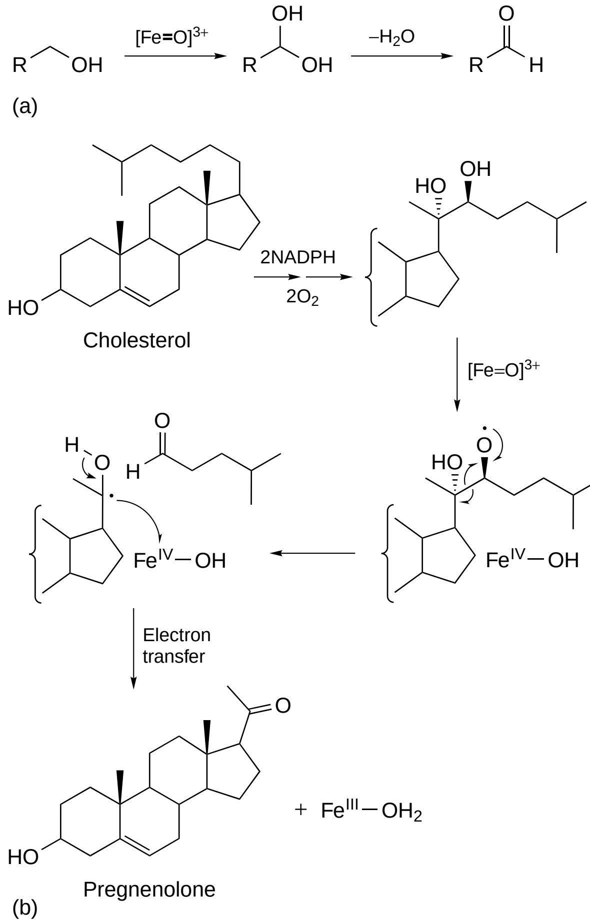

Figure 26 (a) The oxidation of alcohols to aldehydes via an hemiacetal intermediate (b) The sterol side chain cleavage reaction via a diol; note the formation of an O-based radical intermediate

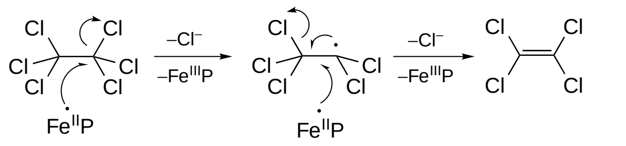

Figure 27 The mechanism of reductive dechlorination of hexachloroethane

coworkers isolated a soluble enzyme from rabbit intestine capable of catalyzing this reaction. The enzyme was found to be a heme-containing protein which could also utilize several other tryptophan derivatives including L-Trp, 5-hydroxy-Trp, tryptamine, and 5-hydroxytryptamine (serotonin).[206,207] It was designated indoleamine 2,3-dioxygenase as only the α-amino group of Trp was found to be essential for Trp derivatives to be substrates of the enzyme.

Indoleamine dioxygenase has been found in many tissues of mammals. It catalyzes the first and rate-limiting step in the main pathway of human tryptophan

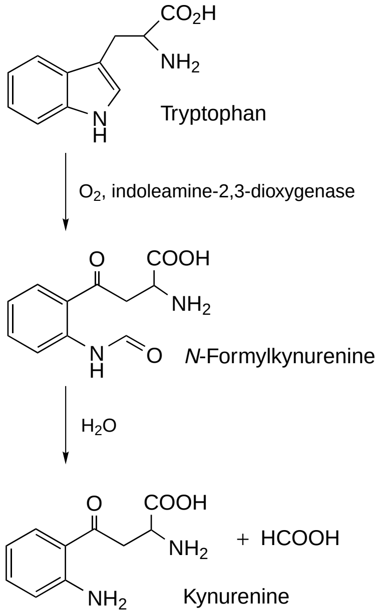

Figure 28 The indoleamine 2,3 dioxygenase pathway of Trp metabolism. Molecular oxygen is incorporated into the pyrrole ring to yield *N*-formylkynurenine which is then degraded to kynurenine and formic acid

catabolism, the kynurenine pathway (Figure 28).[208,209] The induction and metabolism of L-Trp along the kynurenine pathway are implicated in a variety of physiological and pathophysiological processes, including antimicrobial and antitumor defense, immunoregulation, neuropathology, and antioxidant activity.[210] Most of the studies on the purified enzyme have been carried out with rabbit indoleamine 2,3-dioxygenase.[211] The human form of the enzyme has recently been cloned and expressed in *E. coli*.[212] Indoleamine 2,3-dioxygenase catalyzes the same reaction as tryptophan dioxygenase but the two enzymes are distinct in several respects which are summarized in Table 1.

3.2 Heme Environment and the Roles of Superoxide Anion ($O_2^{\bullet -}$) and Cofactors Required for in vitro Activation

Only the primary structure of indoleamine 2,3-dioxygenase has been determined. However, extensive equilibrium and spectroscopy studies have been undertaken to investigate the binding properties of both substrate and oxygen and to identify the proximal and distal heme ligands.

MCD spectra of ferric and ferrous indoleamine 2,3-dioxygenase closely resemble those of myoglobin and horseradish peroxidase. Indoleamine 2,3-dioxygenase can bind a variety of relatively large inhibitors indicating a larger substrate-binding pocket than myoglobin.[213–215] On the basis of EPR studies, the proximal ligand of the heme was proposed to be nitrogen, probably from the imidazole of histidine.[207]

Table 1 Comparison of the properties of indoleamine dioxygenase and tryptophan dioxygenase

Properties	Indoleamine dioxygenase	Tryptophan dioxygenase
Molecular weight	42 000–47 000 Da	122 000–167 000 Da
Subunits	1	4 ($\alpha_2\beta_2$)
Prosthetic Group	One protoheme IX	Two protoheme IX
Oxygen source	O_2 (and $O_2^{\bullet -}$)	O_2
Distribution		
Mammals	Ubiquitous (except liver)	Liver
Bacteria	None	*Pseudomonas acidovorans*
Inducers	Influenza virus Lipopolysaccharide Interferons	Tryptophan Kynurenine Hydrocortisone

The distal ligand has also been proposed to be a histidine imidazole nitrogen based on MCD spectroscopy, as found in hemoglobin and myglobin.[216,217]

Resonance Raman studies on human indoleamine 2,3-dioxygenase indicate that the Fe^{III} state is six-coordinate with a distal water/hydroxide ligand (predominantly high spin at neutral pH) whereas the Fe^{II} state displays a peroxidase-like proximal Fe–His bond which moves the iron out of the porphyrin plane preventing the coordination of a weak distal water.[218] This strengthening of the Fe–His bond has been linked to a hydrogen bond between the NH group of the proximal His and the carboxylate group of a nearby aspartate residue which gives the histidine an imidazolate character.[219] These Raman studies also indicate that the binding of substrate appears to lead to significant changes to the conformation of the heme peripheral groups and the chemical environment of the distal pocket.

Sequence alignments of various forms of indoleamine 2,3-dioxygenase and related myoglobins have revealed several highly conserved residues including three histidines. Mutagenesis studies on these conserved residues have shown that H346 in human indoleamine 2,3-dioxygenase was the only one of the three conserved histidine residues essential for heme binding. This strongly suggests that this residue is the proximal histidine ligand (Figure 29).[220]

Both indoleamine dioxygenase and tryptophan dioxygenase are catalytically active only in their Fe^{II} states. Both are isolated as Fe^{III} enzymes and therefore require reduction for activity. For tryptophan dioxygenase this can be achieved by addition of the substrate, Trp. The Trp-enzyme complex appears to be autoreductive. The catalytically active Fe^{II} form of indoleamine dioxygenase readily autoxidizes in the presence of a substrate. A reducing cofactor is therefore required to initiate and sustain enzyme activity. This is usually achieved in vitro using methylene blue and ascorbic acid.[221] The in vivo cofactor remains unknown, but superoxide is one possible candidate as it can activate rabbit indoleamine dioxygenase and is incorporated into L-Trp.[222,223] The Fe^{III} enzyme readily reacts with $O_2^{\bullet -}$ to yield the enzyme-O_2 complex (Fe^{II}–O_2) which is also generated by addition of O_2 to the Fe^{II} form of the enzyme.

3.3 Catalytic Cycle, Intermediates and Reaction Mechanism

Oxygenases commonly bind substrate before dioxygen. This has been shown to be the case with tryptophan 2,3-dioxygenase.[224] Indoleamine 2,3-dioxygenase can bind oxygen to form a relatively stable, catalytically active complex.[225] Later investigation showed that ferrous indoleamine 2,3-dioxygenase binds L-tryptophan followed by molecular oxygen.[226] The reaction mechanism shown in Figure 30 has been proposed.

It should be noted that no redox changes of the heme iron are involved in indoleamine or tryptophan 2,3-dioxygenase

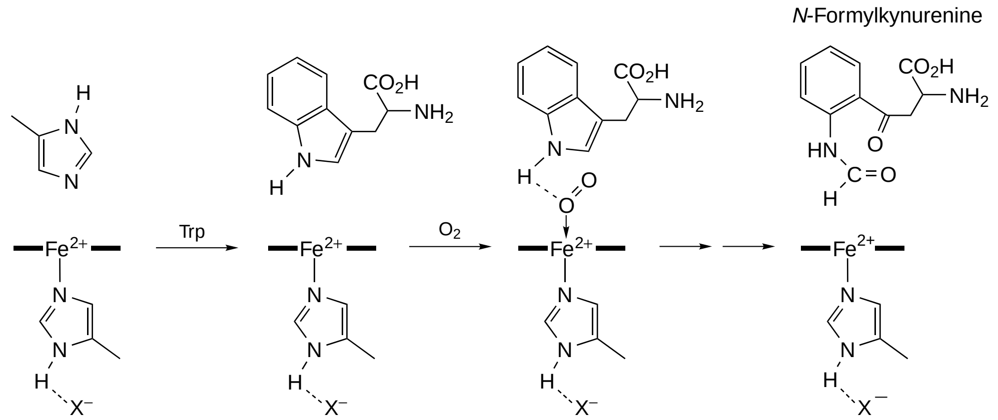

Figure 29 Schematic of the heme environment during the oxidation of Trp by indoleamine dioxygenase. X is probably a carboxylate of aspartate or glutamate

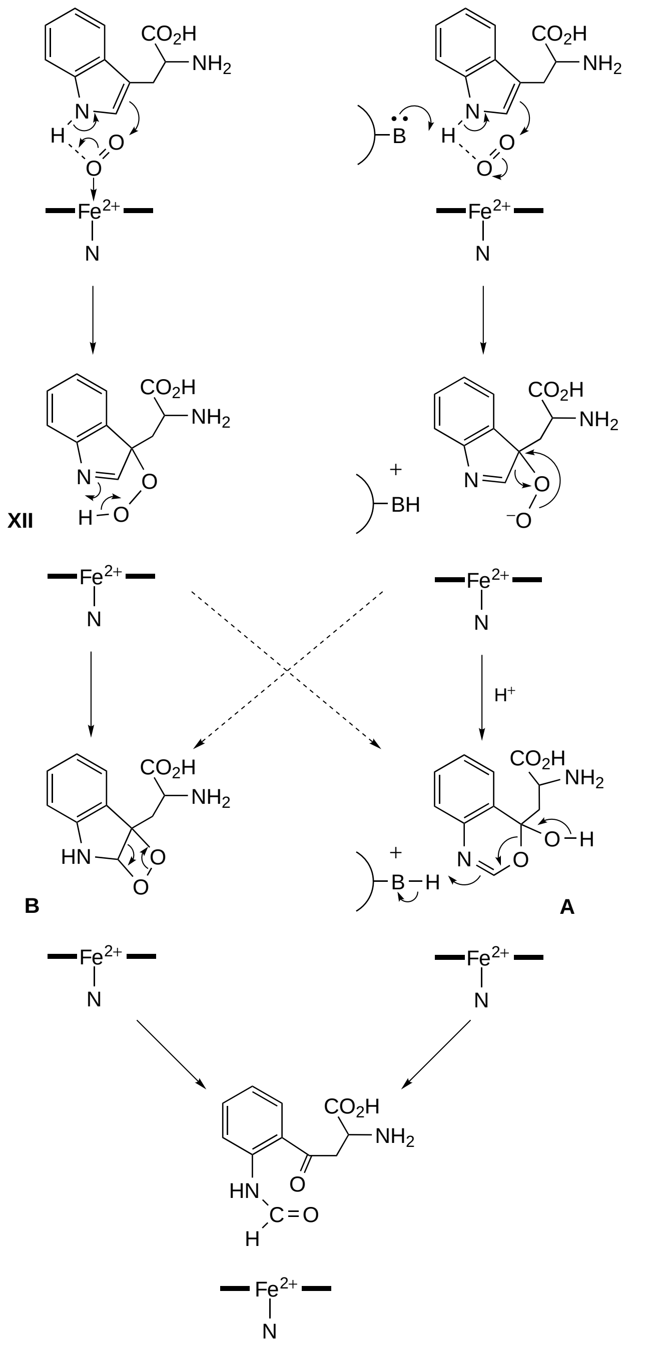

Figure 30 Proposed mechanism for the conversion of Trp to *N*-formylkynurenine catalyzed by indoleamine dioxygenase. Crossover may occur between the two mechanisms as indicated by the dashed lines

activity. Resonance Raman data of the substrate-bound CO complex of human indoleamine 2,3-dioxygenase indicates that strong H-bonding occurs between L-Trp and CO, suggesting a strong interaction between L-Trp and O_2. The electronic effect imposed by this H-bond and the imidazolate character of the strong proximal Fe–His bond is believed to facilitate the electrophilic addition of the dioxygen to the pyrrole ring.[218] This is supported by substrate analogue studies where electron-donating groups at the 5- or 6-position of L-Trp enhance the rate of substrate oxidation but electron-donating groups have the opposite effect.[227] These data suggest an electrophilic reaction involving O_2 attacking the double bond between C-2 and C-3 in indole. The 3-hydroxyperoxyindolenine intermediate (**XII**) has been implicated in chemical studies.[228] An alternative mechanism involves nucleophilic attack of the C-3 of indole on the distal oxygen atom of the bound O_2 coupled with deprotonation.[229] Two pathways to the *N*-formylkynurenine product have been proposed, one involves a Criegee rearrangement-type mechanism (**A**),[229] and the other involves an endoperoxide intermediate (**B**).[230] Further studies are required to establish the exact mechanism of product formation.

Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases

B. Bhaskar, Latesh Lad & Thomas L. Poulos
University of California-Irvine, Irvine, CA, USA

Based in part on the article Iron: Heme Proteins, Peroxidases, & Catalases by Ann M. English which appeared in the Encyclopedia of Inorganic Chemistry, First Edition.

1 Introduction 1
2 Class I Peroxidases 2
3 Class II Peroxidases 7
4 Class III Peroxidase 8
5 Bacterial Di-heme Cytochrome *C* peroxidases (BCcP) 10
6 Prostaglandin Endoperoxide H_2 Synthases-1 and 2 (PGHS) 11
7 Mammalian Peroxidases 13
8 Catalases 16
9 References 17

Glossary

Compound I: two-electron oxidized intermediate of heme peroxidases and catalases
Compound II: one-electron oxidized intermediate of heme peroxidases and catalases

Abbreviations

CcP = Cytochrome *c* Peroxidase; BCCP = Bacterial Cytochrome *c* Peroxidases; APX = Soybean or pea or Tobacco Ascorbate Peroxidase; MNP = Manganese Peroxidase; LIP = Lignin Peroxidase; EPO = Eosinophil Peroxidase; LPO = Lactoperoxidase; MPO = Myeloperoxidase; TPO = Thyroid Peroxidase; ARP = *Arthomyces Ramosus* Peroxidase; SPO = Salivary Peroxidase; PGHsynthase = Prostaglandin Hsynthase; KatG = Catalase-peroxidase; EPR = Electron Paramagnetic Resonance; RR = Resonance Raman; BHA = Benzhydroxamic Acid; FA = Ferulic Acid; DBNBS = 3,5-dibromo-4-nitrosobenzenesulfonic acid; ABTS = 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid); MNPr = Methylnitrosopropane; INH = Isoniazid.

1 INTRODUCTION

The purpose of this article is to review structure–function relationships for heme peroxidases, catalases, and catalase-peroxidases for which detailed crystallographic information is available. Peroxidases catalyze the peroxidation of various substrates and catalases are similar except that a peroxide is both an oxidant and a reductant.

The overall peroxidase cycle is

$$\underset{\text{Resting State}}{Fe^{3+}R + H_2O_2} \longrightarrow \underset{\text{Compound I}}{Fe^{4+} - O\,R^{\bullet} + H_2O} \quad (1)$$

$$\underset{\text{Compound I}}{Fe^{4+} - O\,R^{\bullet} + S} \longrightarrow \underset{\text{Compound II}}{Fe^{4+} - O\,R + S^{\bullet}} \quad (2)$$

$$\underset{\text{Compound II}}{Fe^{4+} - O\,R + S} \longrightarrow \underset{\text{Resting State}}{Fe^{3+}R + H_2O + S^{\bullet}} \quad (3)$$

In the first step (equation 1), peroxide removes two electrons from the protein. One derives from iron and another from an organic group, R, giving the well-known compound I. Compound I thus has two fewer electrons than the native enzyme. In most peroxidases, the oxidized organic group is the porphyrin leading to a porphyrin π-cation radical.[1] However, in cytochrome c peroxidase (CcP), a tryptophan residue rather than the porphyrin is oxidized.[2,3]

Both compounds I and II have distinct spectroscopic signatures and very often are relatively long-lived. This, together with the relative ease of obtaining these enzymes, has enabled peroxidases and catalases to occupy a pivotal position in the history of enzymology. Peroxidases played an important role in the development of modern enzymology as early as the 1930s.[4] The formation of distinct spectroscopic intermediates in the peroxidase reaction cycle helped shape the development of rapid reaction kinetic methods pioneered by Britton Chance in the 1940s.[5] Since then, nearly every conceivable sophisticated biophysical tool has been applied to peroxidases, which has resulted in a vast and diverse range of studies.

The most well-known and thoroughly investigated peroxidases are of nonmammalian origin. Establishment of a detailed sequence database enabled Welinder[6] to divide nonmammalian heme peroxidases into three distinct classes. Class I comprises intracellular and/or peroxidases of prokaryotic origin. These include yeast CcP, chloroplast and cytosolic ascorbate peroxidases (APX), and bacterial catalase-peroxidases (KatGs). Class II peroxidases are the secreted fungal peroxidases. Examples include lignin peroxidase (LIP) and manganese peroxidase (MnP) of *Phanerochaete chrysosporium* and the ink cap mushroom peroxidase, ARP from *Coprinius cinerius* (alternate name *Arthomyces ramosus*). Chloroperoxidase from *Caladariomyces fumago*, while also a secreted fungal peroxidase, does not belong to class II owing to its specialized function and lack of either primary or tertiary structural homology with other fungal peroxidases. Class III peroxidases are the classical

secretory plant peroxidases such as horseradish peroxidase (HRP), the most well-known and thoroughly investigated class III peroxidase.

2 CLASS I PEROXIDASES

2.1 Yeast Cytochrome *c* Peroxidase (CcP)

CcP is the most well-known and thoroughly studied class I peroxidase and has been recently reviewed.[7,8] CcP is a yeast mitochondrial enzyme that catalyzes the following reaction:

$$2\text{cyt. } c(\mathrm{Fe^{3+}}) + \mathrm{H_2O_2} + 2\mathrm{H^+} \longrightarrow \text{cyt. } c(\mathrm{Fe^{3+}}) + 2\mathrm{H_2O} \quad (4)$$

Given the large number of studies centered on CcP, it is surprising that only recently have there been advances in understanding the biological function of CcP. Kwon *et al.*[9] found that yeast CcP levels increase during oxidative stress indicating that the primary function of CcP is to serve as an antioxidant. In addition, yeast CcP may participate in a signaling process during oxidative stress.[10]

2.1.1 Yeast CcP Structure and Mechanism

CcP shares the same overall fold with other class I as well as class II and III peroxidases (Figure 1(a)). CcP contains 10 α-helices with a single β-sheet. The protein is divided into two distinct domains separated by heme *viz.* distal and proximal heme domains. Figure 1(b) shows the active site architecture of CcP with the role of key residues in catalysis, which are typical of most peroxidases. On the distal side of the heme, Arg48, Trp51, and His52 form the catalytic triad and distal heme pocket where exogenous ligands and substrates like hydrogen peroxide bind. On the proximal side of the heme, His175 coordinates the heme iron while Trp191 forms a parallel stacking interaction with His175. Asp235 hydrogen bonds to both His175 and Trp191. The His175-Asp235 H-bond imparts anionic character to the proximal His175, which is important for stabilization of the high oxidation state of iron in compounds I and II.[11,12] As outlined in Figure 1, His52 operates as an acid-base catalyst in promoting heterolytic fission of the peroxide O–O bond while Arg48 helps to stabilize the developing negative charge on the leaving OH group. Mutagenesis studies clearly illustrate the critical role of His52 in CcP[13] and other peroxidases,[14,15] although the effect of changing Arg48 is less dramatic.[16] Similarly mutagenesis of the distal His42 in HRP has demonstrated the critical role of the distal His in peroxidase catalysis.[14,15]

Once compound I is formed, CcP reacts with ferrocytochrome *c* in the following multistep scheme:[17]

1. $\mathrm{Fe^{4+}\ Trp^{\bullet+}} + \text{cyt. } c\ (\mathrm{Fe^{2+}}) \longrightarrow \mathrm{Fe^{4+}Trp^{\bullet+}}/\text{cyt. } c\ (\mathrm{Fe^{2+}})$
2. $\mathrm{Fe^{4+}\ Trp^{\bullet+}}/\text{cyt. } c\ (\mathrm{Fe^{2+}}) \longrightarrow \mathrm{Fe^{4+}Trp}/\text{cyt. } c\ (\mathrm{Fe^{3+}})$
3. $\mathrm{Fe^{4+}\ Trp}/\text{cyt.}c\ (\mathrm{Fe^{3+}}) \longrightarrow \mathrm{Fe^{4+}Trp} + \text{cyt. } c\ (\mathrm{Fe^{3+}})$
4. $\mathrm{Fe^{4+}\ Trp} \longleftrightarrow \mathrm{Fe^{3+}Trp^{\bullet+}}$

In step 1, CcP compound I forms a complex with ferrocytochrome *c* followed by electron transfer (step 2) and dissociation (step 3) of oxidized cytochrome *c*. Step 4 represents the intramolecular electron transfer from Trp191 to the iron giving $\mathrm{Fe^{3+}Trp^{\bullet+}}$, the intermediate required to oxidize the second molecule of ferrocytochrome *c*. In this mechanism, formation of the Trp191 cation radical is essential for both electron transfer steps.

Recent 1.2-Å and 1.3-Å structures of resting state and compound I CcP have provided new insights into the nature and stabilization of compound I.[18] This was possible owing to the unexpected stability of compound I in the X-ray beam. Exposure of metalloprotein crystals to X-rays can often lead to reduction of the metal center,[19] which can be problematic for enzyme intermediates like compounds I and II where the redox potential of the oxyferryl centers are near 1000 mV.[20] Spectroscopic studies of single crystals of resting state and compound I showed that CcP compound I is remarkably stable to X-ray exposure. The oxyferryl center ($\mathrm{Fe^{4+}}$–O) is not affected by X-ray exposure as evidenced by both absorption and single-crystal EPR (electron paramagnetic resonance) spectroscopies.[18] In addition, the single-crystal EPR data indicated that by the end of X-ray diffraction data collection, approximately 50% of the Trp191 π-cationic radical signal remains.

These higher resolution structures have provided insight into small but functionally important conformational differences between resting state CcP and compound I.[18] There are three such regions which occupy two discrete positions in the resting state structure but only one conformation in compound I. The first of these is Arg48 in the distal heme pocket which is considered to be a key residue involved in the formation of compound I.[21,22] In resting state CcP, Arg48 occupies two positions, one '*out*' toward the heme propionate and the other '*in*' toward heme iron. In compound I, Arg48 occupies the '*in*' position which enables Arg48 to hydrogen bond with $\mathrm{Fe^{4+}}$–O oxygen. The '*in*' position is similar to the earlier compound I structures observed at lower resolution[23,24] and in the CcP-fluoride complex.[25] A second region is Met172 in the proximal heme pocket which exists in two conformations in resting state, but becomes more ordered in compound I. In compound I, Met172 occupies a position closer to the His175 ligand (Figure 1). The third region that shows discrete differences between resting state and compound I is the proximal loop region involving residues 190–195 which plays an important role in complex formation with cytochrome *c*. Residues 193–195, including both side chains and the peptide backbone, adopt multiple conformations in the resting state, but become more ordered in compound I. In the single conformation that is observed in compound I, the side chain

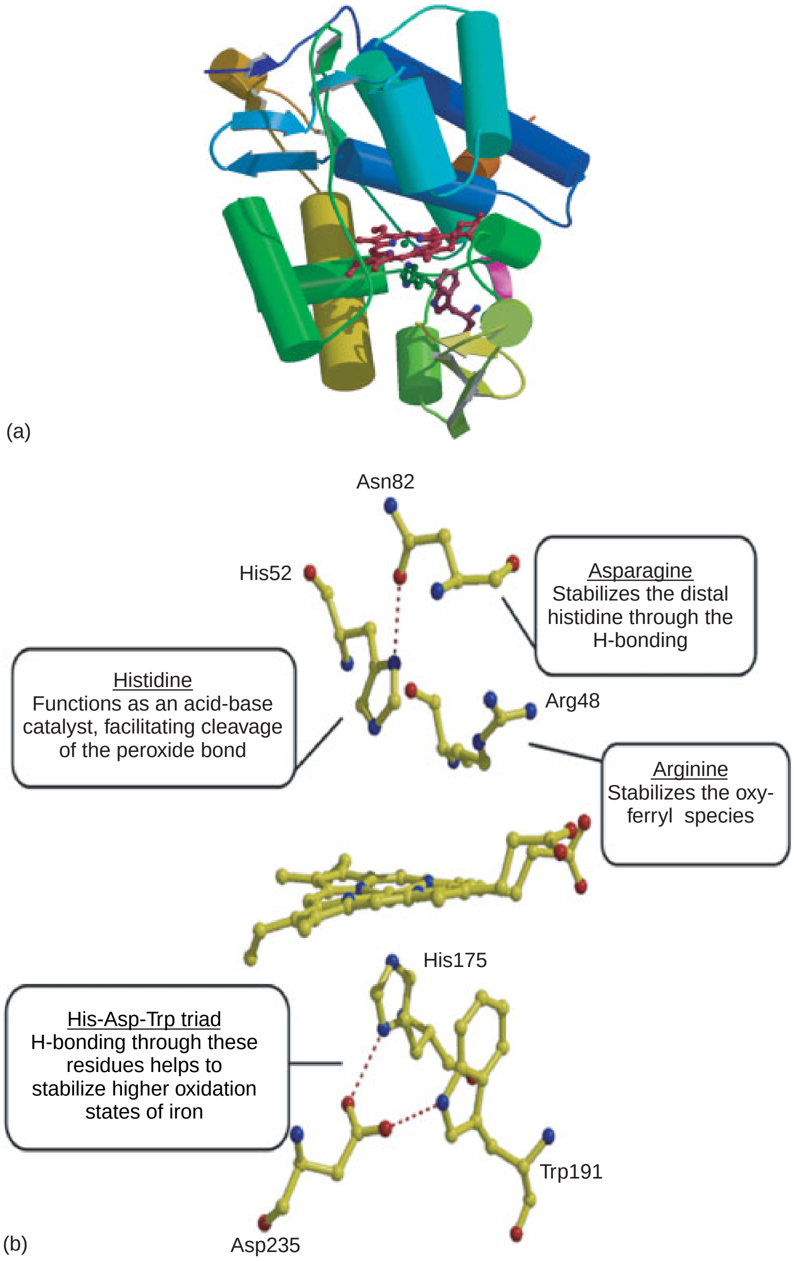

Figure 1 (a) Schematic representation of yeast cytochrome *c* peroxidase (CcP) structure with heme and key active site residues represented as ball-and-stick models. (b) Active site architecture of yeast cytochrome *c* peroxidase (CcP) showing the role of all the key residues in catalysis. The dashed lines represent hydrogen bonds

of Asn195 is in position to donate a hydrogen bond to the peptide carbonyl oxygen of Gly178. Gly178, in turn, is 4.01 Å away from Trp191. Taken together these changes help to stabilize compound I. The movement of Arg48 provides an extra H-bond to the Fe^{4+}–O center while the movement of Met172 and the Asn195 region places polar groups closer to the Trp191 radical which helps to stabilize the Trp191 cationic radical.

Another important insight in the 1.3-Å compound I structure is the nature of the Fe^{4+}–O bond. There were two previous X-ray studies of CcP compound I,[23,24] both of which were of lower resolution. The Laue diffraction methods employed in the 2.2-Å study of compound I by Fulop *et al.*[24] assigned an Fe^{4+}–O distance ranging from 1.7 to 1.9 Å. The structures of catalase compounds I and II determined at lower resolution (2.7 Å) precluded accurate estimation of Fe^{4+}–O bond distances.[26,27] However, results of some recent studies on compound II of horse heart myoglobin and compounds I and II of HRP are comparable to CcP compound I. In the 1.35-Å myoglobin compound II structure, the Fe^{4+}–O was found to be 1.92 Å.[28] The recent X-ray work on HRP compounds

I and II to 1.6 Å resolution gives Fe^{4+}–O distances of 1.7 Å for compound I and 1.8 Å for compound II.[29] The heme of HRP compound II and the heme of CcP compound I are electronically equivalent. Hence, the longer 1.8-Å Fe^{4+}–O distance in HRP compound II is comparable to the 1.87-Å distance found in CcP compound I. These longer Fe^{4+}–O distances are at odds with some of the early EXAFS work on peroxidases. Chance *et al*.[30] estimated a distance of 1.67 Å in CcP compound I while Penner–Hahn *et al*.[31] estimated a distance of 1.6 Å in HRP compounds I and II. However, Chance *et al*.[30] estimated a Fe^{4+}–O distance of 1.93 Å in HRP compound II which is closer to the 1.8 Å found in the HRP crystal structure. Although EXAFS results differ from that of the recent X-ray results, resonance Raman data more closely match the more current results. Reczek *et al*.[32] assigned a stretching frequency for the Fe^{4+}–O stretch in CcP compound I to be 753 cm^{-1}, compared the 773–779 cm^{-1} for HRP[32–35] indicating a weaker Fe^{4+}–O bond in CcP compound I. It was argued that the lower stretching frequency for the Fe^{4+}–O stretch was due to a strong hydrogen bond to the Fe^{4+}–O oxygen and greater single-bond character of the Fe^{4+}–O bond. This is consistent with the high-resolution CcP compound I structure since both Arg48 and Trp51 form hydrogen bonds with ferryl oxygen and the long 1.87 Å Fe^{4+}–O bond indicates a single bond. Overall, the results of the high-resolution structure of CcP coupled with a wealth of spectroscopic data strongly favor a single Fe^{4+}–O bond. A single bond would also inevitably mean that the ferryl oxygen is protonated. In peroxidases, we know that the peroxide O–O bond undergoes heterolytic cleavage[36] which leaves an oxygen atom with six valence electrons bound to the iron. If both electrons now reside primarily on the Fe-linked O atom, this oxygen atom contains a full complement of eight valence electrons, giving an Fe^{4+}–O center which should be a strong base and exist primarily as a Fe^{4+}–OH center if the Fe^{4+}–O bond is a single bond. The –OH group is stabilized by the motion of Arg48 in the high-resolution structure of CcP compound I.[18] Therefore, the ferryl center of CcP may be best described as a hydroxide ion with a single bond to Fe^{4+} stabilized by hydrogen bonding interactions with Arg48 and Trp51.

2.1.2 *Stabilization of the Trp Cation Radical Yeast CcP*

A fascinating aspect of CcP chemistry and biochemistry is the formation and stabilization of the Trp191 cationic radical in compound I while other peroxidases form a porphyrin π-cationic radical. A wealth of biochemical, spectroscopic, and structural results are available on several mutants of CcP which have emphasized the importance of Trp191 to enzyme catalysis.[8] Other class I peroxidases like APX and KatG also have a proximal side Trp analogous to yeast CcP Trp191 but these peroxidase do not form a Trp radical. It now appears that the local environment surrounding Trp191 is designed to electrostatically stabilize the extra positive charge on the Trp191 cationic radical. Indeed, the first clue to this puzzle came from several mutagenesis studies that showed that the Trp191Gly mutation resulted in a cavity that binds cations such as potassium and imidazolium.[37–39] These results and electrostatic calculations suggested that the local environment created a negative potential that can stabilize the Trp radical in CcP[37,40,41] and these results have been further corroborated by computational studies of Poulos and coworkers.[42] Further structural comparisons showed that in APX and plant peroxidases, a cation-binding site [a K^+ site for APX (*see* ***Cation-activated Enzymes***) and a Ca^{2+} for most other peroxidases (*see* ***Calcium-binding Proteins***)] is located ~8 Å away from the Trp/Phe residue, while only a water molecule is present at the same location in CcP.[18,40,43] Therefore, Patterson *et al*.[44] proposed that this cation-binding site may play a role in destabilizing the Trp radical in APX. This hypothesis was tested by engineering a protein whose activity could be modulated by a designed cation site. On the basis of structural homology between APX and CcP, the K^+ binding site of APX was engineered into CcP.[40,45] Crystal structures showed that K^+ binds to the engineered site in CcP exactly as in APX. Moreover, EPR experiments showed that the Trp191 radical becomes increasingly less stable as a function of K^+ concentration while the steady state enzyme activity decreases. These results demonstrated that long-range electrostatic effects can control the reactivity of a redox-active amino acid side chain. Building on this success, further metallo-engineering efforts enabled the selectivity of the engineered site to be switched from K^+ to Ca^{2+}.[46]

2.1.3 *CcP-cytochrome c Complex*

CcP and cytochrome *c* were the first physiological redox partners where the crystal structure of each partner had been determined. As such, the CcP-cytochrome *c* system has served as a paradigm for both protein–protein interactions and interprotein electron transfer studies. The crystal structure of the CcP-cytochrome *c* complex[47] provided a major advance in our understanding of how CcP works. The complex shows that the cytochrome *c* heme is within ≈3.9 Å from Ala194 in CcP. This provides a direct route of electron transfer from the cytochrome *c* heme to the Trp191 cationic radical. There are few strong charge–charge interactions at the interface which was surprising since the complex is strongly dependent on ionic strength.

Various biophysical probes indicate that CcP has two sites of interaction with cytochrome *c* although it is less clear if both sites are involved in electron transfer. To probe this question, CcP and cytochrome *c* have been site-specifically cross-linked using engineered disulfide bonds[48] to generate a covalent complex that mimics the noncovalent complex. CcP in the covalent complex is unable to accept electrons from free ferrocytochrome *c*. A second cross-link was designed to block

the proposed second cytochrome *c* binding site[49,50] but this complex could still accept electrons from ferrocytochrome *c*. Taken together, these results indicate that the covalently attached cytochrome *c* is blocking the one site used by cytochrome *c* for docking and transferring electrons and that this single competent electron transfer site is the same one identified in the crystal structure of the CCP-cytochrome *c* complex.[47]

2.2 Ascorbate Peroxidase (APX)

The primary function of APX is to rid plant cells of toxic peroxides by using ascorbate as the reducing substrate. Pea cytosolic APX is the most thoroughly studied APX and was the first APX crystal structure determined.[43] This now has been followed by the crystal structures of soybean cytosolic[51] and tobacco stromal APX.[52] The overall fold of APX is very similar to CcP except that APX is smaller and contains 250 residues compared to 294 in CcP. The main difference is that APX lacks the β-sheet structure in CcP. APX also exists as a homodimer.

The key elements of the APX active site are the same as in CcP including the homolog to CcP Trp191 (Trp179 in APX) which, in CcP, forms the stable compound I cation radical. However, APX does not form a Trp179 radical but instead forms the more traditional porphyrin π-cation radical.[44] In the absence of reducing substrates, compound I decays to compound I*. Recently Rodriguez–Lopez and coworkers showed by low-temperature EPR and RP-HPLC the existence of a transient Trp cation radical.[53] As noted in Section 2.1.2, this difference has been attributed to the local electrostatic environment of CcP, which is designed to stabilize a Trp191 cation radical.[40,41,43]

Studies on APX provided some of the first evidence that peroxidases can have different substrate binding sites. Early on, it was found that modification of the single Cys in pea APX eliminated enzyme activity but at that time there was insufficient enzyme for more detailed studies. This was followed by work on recombinant APX where both the Cys modified form of APX and the Cys-to-Ser mutant crystal structures led to the hypothesis that the substrate, ascorbate, binds near Cys32 (Figure 2).[54] Moreover, Poulos and coworkers proposed that Arg172 in this region interacts with the ascorbate and helps to hold the substrate in place near the heme propionates.[55] As predicted, mutating Arg172 to other residues blocked the oxidation of ascorbate but not the oxidation of the small phenolic substrate, guaiacol. This led to the view that phenolic substrates interact with APX at a different site near the exposed heme edge. More recently, the crystal structure of the ascorbate-APX complex[51] clearly shows (Figure 2) that the ascorbate is positioned near the propionate edge of the heme where it interacts with Arg172 as predicted by the chemical modification and mutagenesis studies.[55]

2.3 Bacterial Catalase-peroxidases

2.3.1 *Introduction*

Over the last ten years, the catalase-peroxidases have attracted significant interest in the fight against *tuberculosis. Mycobacterium tuberculosis* is a leading pathogen worldwide, infecting an estimated 2–3 million people each year.[56] One of the primary drugs used to treat tuberculosis is isoniazid (INH), a prodrug that is oxidized by the *KatG* (gene encoding catalase-peroxidase) catalase-peroxidase to an activated form that inhibits cell wall synthesis.[57,58] The real surge of interest in catalase-peroxidases started in 1992 when it was confirmed that mutation of *KatG* in *Mycobacterium tuberculosis* confers isoniazid resistance.[59] A putative reaction scheme of catalase-peroxidases is shown in Figure 3(a).

2.3.2 *Structure and Mechanism*

These are difficult enzymes to work with and only recently have crystal structures become available for two catalase-peroxidases: *Haloarcula marismortui* (HMCP)[60] and *Burkholderia pseudomallei* (BpKatG).[61] A typical subunit is approximately 80 kDa in molecular mass, with a single heme *b* prosthetic group. The primary structure of each subunit can be divided into two distinct domains, N terminal and C terminal. The N-terminal domain contains the heme and active site,[62] while the C-terminal domain does not contain a heme binding motif and its function remains unclear. The clear sequence similarity between the two domains suggests gene duplication and fusion.[63] Curiously, despite many years of study, the actual in vivo peroxidatic substrate of the catalase-peroxidases has not been identified.

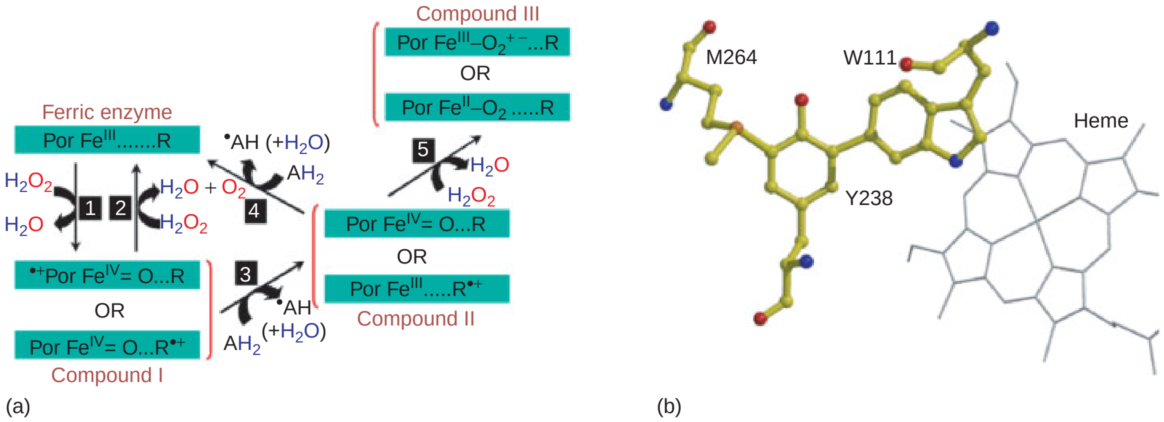

Figure 3 (a) Putative reaction scheme of catalase-peroxidases (KatG). (b) Schematic diagram showing the formation of a novel covalent adduct among side chain of residues Trp111 (Trp95), Tyr238 (Tyr218), and Met264 (Met244) of catalase-peroxidase of *Burkholderia pseudomallei* (BpKatG). The numbers in parenthesis represent the residues of *Haloarcula marismortui* (HMCP) which form a similar adduct. (This figure was generated from coordinates of **1MWV** deposited in the *Protein Data Bank*)

As noted, the N-terminal domain of KatGs exhibits the classic peroxidase fold. Superimposition of the N-terminal segment of either BpKatG or HMCP onto CcP, APX, or HRP give rms deviations of 0.97 Å, 1.22 Å, and 2.03 Å, respectively, for BpKatG and 1.12 Å, 1.31 Å, and 1.99 Å, respectively, for the ten α-helical segments of HMCP. On the other hand, superimposition of the C-terminal region of either BpKatG or HMCP onto the same peroxidase proteins give rms deviations of 3.62 Å, 3.75 Å, and 4.06 Å, respectively, for BpKatG and 3.51 Å, 3.83 Å, and 4.44 Å, respectively, for HMCP.

The organization of the heme active site of both HMCP and BpKatG are almost identical to that of CcP and APX. On the distal side of the heme, Trp, Arg, and His form the peroxide-binding site. On the proximal side, the conserved Asp H-bonds with both the proximal His ligand and proximal side Trp just as in CcP and APX. However, comparison of other residues surrounding the catalase-peroxidase group reveals greater similarity to CcP with decreasing similarity to APX. Most notably, a potassium ion found in APX in a surface loop about 8 Å from the proximal Trp is absent. This same loop forms the Ca^{2+} site in class III peroxidases. However, a Trp radical does not form in BpKatG as in yeast CcP compound I but instead a porphyrin π-cation radical has been demonstrated for both EcKatG (catalase-peroxidase form *Escherichia coli*)[64] and MtKatG (catalase-peroxidase from *M. tuberculosis*).[65]

One of the most surprising results from the crystal structures of the KatGs was the identification of a novel Trp-Tyr-Met covalent cross-link adduct (Trp111-Tyr238-Met264 in BpKatG and Tyr218-Trp95-Met244 in HCMP) in the vicinity of the active site (Figure 3(b)). Although the mechanism leading to the formation of the adduct is unclear, a possible explanation for its formation involves hydrogen peroxide and the heme iron in an oxidative process. What is not clear is whether the adduct provides some functional role. Other unusual adducts have been observed in peroxidases and in monofunctional catalases, including a hydroxy group on the C^{β} of Trp171 in lignin peroxidase,[66] distal Trp51-Tyr52 covalent cross-link in a mutant of CcP,[67] a methionine sulfoxide residue in the catalase from *Proteus mirabilis*,[68] formation of a proximal covalent cross-link between the N^{δ} of His392 and C^{β} of Tyr415 in catalases HPII from *E. coli* concomitant with the cyclization of heme *b* to form oxidized heme *d*[69] in *Penicillium vitale*.[70] One rationale proposed for some of these modifications is that they stabilize the enzyme by reducing the likelihood of other, more damaging oxidations. The Trp-Tyr-Met adduct may impart a similar protective role in that it will prevent further modification of the oxygen-susceptible methionine residue. Another possibility is that the adduct forms a route for electron transfer from the cleft region to the heme.[61] Other metal-based protein modifications are discussed in ***Metal-mediated Protein Modification***.

One of the main goals for the structure determination of the catalase-peroxidases was to determine the INH binding site. The crystal structure of BpKatG revealed a region of undefined electron density in a constricted region in the main channel leading to the distal heme cavity. The location of the density is over 10 Å further away from the heme than is the benzhydroxamic acid bound in HRP.[71] However, the density is in close proximity to Ser324, the equivalent of Ser315 in MtKatG, which is thought to be involved in INH binding. Mutation of this residue to a Thr leads to a loss of INH activation with no loss of either peroxidase or catalase activity.[72] Most of the residues in the pocket surrounding the INH-like electron density are fully conserved between BpKatG and MtKatG, but HMCP and the other catalase-peroxidases of halo-archaebacterial origin have a one residue insertion of Asp269 compared to BpKatG, which is located in a loop adjacent to the pocket. The insertion forces the ring of the adjacent Pro270 into a position that would most interfere with the region of INH-like electron density. This suggests that HMCP should not bind INH in this region, and

thus explains why a similar region of electron density was not observed in the HMCP electron density maps.

3 CLASS II PEROXIDASES

3.1 Lignin Peroxidase (LIP)

Lignin is a major component of woody plant cell walls and lignin biodegradation plays a pivotal role in the earth's carbon cycle. Lignin is not only an abundant renewable carbon source but also protects cellulose against enzymatic degradation. The metalloenzymes, LIP and laccase, secreted by filamentous white-rot fungi from *Basidiomycetes*, are the only known sources capable of degrading the recalcitrant lignin. This rather heterogenous and complex biopolymer consists of phenyl propanoid units linked by various nonhydrolyzable C–C and C–O bonds.[73] The best studied white-rot fungus, *Phaenerochaete chrysosporium*, secretes two heme peroxidases, LIP and a MnP. Both of these peroxidases appear to be major components of the extracellular degradative system of the fungus.[74]

The crystal structures of two fungal LIP isozymes have been characterized[66,75,76] and more recently the recombinant enzyme.[77] Fungal LIPs are globular and mostly helical glycoproteins of about 40 kDa (including carbohydrate), with 343–344 amino acids depending on the isozyme. LIP also contains the two Ca^{2+} sites found in the class III peroxidases (Figure 4). The overall fold of LIP is that of a typical heme peroxidase, as in CcP,[18,22] MnP,[78] HRP,[79] barley grain peroxidase[80] and other nonligninolytic fungal peroxidases like those from ARP[81] and *C. cinerius*.[82] The heme, which divides the protein into a proximal and a distal heme domain, is buried in the interior of the protein with restricted access via a small channel. This channel, which is similar to substrate access channel found in ARP[83] and HRP,[71] has a significantly smaller entrance than other peroxidases. Attempts to determine crystal structures of substrate bound form LIP have been unsuccessful.

LIP undergoes the typical peroxidase reaction cycle and forms compounds I and II. However, LIP compound I is not very stable and readily converts to compound II, even in the absence of reducing substrates. In the crystal-structure determination of LIP, a significant residual electron density was visible close to the surface residue Trp171. It was interpreted as a hydroxy group covalently bound to the C^{β} atom of Trp171. Subsequent chemical and EPR spectroscopic analysis by spin trapping proved that Trp171 had, indeed, been hyroxylated (Figure 4(b)).[84] In view of the above findings, it was proposed that Trp171 acts as an endogenous electron donor of LIP compound I reduction, which implies the formation of a Trp radical may be part of the catalytic cycle. This assumption was tested by treating LIP with the tryptophan-specific agent *N*-bromosuccinimide (NBS), which led to drastically reduced activity with respect to

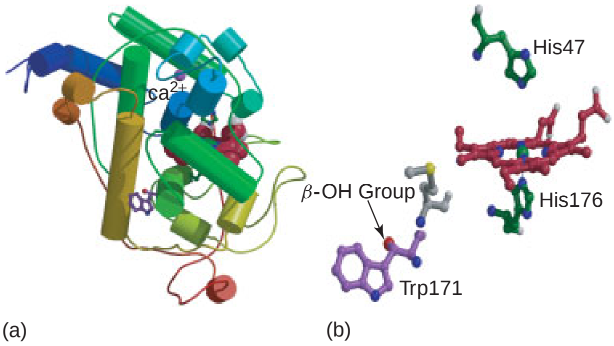

Figure 4 (a) Schematic diagram showing the overall fold of the recombinant pristine lignin peroxidase (LIP) with key residues involved in catalysis. Only one of the $2Ca^{2+}$ ions is shown. The second is hidden in this view. (b) Diagram showing the environment around β-hydroxy-Trp171. (This figure was generated from coordinates of **1LLP** deposited in the *Protein Data Bank*)

veratryl alcohol (VA) oxidation.[85] Site-directed mutagenesis of Trp171 to Phe or Ser showed no residual activity toward VA.[86] These experiments proved the involvement of Trp171 in LIP catalysis. On the basis of this, a catalytic mechanism was proposed for the hydroxylation of Trp171 starting with the formation of Trp cation radical.[85] Evidence for a transient Trp171 radical intermediate was obtained by using elegant spin-trapping experiments with methylnitrosopropane (MNPr) in combination with peptide mapping and crystallography.[84] In the presence of H_2O_2, MNPr forms a covalent adduct with Trp171 which was confirmed by the crystal structure of MNPr-modified LIP.[84]

In order to complement kinetic work, crystal structures of recombinant LIP isozyme H8 expressed in *E. coli* in the pristine state (lacking hydroxylation at Trp171), of the oxidatively processed enzyme (hydroxylated at Trp171), and a Trp171 Phe mutant,[77] were solved. Recombinant enzymes were not glycosylated and had to be refolded *in vitro*.[87] The structure of the pristine state was virtually identical to that of C^{β}-hydroxylated form, except for the absence of the –OH group attached to Trp171. A water molecule was found in both structures in a small cavity near the C^{β} atom of Trp171, ideally positioned to attack the C^{β} atom stereospecifically, leading to an *S*-configured C^{β} atom only.[77] The Trp171Phe mutation exhibited no structural changes of the helix except in the side chain position of residue 171. Complete lack of activity of this mutant has been attributed to the absence of the redox-active indole side chain. Mutation experiments have not only underlined the importance of Trp171 for the catalytic mechanism but also show that there are two distinct substrate interaction sites in LIP.

3.2 Manganese Peroxidase (MnP)

Like LIP, MnP is produced by *P. chrysosporium* and the structure[78] closely resembles LIP. MnP, however, oxidizes Mn(II) to Mn(III). Once formed, Mn(III) is bound to and

stabilized by a dicarboxylic acid and the Mn(III)-acid complex serves as a diffusible redox mediator that can oxidize various substrates including lignin model compounds.[88,89] The binding site for Mn(II) is shown in Figure 5 which was correctly predicted by homology modeling.[90] Note that one Mn(II) ligand is a heme propionate leading to the proposal that the heme propionate mediates electron transfer from Mn(II) to the porphyrin radical of compound I. It is also interesting that the specialized site for Mn(II) binding near one heme propionate is also where ascorbate binds in APX. Thus, both APX and MnP use the same region of the protein, near one heme propionate, for selective binding of the physiologically important substrate.

Using crystallographic methods, this binding site was probed by altering the amount of Mn^{2+} bound to the protein. Crystals grown in the absence of Mn(II), or in the presence of EDTA, exhibited diminished electron density at this site. Crystals grown in excess Mn(II) exhibited increased electron density at the proposed binding site but nowhere else in the protein. This suggested that there is only one major Mn(II) binding site in MnP. Crystal structures of a single mutant (D179N) and a double mutant (E35Q-D179N) at this site were determined.[91] The mutant structures lack a cation at the Mn(II) binding site. The structure of the Mn(II) binding site is altered significantly in both mutants, resulting in increased access to the solvent and substrate. Kinetic analyses of the single mutants, E35Q, E39Q, and D179N, yielded K_m values for the substrate Mn(II) that were ~50-fold greater than the corresponding K_m value for the wild-type enzyme. Similarly, the k_{cat} values for Mn(II) oxidation were ~300-fold lower than that for the wild-type MNP.

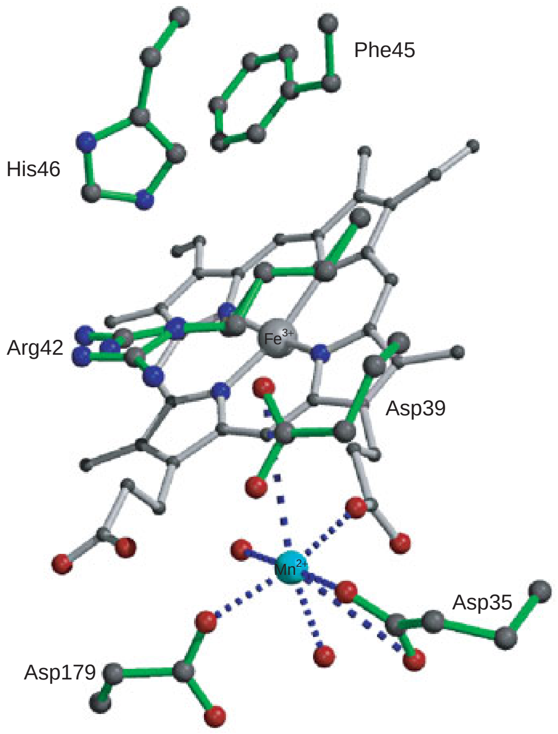

Figure 5 Schematic diagram showing the heme environment and Mn-binding site of manganese peroxidase (MnP)

Despite the presence of this unique Mn(II) binding site, the overall structure of MnP is very similar to all other nonmammalian heme peroxidases. The localized structural alterations near the surface of the protein required to form the Mn(II) site do not induce significant changes in the core peroxidase structure. For example, the structure of *P. chrysosporium* LIP is very similar to that of MnP but lacks the Mn(II) site. LIP has only one of the three acidic residues, Glu39 (Glu40 in LIP). In place of Glu35 and Asp179, LIP has Ala36 and Asn182, respectively.[78] Although it is possible to accommodate an aspartic acid in place of Asn182 in the LIP structure, the space occupied by the side chain of Glu35 in MnP is filled by the backbone structure of the C terminus in LIP. MnP has a longer C terminus, which deviates considerably in its course from that of LIP. In addition, Arg177 pushes the polypeptide chain out and away from the main body of the protein to form the Mn(II) site in MnP. The corresponding residue in LIP is an Ala180. Finally, MnP has an extra disulfide that helps to force the polypeptide chain away from the body of the protein. These differences result in the formation of space for Glu35 near the cation-binding site. These comparisons suggest that constructing a productive Mn(II) binding site in LIP by iterative protein engineering should be possible.

4 CLASS III PEROXIDASE

4.1 Horseradish Peroxidase (HRP) Structure

HRP is prepared from horseradish roots and over 30 isozymes have been identified. Owing to its relative abundance and ease of preparation, HRP is one of the most well-known and thoroughly investigated peroxidases. For reviews see references.[7,92]

HRP consists of a single polypeptide chain of 308 amino acids of M_r 33 890 Da and with one noncovalently bound protoporphyrin IX heme, four disulphide bridges, the two conserved Ca^{2+} binding sites, and contains ~22% carbohydrate. HRP-C can also be overexpressed in *E. coli* from a synthetic gene comprising 309 amino acids including an N-terminal Met required for translation initiation.[93] The production and refolding of unglycosylated recombinant protein paved the way for the long-awaited determination of the crystal structure to 2.15 Å.[79]

HRP exhibits the typical peroxidase fold and active site structure as shown in Figure 6(b). As with CcP, the native resting form of HRP-C contains a five-coordinate, high-spin Fe^{3+} heme. Compound I of HRP contains two oxidizing equivalents, one as oxyferryl (Fe^{4+}–O) and the other as porphyrin radical.[94] A transient Trp π-cation radical has been detected in the Phe221Trp mutant of HRP-C compound

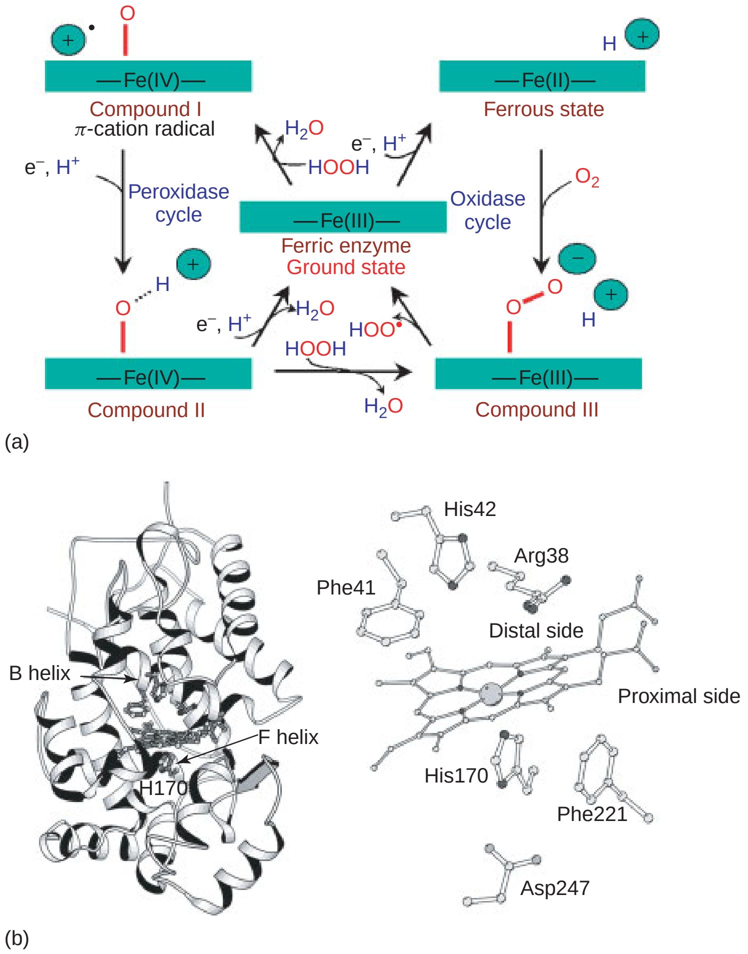

Figure 6 (a) The five redox states of horseradish peroxidase (HRP) as determined from the high-resolution crystal structure of horseradish peroxidase (HRP). (b) Diagram showing the overall fold and active site environment containing key residues in catalysis of horseradish peroxidase (HRP)

I.[95] Recently, Hajdu and coworkers[29] worked out an effective strategy to obtain the 1.57–1.62 Å crystal structures for high-valence redox intermediates and continuous snapshots of the X-ray driven catalytic reduction of a bound dioxygen species. These high-valence intermediates are readily susceptible to reduction by the X-ray beam and as such, the structure of compound I was obtained by merging data from 11 crystals. Despite the problems with deconvoluting a mixture of states, this *tour de force* study has provided the first crystallographic picture of all five HRP redox states as shown in Figure 6(a).

4.2 HRP-substrate Complexes

Crystal structures of HRP-C:substrate/inhibitor complexes have also been solved. Of particular interest is the structure of HRP-C:benzhydroxamic acid (BHA) complex which was solved by Gajhede and coworkers,[71] the HRP-C:ferulic acid (FA) complex,[96] and the HRP-C:FA:cyanide ternary complex.[96] In all three complexes, changes in structure are restricted to the substrate access channel and the heme surroundings. The prevailing view is that enzyme-substrate complexes are relatively nonspecific and weak in peroxidases. One possible reason is that tight binding of an oxidized substrate could lead to enzyme modification. The products of oxidation of substrates are phenoxyl radicals, very similar in structure to their respective substrate molecules, but are chemically reactive species. These products must leave the active site immediately after formation, polymerize or disproportionate. A prolonged retention of the radical in close proximity to the enzyme active site would increase the risk of oxidative damage. Loose association of the reducing substrate with the enzyme, as found in the structure of HRP-C: FA complex,[96] is presumed to be an advantage.

These various structures together with the conserved structures around the δ-edge heme suggests a common pattern of binding between class III peroxidases and aromatic substrates. Such common aromatic contacts have also been observed in the complexes between class II peroxidase ARP and BHA, and salicylhydroxamic acid, respectively.[83,97]

5 BACTERIAL DI-HEME CYTOCHROME *C* PEROXIDASES (BCcP)

5.1 Introduction

Bacterial CcPs have been isolated from a number of organisms: *Pseudomonas aeruginosa*,[98] *Nitrosomonas europea*,[99] *Paracoccus pantotropus*,[100] *Paracoccus denitrificans*,[101] *Rhodobacter capsulatus*,[102] *Methylococcus capsulatus*,[103] *Pseudomonas stutzeri*,[104] and *Pseudomonas nautica*.[105] The most well-studied and characterized BCcPs are those from *P. aeruginosa* and *Par. denitrificans*. BCcPs are homodimers with about 300 residues per monomer. Each monomer contains two hemes which are covalently tethered to the protein via thioether links between the heme vinyl groups and Cys residues, exactly as in many *c*-type cytochrome. One heme is high-potential (+270 mV), while the other is low-potential (between −190 and −310 mV). Greenwood *et al.*[106] proposed the following mechanism:

$$\underset{\text{high}}{Fe^{2+}}\ \underset{\text{low}}{Fe^{3+}} + H_2O_2 \longrightarrow \underset{\text{Compound I}}{\underset{\text{high}}{Fe^{3+}}\ \underset{\text{low}}{Fe^{4+}}} {=} O + H_2O \qquad (5)$$

$$\underset{\text{Compound I}}{\underset{\text{high}}{Fe^{3+}}\ \underset{\text{low}}{Fe^{4+}}} {=} O + e^- + 2H^+ \longrightarrow \underset{\text{Compound II}}{\underset{\text{high}}{Fe^{3+}}\ \underset{\text{low}}{Fe^{3+}}} + H_2O \qquad (6)$$

$$\underset{\text{Compound II}}{\underset{\text{high}}{Fe^{3+}}\ \underset{\text{low}}{Fe^{3+}}} + e^- \longrightarrow \underset{\text{high}}{Fe^{2+}}\ \underset{\text{low}}{Fe^{3+}} \qquad (7)$$

The high-potential heme accepts an electron from the physiological electron donor, which is then transferred to the low-potential heme where peroxide reacts with the heme to give compound I. In this case, the high-potential heme provides one of the two electrons required to activate peroxide rather than a Trp residue as in yeast CcP.

Most BCcPs require Ca^{2+}. Addition of calcium chloride to the reduced enzyme results in a transition of the low-potential heme from low-spin to high-spin, which indicates a significant change in the heme environment of the enzyme.[107] It has been proposed that calcium triggers a conformational change that removes the sixth ligand from the low-potential heme giving a high-spin heme and freeing up one axial coordination position for reaction with peroxide.[105]

5.2 Structure and Mechanism

The three-dimensional structure of the completely oxidized di-heme peroxidase (PAP) from *P. aeruginosa* was determined at 2.4 Å resolution.[108] More recently, the three-dimensional structure of the completely oxidized di-heme peroxidase from *N. europea* (NEP) was determined at 1.8 Å resolution.[109] Preliminary X-ray diffraction analysis of di-heme peroxidases from *R. capsulatus*[110] and *P. nautica*[111] also have been reported. Unfortunately, the di-heme peroxidases have proven extremely difficult to overexpress in homologous/heterologous systems except in the case of the purple phototrophic bacterium *R. capsulatus*.[112]

Figure 7 shows the overall structure of di-heme peroxidases with key residues involved in catalysis from *P. aeruginosa* and *N. europea*. Each monomer folds into two distinct domains with the fold of each domain closely resembling that found in class I *c*-type cytochromes. Each domain houses one heme which have been designated the high- and the low-potential heme. Electrons enter from a redox partner to the high-potential heme followed by intramolecular electron transfer to the low-potential heme. The closest approach of the 2 hemes is ≈10 Å although the heme propionates are directly bridged by the indole ring of Trp82. This interaction is the same as in Trp94 of PAP which is believed to act as an electron transfer conduit between the two hemes.[108] The two domains are related by a quasi two-fold axis, and the domain interface holds a divalent cation, which is now known to be calcium. The likely function of calcium is to maintain structural integrity and/or to modulate electron transfer between two heme domains. In both enzymes, calcium is not coordinated by negatively charged carboxylates but by solvent and peptide carbonyl oxygens. It is also known that calcium plays an important, if as yet ill-defined, role in other peroxidases.

The high-potential heme in both enzymes has Met and His as axial ligands. In the *Pseudomonas* enzyme, the low-potential heme has two His residues as axial heme ligands.[108] Since the site of reaction with hydrogen peroxide is the low-potential heme, one His ligand must dissociate. Relevant to this difference, the high-potential heme in PAP must first be reduced in order to activate the enzyme while NEP is fully active in the oxidized state. This implies that reduction of the high-potential heme in PAP leads to dissociation of the His ligand in the PAP low-potential heme. The low-potential heme of the *Nitrosomonas* enzyme is already in an activated state since the low-potential heme has only one His ligand and hence, has an open axial coordination site available for reaction with peroxide.[109] A comparison between the two enzymes illustrates the range of conformational changes required to activate the *Pseudomonas* enzyme. This change involves the large repositioning of a loop containing the dissociable His heme ligand from the heme pocket to the molecular surface where the His forms part of the dimer interface. In the *Nitrosomonas* enzyme, the His ligand is already dissociated so activation by reduction of the high-potential heme is not required. The mechanism by which a single electron can induce such a large change remains a fascinating yet unsolved problem. Similar redox induced conformational changes and ligand rearrangements have also been observed in cytochrome cd_1 nitrite reductase.[113] This enzyme also has two hemes and upon reduction a Tyr ligand of one heme is displaced, which opens up a distal site for required nitrite reduction chemistry.

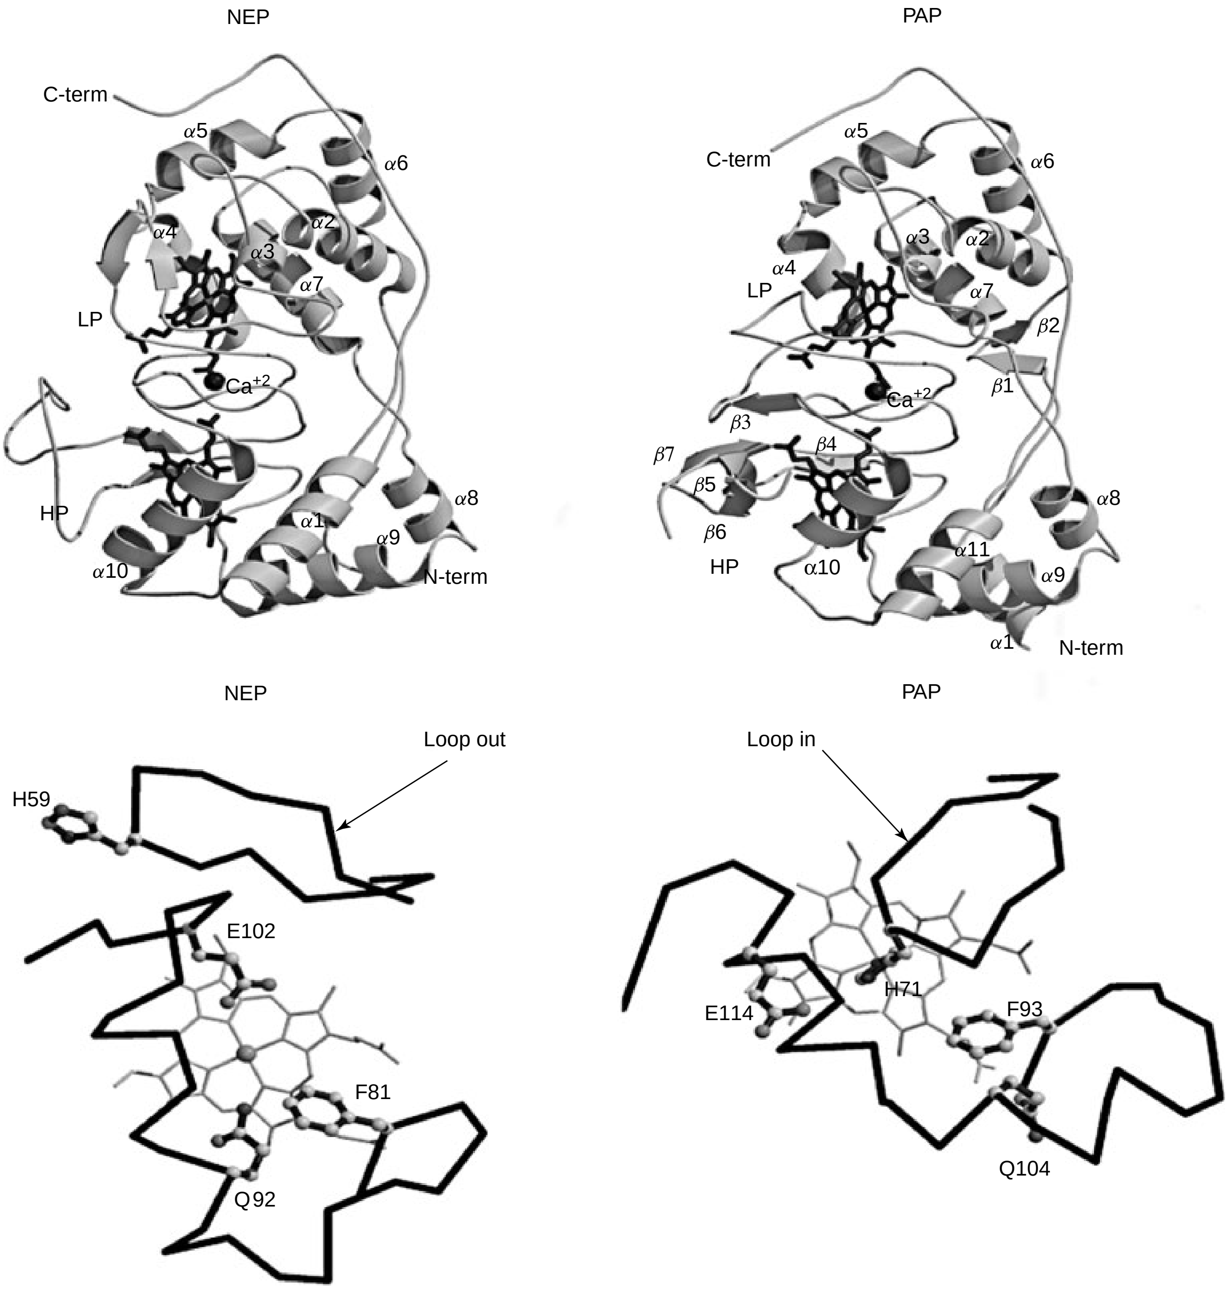

Figure 7 Schematic representation of the of di-heme peroxidases from *Pseudomonas aeruginosa* (PAP) and *Nitrosomonas europea* (NEP) showing key residues involved in catalysis. (This figure was generated from coordinates of **1EB7** and **1IQC** deposited in the *Protein Data Bank*)

Little is known about the peroxide activation process in BCcPs. However, the NEP structure revealed a peroxide-binding site quite different from the more traditional peroxidases. BCcPs do not have a distal His that serves as the catalytic acid-base required for heterolytic cleavage of the peroxide O–O bond. The NEP structure has a Glu residue directly adjacent to the peroxide-binding site that most likely operates as the acid-base catalyst. The only other peroxidase known to have a Glu in this position is chloroperoxidase.[114]

6 PROSTAGLANDIN ENDOPEROXIDE H_2 SYNTHASES-1 AND 2 (PGHS)

6.1 Introduction

Prostaglandin endoperoxide H_2 synthase (PGHS) [EC 1.14.99.1] isoenzymes 1 and 2 catalyze the committed step in prostanoid synthesis[115] via two sequential enzymatic reactions

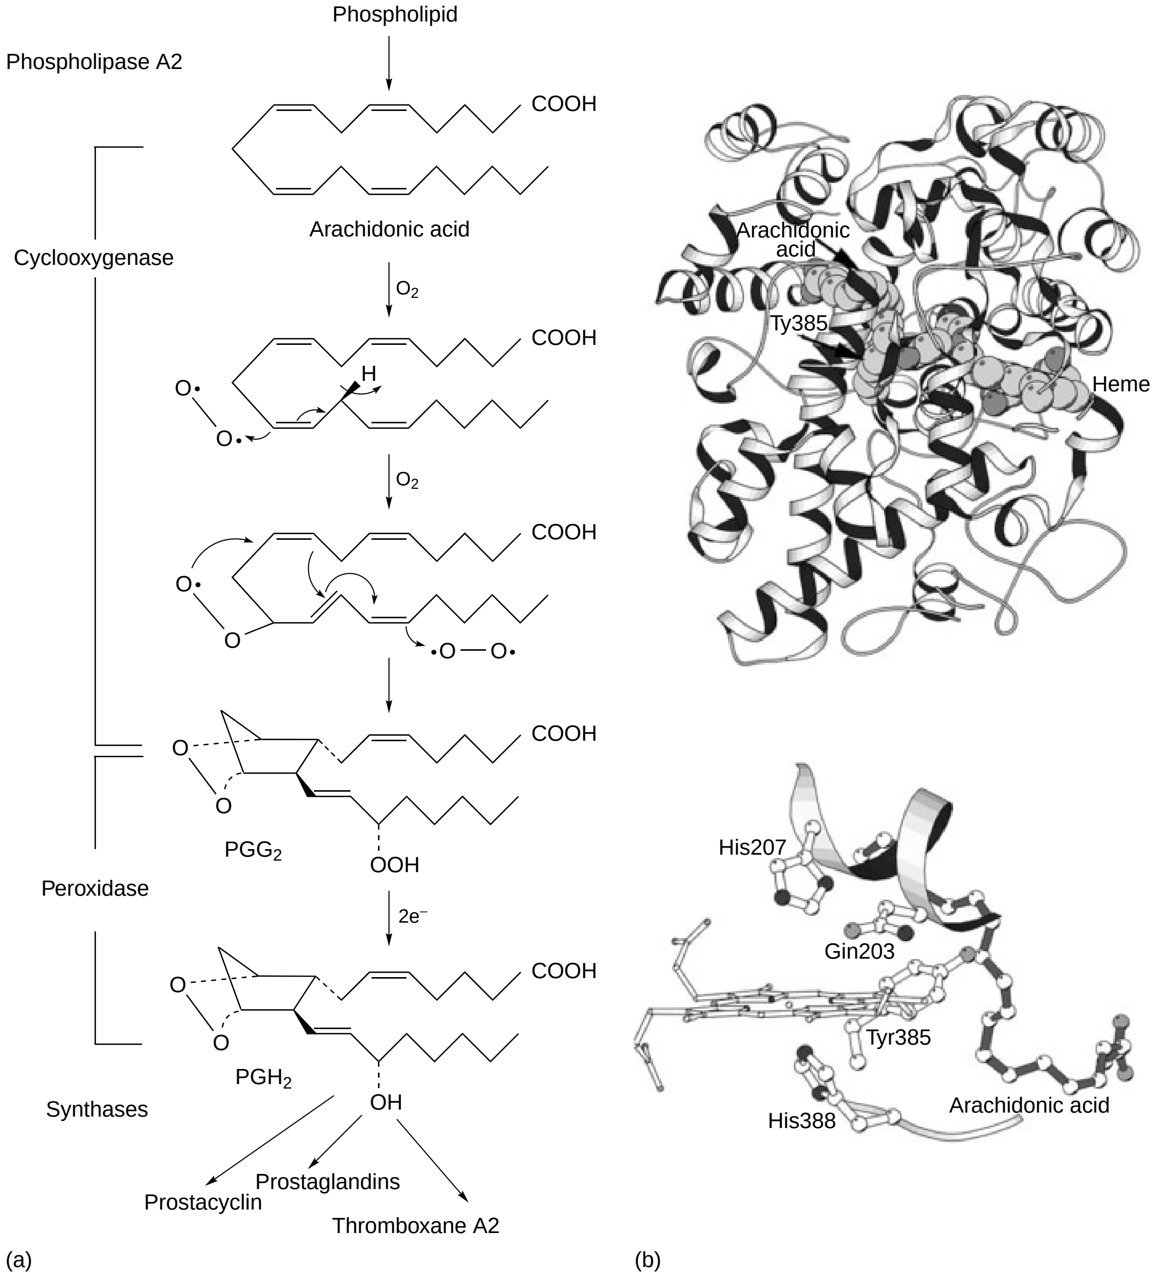

Figure 8 (a) Putative reaction scheme of prostaglandin endoperoxide H_2 synthases (PGHS). (b) Structure of PGHS-1 with key residues in catalysis in complex with substrate arachidonic acid (AA). (This figure was generated from coordinates of **1DIY** deposited in the *Protein Data Bank*)

(Figure 8(a)): (1) the bis-oxygenation of arachidonic acid (the cyclooxygenase activity or COX) forms PGG_2; and (2) reduction of 15-hydroperoxide of PGG_2 in the peroxidase (POX) active site to form PGH_2.

PGHS enzymes are targets of nonsteroidal anti-inflammatory (NSAI) drugs, which include over the counter drugs such as aspirin and ibuprofen (Advil®/Motrin®). Moreover, PGHS isozymes play essential roles in pathologies that include, for PGHS-1, thrombosis and for PGHS-2, inflammation, pain, fever, various cancers, and neurological disorders like Alzheimer's and Parkinson's diseases.[116] PGHS-1 (*cox1* gene) is thought to be a housekeeping enzyme present in all tissues. The isolated protein is usually a homodimer of M_r140 kDa, which includes 3.5% carbohydrate. A second more recently discovered PGHS (PGHS-2, *cox2* gene) is induced in a few specific tissues by mitogens, growth factors, and cytokines.[117] Despite the 60% sequence identity between the 2 PGHSs, specific inhibitors of PGHS-1 are

available and selective inhibitors of PGHS-2 are already on hand.[118,119] Inhibition of PGHS-1 may be associated with gastric and renal toxicity of the NSAI agents and specific inhibitors of PGHS-2 can alleviate unwanted side effects of anti-inflammatory reagents.

6.2 Structure and Mechanism

Garavito and coworkers solved the first structure of a PGHS at 3.4 Å resolution.[120] Crystal structures of other PGHS isoforms are structurally homologous[121,122] as might be expected from high sequence identity. PGHS is a homodimeric membrane protein with one heme per subunit. Each monomer consists of three structural domains: a N-terminal epidermal growth factor (EGF) domain, a membrane-binding domain of about 48 amino acids in length, and a large C-terminal globular catalytic domain with heme binding site facing the solvent and containing both cyclooxygenase and peroxidase active sites. The structure of the C-terminal segments beyond Pro583 (17 amino acids in PGHS-1 and 35 amino acids in PGHS-2) have not been resolved crystallographically. Nonetheless, this region is of great interest as PGHS-1 and PGHS-2 contain C-terminal Lys-Asp-Glu-Leu (KDEL) like sequences that may target PGHSs to the endoplasmic reticulum and the associated nuclear envelope.[115] The structure supports the proposed model from biochemical studies that cyclooxygenase and peroxidase active sites are distinct but share a common heme cofactor. Despite the low sequence homology between PGHSs and other peroxidases,[123] the secondary and tertiary structure of PGHS is similar to the structure of myeloperoxidase[123] and CcP.[22] However, unlike other systems, the heme in PGHS is more exposed to solvent.

The structure of PGHS-1 in a complex with arachidonic acid is shown in Figure 8(b). The peroxidase active site is very similar to other peroxidases. Histidine serves as an axial heme ligand (Figure 8(b)), while in the distal pocket, His207 serves as the acid-base catalytic group required for heterolytic fission of the peroxide O–O bond. However, PGHS-1 has Gln203 in place of the distal Arg found in other peroxidases. This same type of His/Gln distal site pocket is found in another mammalian peroxidase, myeloperoxidase.

The mechanism shown below requires that Tyr385 first be oxidized to a radical. This reaction is achieved via the traditional peroxidase mechanism.

(1) $Fe^{3+}PTyr385 + ROOH \longrightarrow Fe^{4+}-OP^{\bullet}Tyr385 + ROH$
Compound I

(2) $Fe^{4+}-OP^{\bullet}Tyr385 \longrightarrow Fe^{4+}-OPTyr385^{\bullet}$

(3) $Fe^{4+}-OPTyr385^{\bullet} + AA \longrightarrow Fe^{4+}-OPTyr385 + AA^{\bullet}$
Compound II

(4) $Fe^{4+}-OPTyr385 + AA^{\bullet} + 2O_2 \longrightarrow Fe^{4+}-OPTyr385 + O_2AAOO^{\bullet}$

(5) $Fe^{4+}-OPTyr385 + O_2AAOO^{\bullet} \longrightarrow Fe^{4+}-OPTyr385^{\bullet} + O_2AAOOH$

In step 1, the usual compound I is formed via reaction with a hydroperoxide. Tyr385 is less than 5 Å from the heme, so the oxidation of Tyr385 to a radical in step 2 by the porphyrin radical can readily occur. As shown in Figure 8(b), C13 of arachidonic acid (AA) directly contacts Tyr385 thus enabling regio- and stereoselective abstraction of the *pro*-S hydrogen to give the arachidonic acid radical, $AA^{\bullet}$. After the two oxygenation reactions in steps 4 and 5, the AA peroxy radical in step 5 oxidizes Tyr385 to regenerate the Try385 radical. Details of the cyclooxygenase reaction in steps 4 and 5 are outlined in Figure 8(a). The product dissociates and another arachidonic acid can bind to compound I, without regenerating the resting protein. Thus the oxyferryl center appears to be an innocent bystander. Reduction of O_2AAOOH to O_2AAOH proceeds via the traditional peroxidase mechanism to give compound I.

7 MAMMALIAN PEROXIDASES

7.1 Myeloperoxidase (MPO)

MPO (Myeloperoxidase) [EC 1.11.1.7] catalyzes the hydrogen peroxide–dependent two-electron oxidation of halides (Cl^-, I^-, Br^-) and thiocyanate to the corresponding hypohalous acids and hypothiocyanate which are cytotoxic to invading pathogens. In addition, MPO is capable of the single-electron oxidation of a wide variety of aromatic alcohols and amines.[124]

MPO occurs in two types of mammalian phagocytic white blood cells: monocytes and neutrophils. MPO is localized in azurophil granules, which comprise 1–5% of dry weight of neutrophils. Following microbial ingestion, degranulation leads to rapid release of MPO into the phagosome.[125] Microbial ingestion or phagocytosis is accompanied by a ‘respiratory burst’ giving rise to the superoxide anion O_2^- which, in turn, dismutates to molecular oxygen and hydrogen peroxide. MPO is able to oxidize chloride ions to HOCl, an effective agent in killing bacteria, fungi, and viruses.

MPO is a covalently linked dimeric glycoprotein of M_r 140 kDa comprised of 745 amino acids. MPO consists of three different isoenzyme forms termed a, b, and c.[126] The nature of the chemical differences between these isoforms is not fully understood, and only isoform c has been crystallized.[127] Catalytically active recombinant human MPO has been expressed in Chinese hamster ovary cells. However, incomplete posttranslational processing of the recombinant enzyme yields a monomeric form of the enzyme consisting of a single polypeptide chain of M_r 84 kDa with altered carbohydrate content.[128]

The heme in ferric MPO exhibits a relatively strong absorption band near 680 nm, which is responsible for the characteristic green color. The heme Soret band is considerably red-shifted compared to other heme-containing

proteins including its close relatives, EPO (415 nm) and LPO (412 nm).[124] The origin of the red-shift has been attributed to the effects of heme-protein covalent linkages in distorting the planarity of the porphyrin ring and to possible electron-withdrawing effects of the unique sulfonium ion linkage to Met243.[129,130] MPO exhibits a characteristic EPR spectrum of high-spin ferric heme in an environment of rhombic symmetry with $g_x = 6.90$, $g_y = 5.07$.[124] Compound I of MPO exhibits an EPR spectrum characteristic of a hexa-coordinated low-spin heme iron similar to other heme peroxidases.[124] However, complete formation of compound I requires a large excess of peroxide and binding of H_2O_2 to the ferric (Fe^{3+}) enzyme and this appears to be reversible.

7.1.1 *Structure of MPO*

The crystal structure of MPO was first determined in 1987,[131] and more recently, the data have been extended to 1.8 Å (Figure 9)[132] which has enabled the nature of the heme to be unambiguously established. The heme is covalently attached to the protein via two ester linkages between the carboxyl groups of Glu242 and Asp94 and modified methyl groups on pyrrole rings A and C of the heme as well as a sulfonium ion linkage between the sulfur atom of Met243 and the beta-carbon of the vinyl group on pyrrole ring A.

MPO is a covalently linked dimer which is ellipsoidal in shape with overall dimensions of $110 \times 60 \times 50$ Å^3. The dimer can be cleaved by reduction of a disulfide bond into two identical halves. Each half of the dimer termed *hemi-MPO* has the same optical and catalytic properties of the dimer. Hemi-MPO consists of two polypeptides of 466 and 108 amino acid residues, and a heme prosthetic group covalently bound to the large polypeptide. Like CcP and LIP, MPO is largely a helical bundle protein with very little β-sheet structure. The bulk of the large polypeptide folds into five separate domains and one open loop that surround this core. The small polypeptide wraps around the surface of the molecule with its C-terminal helix penetrating the interior core. There are four intrachain disulfide bonds in the large polypeptide and a single disulfide bridge in the small polypeptide. Four potential asparagine-linked glycosylation sites have been identified in the larger subunit. Sugar residues near the Asn317 glycosylation site close to the dimer interface play a role in dimer–dimer interaction, in addition to the lone disulfide bridge.

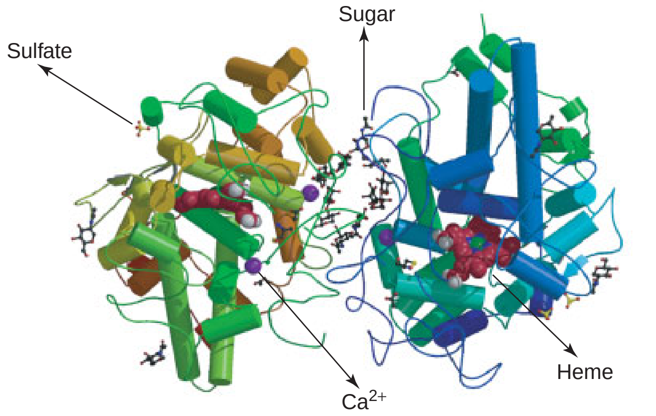

Figure 9 Structure of myeloperoxidase (MPO) along with the heme environment as observed in the high-resolution crystal structure. (This figure was generated from coordinates of **1CXP** deposited in the *Protein Data Bank*)

Crystallography revealed a bound chloride ion at the amino terminus of the helix containing the proximal His336 which can be replaced with bromide.[132] Crystal structures of the human MPO-cyanide, MPO-cyanide-bromide, and MPO-cyanide-thiocyanate have also been determined by Fenna and coworkers to 1.9 Å.[133] These results support a model for a single common binding site for halides and thiocyanate as substrates or as inhibitors near the δ-*meso* carbon of the porphyrin ring in myeloperoxidase.

7.2 Lactoperoxidase (LPO)

The mucosal surfaces of the body provide protection against potential infections. The exocrine glands and their secretions provide both specific immunological and less specific nonimmunological protection to the mucosal surfaces of eye, nose, mouth, trachiobronchial tree, and intestinal tract. The antibacterial system includes lysozyme, lactoferrin, and peroxidase. Peroxidase also provides an antibacterial system in bovine and human milk. LPO (lactoperoxidase) is a heme-containing, calcium-containing glycoprotein of M_r 78 kDa with one heme group per molecule. In bovine milk, LPO is, next to xanthine oxidase (*see* ***Molybdenum: MPT-containing Enzymes***), the most abundant enzyme. Its concentration is around 30 mg/L, constituting 0.5% of whey proteins.[134] Variations in enzyme levels were reported to depend on the sexual cycle of the cow, season, feeding regime, and breed.[135]

The properties and biological function of LPO have recently been reviewed.[7,136] This secretory peroxidase is isolated from cow's milk. Crystalline LPO from bovine milk was obtained in 1943 and shown to be green colored like MPO. Its isolation and purification was simplified by precipitation of casein by rennet. The enzyme with a single polypeptide chain has been known to exist as several isoenzyme forms. The Soret maxima of LPO of 412 nm with molar absorptivity of 112 mM^{-1} cm^{-1} is typical of most peroxidases. It recently has been demonstrated that the heme in LPO is attached to the protein by ester bonds between the heme 1- and 5-methyl groups, and Glu375 and Asp275, respectively.[137]

The heme environment of MPO, both in the proximal and distal heme pockets, is conserved in LPO.[123] As with other peroxidases, LPO reacts with H_2O_2 to give compound I. In the absence of any electron-donor substrate, compound I decomposes to compound I* species which is spectroscopically different from compound I. Compound II is formed spontaneously upon addition of one equivalent of

hydrogen peroxide to native LPO and is stable for 20 min. A threefold excess of peroxide can also be used to obtain pure compound II, and addition of 117-fold excess peroxide to the same solution produces pure compound III.[138]

Recent studies have shown that LPO reacts with H_2O_2 to sequentially give two compound I intermediates: the first with an oxyferryl (Fe^{4+}–O) and a porphyrin radical cation, and the second with the same ferryl species and a presumed protein radical.[139,140] Using spin-trapping experiments followed by EPR spectroscopy, LPO was found to react with the spin-trap 3,5-dibromo-4-nitrosobenzenesulfonic acid (DBNBS) to give a protein-bound radical. Furthermore, LPO was shown to undergo H_2O_2-dependent formation of dimers and trimer. The dimer involves a cross-link between Tyr289 in each of two LPO molecules and retains full catalytic activity.[139]

A recent study by Harvey and Bruck followed the oxidation of mitoxantrone, an anthraquinone type anticancer drug, spectrophotometrically under turnover conditions and single turnover conditions using stopped-flow methods. With compound I and compound II, mitoxantrone formed binding complexes that were deactivated with increasing substrate concentration.[141] Under turnover conditions, compound II was the steady state intermediate, but with increasing H_2O_2, compound II reacted with H_2O_2 to form the catalytically inactive intermediate compound III. Nitrite prevented formation of compound III by reducing compound II to the native state.

The physiological role of LPO is to use H_2O_2 to generate $OSCN^-$ which inhibits microbial growth. H_2O_2 is generated endogenously, for example, by polymorphonuclear leukocytes (PMN), in the process of phagocytosis. In addition, under aerobic conditions many lactobacilli, lactococci, and streptococci produce sufficient H_2O_2 to activate LPO. Figure 10 outlines the proposed LPO reaction mechanism.[134] The first step in the enzymatic mechanism is the initiation reaction of the resting ferric (Fe^{3+}) LPO to its ground state, using H_2O_2, according to $Fe^{3+} + H_2O_2 \rightarrow Fe^{2+} + HO_2^{\bullet}$, followed by propagation reactions, as illustrated in Figure 10. The propagation reactions include conversion of LPO from ground state to compound I by reaction with H_2O_2. At low SCN^- ($<3\,\mu M$) and halide concentrations, compound I reacts with one-electron donors that are present (proteins, peptides) to form compound II that is continuously reduced to ground state at a low rate. At an excess of $[H_2O_2]$ ($>0.5\,mM$), compound II may react to form compound III, leading to a ferrylperoxidase adduct and irreversible inactivation of LPO. The agent that oxidizes SCN^- or halides is compound I. Much of the interest in the LPO system stems from its potential for generating natural biopreservatives in food, feed specialities, cosmetics, and related products. Some of the applications of

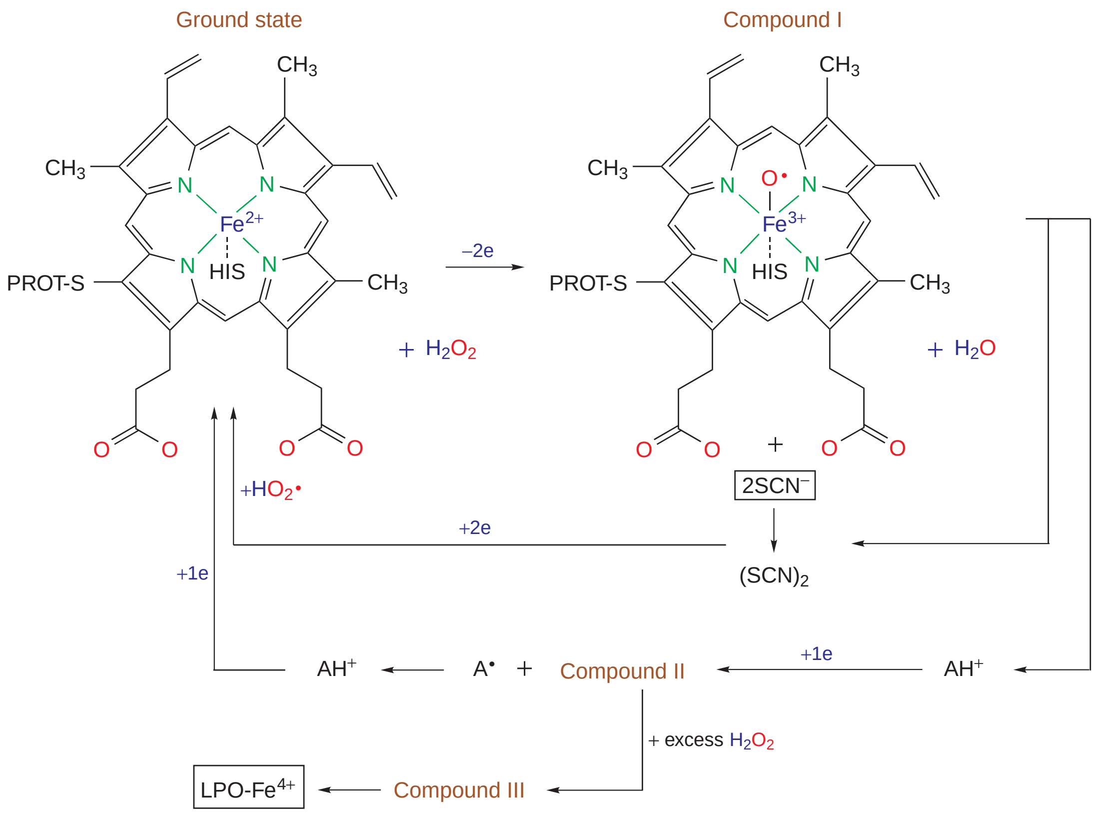

Figure 10 Proposed pathways in the lactoperoxidase-catalyzed reaction mechanism (LPO system)

LPO and their functionality have been reviewed by de Wit and van Hooijdonk.[134]

8 CATALASES

8.1 Introduction

Catalases are ubiquitous metalloenzymes present in almost all aerobic prokaryotic and eukaryotic organisms. Although the full range of biological functions of catalases remains uncertain, the primary role is the removal of hydrogen peroxide from aerobic organisms by catalyzing its dismutation to water and oxygen (equation 8)

$$2H_2O_2 \longrightarrow 2H_2O + O_2 \qquad (8)$$

This type of antioxidant function is essential for all organisms that are exposed to dioxygen, which readily forms H_2O_2 both enzymatically, through the action of oxidases, and nonenzymatically, as a side product of respiration or auto-oxidation of cell components. Hydrogen peroxide exerts its toxic effects in a variety of ways, including transition metal activation of peroxides via Fenton chemistry that generates highly reactive superoxide or hydroxy radicals that can lead to DNA, protein, and lipid damage. Catalase deficient (acatalasemic) cells lead to an accumulation of oxidative agents resulting in increased susceptibility to thermal injury[142] or HIV proliferation,[143] high rates of DNA mutations,[144] and inflammation.[145] Besides this primary protective role, the catalase system is also believed to have physiological significance in various biological oxidations, such as the metabolization of methanol and ethanol.[146,147]

8.2 Functional Classes

Four groups of catalases have been identified. The first, most fully characterized group contains the monofunctional '*classic*' heme-containing catalases, which are homotetramers with one heme per subunit and are present in both prokaryotes and eukaryotes.[69,148] The subunit sizes within this group vary, consisting of approximately 500 residues (small-subunit catalases) or 700 residues (large-subunit catalases). The second group is composed of the nonheme manganese-containing catalases, homohexameric enzymes with two manganese ions in the active site, that have so far only been reported in prokaryotes.[149–151] The third group, heme-containing catalase-peroxidases, were described in Section 2. The final group is composed of miscellaneous heme-containing enzymes with secondary reactions in the form of low levels of catalase activity. Heme-containing enzymes that fall in this group include methemoglobin, metmyoglobin and chloroperoxidase from *Caldariomyces fumago*.

8.3 'Classic' Monofunctional Heme-containing Catalases

Catalases of *Penicillium vitale* (PVC)[152] and beef liver catalase (BLC)[153,154] were the first catalases crystallographically characterized. At present, the crystal structures of seven catalases from this group are known: beef liver,[155] *Penicillium vitale*,[70,156] *Micrococcus lysodeikticus* (MLC),[157] *E. coli* hydroperoxidase (HPII),[158] *Proteus mirabilus* (PMC_PR),[159] *Saccharomyces cerevisiae* (SCC-A),[160] and human erythrocyte (HEC).[161] There is considerable structural similarity among the catalases in this subgroup. The conformation displayed by the homologous molecular regions appears to be exclusive of '*classic*' monofunctional heme catalases, and hence is now typically referred to as the '*catalase fold*'. A typical catalase fold consists of four consecutive regions along the polypeptide chain (Figure 11(a)), which entail an amino

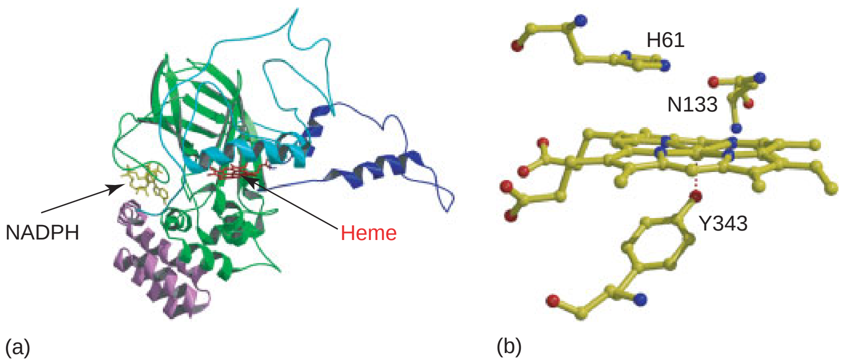

Figure 11 (a) Ribbon drawing of the beef liver catalase structure (PDB code **7CAT**) showing the location of the heme (red) and NADPH (yellow). The four regions of a typical catalase fold are represented with different colors: amino acid terminal arm (purple); anti-parallel eight-stranded β-barrel domain (green); wrapping domain (blue), and α-helical domain (cyan). (b) Diagram showing the heme environment in a monofunctional heme-containing MLC catalase. (This figure was generated from coordinates of **1GWE** deposited in the *Protein Data Bank*)

acid terminal arm, an anti-parallel 8-stranded β-barrel domain, an extended structural part which is referred to as the '*wrapping*' domain, and finally an α-helical domain. Of the various regions in monofunctional heme catalases, the anti-parallel domain appears to be the central feature of a typical catalase fold since the first half of the β-barrel domain contains most of the residues that define the heme distal side, whereas the second half of the β-barrel contributes to the NADPH binding pocket in those catalases that bind this cofactor.[162]

Each subunit of a heme catalase binds a single molecule of heme and some mammalian catalases also possess a second cofactor, NADPH. The binding of NADPH in catalases was at first totally unexpected,[162,163] but has since been a frequent feature of small-subunit catalases from both prokaryotic and eukaryotic organisms. However, the actual biochemical function of NADPH in these catalases is still not fully understood. One possible role is protection of the enzyme against inactivation by its own substrate, especially under conditions of low-peroxide concentrations.[164] The NADPH binding pocket is located on the molecular surface, just above an entrance channel with the nicotinamide active carbon situated approximately 20 Å from the closest heme atom (Figure 11(a)).[162]

The heme group characterized in the active site of various catalases varies from either being a heme *d* (a *cis*-hydroxy γ-spirolactone) as observed in the active site of HPII and PVC[70,165] or the conventional heme *b* as seen in all other catalase structures. Catalase HPII and presumably PVC, initially bind heme *b* and then catalyze its conversion to heme *d* utilizing H_2O_2.[166] This heme conversion is concomitant with formation of a unique covalent bond between C^β of the essential Tyr415 and the N^δ of His392, and a mechanism relating to its formation to heme modification has been proposed.[69] Although different heme variant groups exist among the catalases, the location and environment of the heme group is very similar among the catalase structures. In general, the heme groups are deeply buried in the catalase tetramer with iron atoms situated approximately 20 Å from the nearest molecular surface. The deep burial of the heme groups results in catalases requiring channels for efficient communication between the active center and the surface molecule. The most significant and best-conserved channel reaches the distal side of the heme pocket, whereas a second, less conserved channel is observed at a location that corresponds to the NADPH binding pocket in catalases that bind the dinucleotide. These channels narrow as the heme is approached and the narrow entrance of these channels is strongly believed to be a 'discrimination gate' between substrates of various sizes and thus accounts for the reduced activity of certain catalases toward larger substrates such as aliphatic alcohols.[167] This is in good agreement with the evidence that MLC, which has one of the narrowest entrances, is slower at catalyzing larger substrates and faster for small substrates relative to other catalases.[168]

The heme pocket in these catalases differs considerably from that of a typical heme peroxidase (Figure 11(b)). The most obvious difference between the two sets of enzymes is the coordination of the proximal iron ligand. In peroxidases, the proximal ligand is a histidine, while in the classic monofunctional heme catalases, the imidazole nitrogen is replaced by an oxygen of the phenolic hydroxy group of a tyrosine. This oxygen, which also hydrogen bonds with a conserved arginine, is most likely deprotonated possessing a localized negative charge that can contribute to the stabilization of the Fe^{4+} oxidation state required in the catalytic cycle.[162] On the distal side of the heme, a His and Asn residue form the peroxide pocket and are considered essential for catalysis. The His is generally considered to operate as an acid-base catalytic group as in peroxidases,[7,21] while the Asn serves the function of the distal side Arg in peroxidases.

8.4 Catalytic Mechanisms

The catalytic mechanism for the formation of compound I in the catalase-peroxidases is believed to occur in a manner very similar to that of the heme peroxidases.[60,61] The main difference in the enzymatic mechanism between catalases and peroxidases is compound I reduction. In the catalase cycle, a second peroxide molecule is also used as a reducing agent for compound I rather than a small organic molecule as in most other peroxidases. Crystal structures of the various catalytic intermediate states (compound I and compound II) have been determined for classic monofunctional heme-containing catalases.[27,160,169] Only minor local rearrangements are observed relative to the native enzyme.[27] In both compounds I and II, the iron appears slightly displaced above the heme ring toward the bound oxygen. In compound I, but not in compound II, the presence of extra electron density, assigned as weakly bound anion, is situated on the heme proximal side ∼18 Å from the iron. Interestingly, in the higher resolution compound I structure of PVC at 1.8 Å, no extra density was observed, similar to that reported in PMC_PR.[159] In both the PMC_PR and the PVC compound I structures, the coordinated oxygen is situated between 1.7 and 1.8 Å above the iron atom which is similar to that found in the HRP compound I structure (1.7 Å).[29] In both the PMC_PR and the PVC compound I structures, this coordinated solvent molecule is hydrogen bonded to the N^ε and N^δ atoms of the essential His and Asn residues.

1 INTRODUCTION

Iron (Anglo-Saxon, isarn; Latin, ferrum), the twenty-sixth element in the periodic table, is the most indispensable of all the metals. ^{56}Fe is the most stable isotope with the highest nuclear binding energy per nucleon. The Earth's dense molten core (diameter ca. 4300 miles) is thought to be largely metallic iron. In the biosphere, it is the most abundant transition element, and the fourth most abundant element (6.2%). Only oxygen (45.5%), silicon (27.2%), and aluminum (8.3%) are more common.[1] Iron became incorporated into biological systems, and is essential in all higher life forms.[2] The human body contains between 4 and 5 g of iron. Iron chemicals have many essential industrial applications, and the metal is of fundamental importance to modern human activities as fabrication and construction material. The period when man began using the metal is known as the Iron Age, but pure iron is too soft for use in implements, and it took a long time to control the carbon content to harden it to an appropriate degree. Some five hundred years ago, considerable quantities of iron were manufactured via reduction with charcoal and the amount increased dramatically through the Industrial Revolution until today large quantities of ores are extracted each year and reduced to iron.

As life evolved on Earth, photosynthetic processes released oxygen into the atmosphere and made it increasingly oxidizing. Iron(II) salts in aqueous solution are readily oxidized by oxygen, and increased oxygen levels led to the formation of insoluble iron(III) hydroxide species in lakes and oceans that became vast oxide ore deposits. The principles underlying the chemistry of iron in natural waters have been presented in Stumm and Morgan's long-established text[3] and in Pankow's more recent book.[4] Chester gives a more geologically oriented treatment.[5] Books on environmental chemistry discuss complexes of iron in general,[6,7] their presence in groundwater in particular,[8] and their kinetic aspects in detail.[9] Today, iron is not a significant contaminant in the sea but it has come to prominence as a result of dumping 'red mud' from the extraction of aluminium from bauxite – this waste material contains between 5 and 40% iron[10] – and acidic iron(II) sulfate from the traditional production of titanium dioxide. In Western Europe, several million tons of acidic iron(II) sulfate solution were discharged each year into the sea directly or via rivers. As Fe(II) becomes oxidized, it is precipitated as complex hydroxo-iron(III) species that drift as a suspension before settling on solid objects. Contamination of shellfish and the gills of fish have been reported, but there does not appear to have been major ecological damage. Nevertheless, the disposal of iron(II) sulfate waste in this way has been markedly reduced. However, it has been suggested[11] $FeSO_4$ be dosed into the ocean at very low concentrations to stimulate plankton growth and encourage them to absorb CO_2, convert it to $CaCO_3$, and hence deposit an excess of greenhouse gases on the ocean floor. Early experiments to test this failed because the high affinity of Fe^{3+} for hydroxide and oxide ligands led to deposition of the added iron on the ocean floor before it could have a significant effect. Alterobactin A, a hydroxycarboxylate-catechol siderophore from an oceanic bacterium, has an extremely high affinity for iron(III) (see Table 9),[12] and its photolysis in the surface ocean produces iron(II), increasing iron availability for plankton.[13] There is a copious literature on iron biominerals in the environment,[14,15] and on the oxidation of iron(II) species[16] and the precipitation of iron(III) in environmental systems.[17] The effects of biological ligands on the precipitation of oxides and hydroxides of iron in marine environments have been considered.[18] A review of model compounds for iron–oxygen aggregation and biomineralization links fairly simple complexes to metalloproteins such as ferritin and hemerythrin; carboxylate bridges support simple oxo bridges throughout the range.[19] Iron(II) salts are generally believed to be toxic to plant life, for example, in the use of iron(II) sulfate as a moss killer, but conversely iron complexes are used to provide essential iron for pin oak and citrus fruit trees in high pH soils and to make hydrangeas blue. Iron toxicity in asbestos chemistry and carcinogenicity has been reviewed.[20]

Included in this article is some information on the distribution of iron and the chemical processes involved in converting its ores into metal, but we are mainly

concerned with the chemistry of iron salts and iron coordination complexes. Metallurgical aspects are not considered. Discussion about biologically important systems such as iron porphyrins, iron-containing proteins, iron–sulfur clusters and their model compounds, as well as the chemistry of biological iron storage and transport mechanisms are not discussed in detail, but can be found elsewhere in this Encyclopedia.

2 THE ELEMENT

This section deals with the production of metallic iron, outlines some of its physical properties, and chemical reactivity. Chemically relevant nuclear properties are also discussed.

2.1 Production

Primary reduction of iron oxide ores takes place industrially in a blast furnace (in which many impurities are removed by volatilization) or a direct reduction unit (with synthesis gas – a mixture of H_2, CO, and CO_2) to provide pig iron or iron sponge. Subsequently, this is refined and appropriate elements are added to provide steels of the required composition to achieve a wide spectrum of properties.[21] The chief ores now of commercial importance are hematite (specularite, Fe_2O_3), magnetite (Fe_3O_4), and limonite (FeOOH). The carbonate, siderite, is no longer important, nor are pyrite (disulfide ore) and silicate-containing ores. However, oxidative bacterial action on pyrite gives an acidic solution containing iron(III), which is an important intermediate in the bacterial dissolution of some other metals from their ores, the basis of a method of biological metal extraction.[22]

2.2 Physical Properties

Pure iron is a fairly soft silver/white ductile and malleable metal melting at 1535 °C. It exists in three allotropic forms: body-centered cubic (alpha), face-centered cubic (gamma), and a high-temperature body-centered cubic (delta). In reviewing the literature on the structure of iron, Donohue[23] concluded that the best average value for the lattice constant for α-Fe at 20 °C was 2.86 638(19) Å. Details of the phase transitions and other numerical information are given in Table 1. The physical properties of iron depend on the presence of low levels of impurity, such as carbon or silicon, and the pure metal is of little commercial importance. In contrast the properties of iron containing varying amounts of other components, namely steels, make them commercially very important. Table 1 contains data for some thermal and mechanical properties of technically pure iron (99.5–99.9%). The magnetic properties are also sensitive to impurities; at room temperature, pure iron is ferromagnetic, but above the Curie point (768 °C), it is paramagnetic.

Table 1 Selected properties of iron

Atomic Number	26
Atomic Weight	55.847
Density	7.87 g cm^{-3} (20 °C) 7.08 g cm^{-3} (1550 °C)
Coefficient of Thermal Expansion	1.45×10^{-5} K^{-1} (0–800 °C)
Thermal conductivity	72.44 W m^{-1} K^{-1} (100 °C)
Standard Entropy	27.2 J mol^{-1} K^{-1}
Molar heat capacity	α Cp = 17.50 + 24.77 × T J mol^{-1} K^{-1} (273–1033 K) γ Cp = 7.70 + 19.51 × T J mol^{-1} K^{-1} (1183–1673 K) δ Cp = 43.96 × T (1673–1812 K) liquid Cp = 41.87 × T (1812–1873 K)
Transition Points	
Curie Point	760 °C (2.76 kJ mol^{-1})
alpha/gamma	910 °C (0.92 kJ mol^{-1})
gamma/delta	1400 °C (1.17 kJ mol^{-1})
delta/melt	1539 °C (15.28 kJ mol^{-1})
melt/vapor	2880 °C (340.4 kJ mol^{-1})
Structures and lattice constants:	
alpha-iron body-centered cubic	a = 0.2866 nm
gamma-iron face-centered cubic	a = 0.3647 nm
delta-iron body-centered cubic	a = 0.2932 nm
Mechanical Properties[a]	
Tensile strength	220–280 N mm^{-1}
Elongation to fracture	40–60%
Modulus of elasticity	10 × 103 N mm^{-1}
Shear modulus	82 × 103 N mm^{-2}
Brinell hardness	44–55 HB

[a]Typical data for samples containing 0.005% carbon.

2.3 Nuclear Properties

2.3.1 Isotopes

There are four naturally occurring isotopes of iron. Their abundances and atomic masses are listed in Table 2 together with data for other man-made isotopes of iron whose atomic masses have been determined with precision. The most abundant of the natural isotopes is ^{56}Fe, and this is also the most stable nuclear configuration of all the elements in terms of nuclear binding energy per nucleon. Its stability, viewed in terms of nuclear equilibria established in the last moments of supernovae, perhaps explains its widespread occurrence in the cosmos.[24] The isotope ^{57}Fe has several applications, most notably in Mössbauer spectroscopy, and it has proved to be

Table 2 The isotopes of iron (Z = 26)

Isotope	N	Abundance	Atomic Mass	Half-life
^{51}Fe	25		50.956825	0.25 s
^{52}Fe	26		51.948114	8.28 h
^{53}Fe	27		52.945310	8.51 min
^{54}Fe	28	5.82%	53.939612	
^{55}Fe	29		54.938296	2.7 years
^{56}Fe	30	91.66%	55.934939	
^{57}Fe	31	2.19%	56.935396	
^{58}Fe	32	0.33%	57.933277	
^{59}Fe	33		58.934877	44.5 days
^{60}Fe	34		59.93408	ca. 10^5 years
^{61}Fe	35		60.936748	6.0 min
^{62}Fe	36		61.936773	68 s
^{63}Fe	37		62.94075	4.9 s

Note: Relative atomic mass of natural iron = 55.847.

of some value in studying iron-containing compounds and complexes by EPR spectroscopy;[25] its nuclear properties (low sensitivity, low abundance, and long relaxation times[26]) make the acquisition of serviceable ^{57}Fe NMR spectra difficult.[27] Recently, in the form of single crystals, it has been used in short wavelength neutron monochromators (spin up/down). This isotope has been produced in considerable quantities at the Oak Ridge National Laboratory (Tennessee USA) using electromagnetic separators known as calutrons. The isotope ^{52}Fe has been considered for use in positron emission tomography (PET).[28]

2.3.2 *Mössbauer Spectroscopy*

The ^{57}Fe nucleus is particularly amenable to study by the Mössbauer technique.[29] The effect arises from reabsorption by ^{57}Fe in the sample of γ-rays derived from an excited state of ^{57}Fe at a source formed in the radioactive decay of ^{57}Co, which has a half-life of 270 days. The nuclear transitions involved are shown in Figure 1. The ^{57}Fe nuclide is sufficiently abundant (Table 2) for excellent spectra to be obtained routinely with compounds containing iron of natural isotopic abundance, whilst materials enriched in ^{57}Fe give spectra in less time. However, in some cases (e.g. where samples have a low overall iron content), it may prove essential to use enriched iron. The Döppler shift velocity of the source at which absorption occurs is a measure of absorption frequency, and this is different when the chemical environment of the absorbing nucleus is different. A reference material, usually stainless steel or sodium nitroprusside, is assigned a value of zero and the shift of the sample measured relative to it. This chemical shift (δ) is affected by the electronic environment of the iron and is temperature dependant. It arises from the interaction of s electrons at the nucleus and is a linear function of their density there. With high-spin complexes, δ depends on the oxidation state: from +1.0 to +1.6 mm s^{-1} for iron(II), and from +0.45 to +0.75 mm s^{-1} for iron(III) complexes. The ligand type

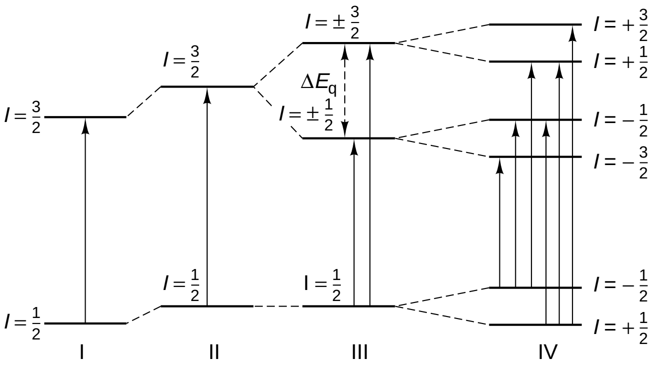

Figure 1 Nuclear energy levels responsible for one-, two-, and six-line iron Mössbauer spectra: I, original energy levels; II, small perturbation via interaction with s-electron density; III, quadrupole interaction splitting; IV, magnetic splitting of the ground and excited states

also influences the value of δ. Large chemical shifts are not observed with low-spin complexes; both iron(II) and iron(III) low-spin complexes have δ in the range 0.0–+0.3 mm s^{-1}.

The $I = 1/2$ to $I = 3/2$ nuclear transition is split by an electric quadrupole to give a two-line Mössbauer spectrum (quadrupole splitting energy ΔE_q), and if the sample is also in a magnetic field, a six-line spectrum results when the nuclear spin degeneracy is removed (Figure 1). An electric field gradient at the iron nucleus can arise from asymmetric occupancy of d orbitals, or from asymmetry of the ligand field. Accordingly, high-spin iron(III) complexes with identical ligands have small ΔE_q values, but similar iron(II) complexes have a two-line Mössbauer spectrum. The symmetrical electronic configuration and ligand environment of low-spin iron(II) complexes with identical ligands, for example, $[Fe(CN)_6]^{4-}$, has a single-line Mössbauer absorbance, while the asymmetric electronic configuration of low-spin iron(III) complexes results in them having a spectrum similar to those of high-spin iron(II). Many low-spin $[FeX_4Y_2]$ and $[FeX_5Y]$ complexes with asymmetric ligand environments have had their two peak Mössbauer spectra recorded.[30] In appropriate situations, iron Mössbauer spectroscopy can be a valuable characterization tool. New Mössbauer techniques using synchrotron radiation, and thus operating in the time domain rather than in the usual energy domain, have been applied to the study of iron porphyrin complexes.[31]

2.4 Chemical Properties

2.4.1 *General Reactivity*

Iron is reactive and, if sufficiently finely divided, is pyrophoric in air. It forms binary compounds by direct reaction with many elements, and some of these are described in more detail later. It reacts with oxygen, sulfur, halogens, phosphorus, and even forms a nitride with dinitrogen. With

ammonia, nitride is readily formed above 400 °C, and is the basis of a 'nitriding' process to harden steel surfaces.[32] At elevated temperatures, iron reacts with steam to give hydrogen and one or more iron oxides; Fe_3O_4 is formed below about 570 °C, and FeO at higher temperatures. These oxides are also formed when carbon dioxide is reduced to carbon monoxide by iron. At high pressure, carbon monoxide reacts with the metal to form volatile iron pentacarbonyl ($Fe(CO)_5$, bp 104 °C), a process which is catalyzed by sulfur compounds. Iron dissolves in dilute mineral acids with the evolution of hydrogen and formation of iron(II) salts. However, concentrated nitric acid and other powerful oxidants passivate iron. Iron filings (or turnings) are still used commercially to reduce aromatic nitro compounds, for example, nitrobenzene to aniline, and in one variation of this process, a morphological variant of Fe_3O_4 is produced, which is used as a pigment.

2.4.2 Catalytic Properties

There are many catalytic applications in which metallic iron or its oxides play a vital part; the best known are in the synthesis of ammonia from hydrogen and nitrogen at high pressure (Haber process), and in hydrocarbon synthesis from $CO/CO_2/H_2$ mixtures (Fischer–Tropsch synthesis).[33] Iron oxides also have catalytic activity in mild hydrogenation reactions, for instance, magnetite has long been used to bring water gas (a mixture of hydrogen and carbon monoxide) to equilibrium with excess steam.[34] They were also used to absorb sulfur compounds from town gas, which was obtained by dry distillation of coal.[35]

2.4.3 Rusting

Iron is an electropositive element (−0.44 v) although the massive metal is stable in dry air. However, in the presence of oxygen and water, or even deoxygenated water and carbon dioxide, rusting (formation of hydrated mixed iron oxides) takes place with the formation of the characteristic brown hydrated surface oxides. These flake away permitting the process to continue causing metal loss, and ultimately mechanical failure. Mild steel rusting is essentially electrochemical in nature involving dissolution of iron to give mobile iron(II) salts, subsequent precipitation of insoluble iron(III) oxo species, and recycling of the anions concerned. Thus, chloride (found on many roads in winter), sulfate, and other common anions significantly enhance rusting rates, which are faster in urban environments than in rural ones, and even more rapid in industrial and marine environments.[36] Approaches to rust inhibition include placing a barrier between the metal surface and the environment to slow oxygen transfer, or retardation of iron diffusion near the interface. A variety of coatings are used such as phosphate treatments and paints and these approaches have been used to prevent rusting of automobiles.[37] In well-controlled situations, such as the steam generating systems of power and chemical plants, it is possible to maintain a sufficiently high pH for a coherent film of magnetite to be formed, which prevents further significant corrosion. Under milder conditions, filming amines are used. Since electrochemical dissolution of metal is a key step in rusting, it can be inhibited by cathodic protection: applying a small potential between the steel and an electrode. The latter may be sacrificial (e.g. zinc, specifically as an electrode or as a coating in galvanizing) if it has a higher electrochemical potential than iron, and therefore dissolves preferentially. In contrast to rust formed at ambient conditions, scale formed on steels during hot rolling and other heat treatments comprises all three iron oxides (see Section 3.1.1) in ratios dependent on steel composition, and processing conditions. Removal of scale by dissolution in mineral acid is known as pickling. The most common acids employed with iron and mild steels are sulfuric acid, and increasingly, hydrochloric acid. Phosphoric, nitric, and hydrofluoric acids are used for stainless steels and special purposes. Crystallization of spent pickling solutions is an important source of iron(II) salts, although an electrolysis process has been developed which affords metallic iron, and spray-roasting chloride solutions give iron(III) oxide that is suitable as a raw material for manufacturing ferrites.

Stainless steels do not rust in the same way as mild steel. They contain chromium (typically 18%), and form a thin (tens of Ångstroms) chromium-rich oxide film that inhibits further reaction under normal conditions. Oxidation does however take place at high temperature, but incorporation of nickel (8% or more) gives improved performance alloys, which are widely used in the chemical industry.[38] They are however, considerably more costly than mild steel.

3 BINARY COMPOUNDS

Iron is a reactive element that forms binary compounds with a variety of nonmetallic elements. Oxide and sulfide ores are widely distributed in nature and as such form huge ore reserves. Carbides and phosphides have key roles in steel making. The most common form of iron oxide is probably rust, hydrated iron(III) oxide (see Section 2.4.3). Other oxides are important in corrosion science, and they have a variety of applications based on their physical properties; magnetic (e.g. recording media), light absorption (e.g. inorganic pigments), or hardness (e.g. polishing powders).

3.1 Oxides

3.1.1 Oxides and Hydroxides[39]

The important iron/oxygen system has been extensively studied, and a simplified phase diagram is shown in

Figure 2. Here, the primary concern is the chemistry of the oxides, and for convenience, hydroxides are also included in this section. The mixed oxide ferrites, some of which are manufactured on a large scale, are dealt with in Section 3.1.2.

Several iron oxides and hydroxy oxides exist as minerals, and the more important are listed in Table 3. Three iron oxides are known with ideal compositions: FeO (wüstite), Fe_2O_3 (hematite), and Fe_3O_4 (magnetite). However, all of them tend to be nonstoichiometric. Wüstite is only stable at temperatures above 570 °C, but can be prepared by heating pure $Fe(OH)_2$ under nitrogen at 200 °C. It contains defect clusters related to the magnetite structure (see below), and is an intermediate in the reduction of higher iron oxides. The wide range of stoichiometry of $Fe_{1-x}O$ results from the ease of formation of iron(III) from iron(II). For example, in the omission of one iron(II) center with oxidation of two

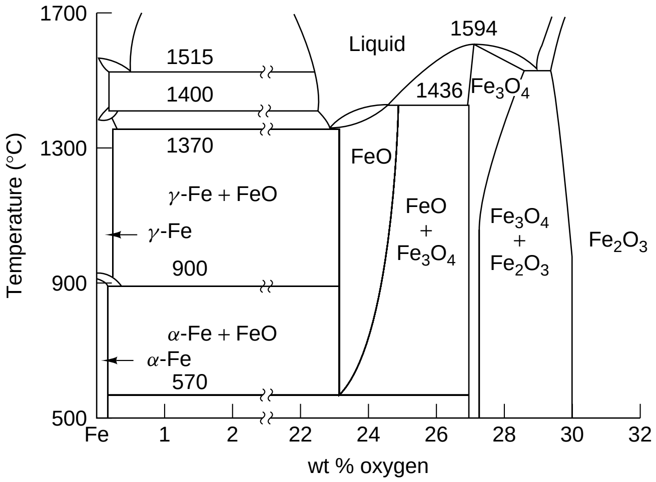

Figure 2 Phase diagram for the iron/oxygen system

Table 3 Iron oxide and oxyhydroxide minerals

Mineral	Formula	Structure	Density[a]	Color[b]
Goethite	α-FeO(OH)	Orthorhombic	4.26	Yellow brown
Akaganeite	β-FeO(OH)	Tetragonal	3.56	Yellow brown
Lepidocrocite	γ-FeO(OH)	Orthorhombic	4.09	Orange
Feroxyhyte	δ'-FeO(OH)	Hexagonal	4.20	Red brown
Ferrihydrite	$Fe_5HO_8 \cdot 4H_2O$	Trigonal	3.96	Red brown
Magnetite	Fe_3O_4	Cubic	5.18	Black
Hematite	α-Fe_2O_3	Trigonal	5.26	Bright red
Maghemite	γ-Fe_2O_3	Cubic/ Tetragonal	4.87	Red brown

[a]$g\,cm^{-3}$. [b]Color depends to a significant extent on particle size and morphology.

of those remaining to iron(III), some of the iron(III) atoms are in tetrahedral sites and the resulting defect unit (one tetrahedral iron(III) and two octahedral cation vacancies), can be ordered through the lattice. The main iron ore deposits in the Earth's crust are hematite and magnetite. Bright red hematite has layers of FeO_6 octahedra connected by shared edges and faces and stacked perpendicular to the c-axis. Owing to the face sharing, the octahedra are slightly distorted so there is a regular displacement of the iron centers. Mixed-valence magnetite is black due to charge transfer. It is strongly magnetic and has an inverse spinel structure with the tetrahedral positions occupied by Fe(III), and the octahedral sites by equal amounts of Fe(III) and Fe(II). Crystals, formed by chemical transport, are well-formed octahedra with shiny faces and can be up to 5 mm across.[40] Small spheres (~12 nm) of polymers with a hematite surface are being assessed for the removal of arsenic contamination from drinking water in India and Bangladesh.[41]

Slow hydrolysis of iron(III) can be used to prepare hydrated iron(III) oxide;[42] a more convenient preparation involves aerial oxidation of $[FeCl_2(py)_4]$ to the hydrated oxide $Fe_2O_3.H_2O$, which may be dehydrated to ferromagnetic γ-Fe_2O_3 at 250 °C. When heated at 400 °C, this irreversibly gives[43] α-Fe_2O_3 (hematite). Iron(II) hydroxide is obtained as a white precipitate on addition of hydroxide ion to a solution of an iron(II) salt, and when crystalline it has the magnesium hydroxide structure. It is strongly reducing and there is some evidence that it reduces dinitrogen to ammonia.[44] On exposure to air, it turns brown, finally forming hydrated iron(III) oxide. The identification of ores containing similar iron(III) oxides in precambrian deposits has been taken as evidence that the Earth's atmosphere contained oxygen at that time.

The aquated iron(III) cation has a pK_a about 2.5, and readily undergoes hydrolysis; except at low pH it does not exist as $[Fe(H_2O)_6]^{3+}$. Above pH~1, hydrolytic polymerization involving deprotonation takes place to form hydroxo and oxo species leading progressively to increasingly insoluble hydrated iron(III) oxides, similar to rust. When a solution of an iron(III) salt is made alkaline, the nature of the product depends on the final pH, the rate of pH change, temperature, and any other ions present. Equilibria resulting in low-molecular weight hydrolysis products such as $FeOH^{2+}$, $Fe(OH)_2^{+}$, and $Fe_2(OH)_2^{4+}$ (for simplicity water ligands are omitted) are rapidly established, and are well understood.[45] From these, larger soluble polynuclear species form, and further polymerization gives colloidal red–brown material, with for example, the β-FeO(OH) structure. Low-temperature hydrothermal synthesis can yield β-FeO(OH), in the form of tunnel-type nanorods, and α-Fe_2O_3 nanorods of porous structure.[46] Illustrated in Figure 3 are the three fundamental cationic hydrate cores found in iron(III) polynuclear species: μ-oxo bridged dimers, μ-dihydroxy dimers, and μ-oxo triiron. These basic units are also found in many iron(III) complexes, for example, the basic carboxylates, which contain three iron(III) centers and a central oxygen atom.[47] Layered

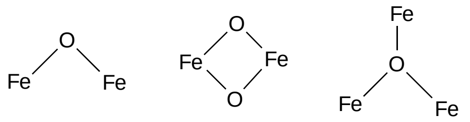

Figure 3 Schematic representation of the fundamental iron–oxygen cores found in many iron(III) polymeric hydroxy/oxide systems

double hydroxides are of current interest; iron-containing versions include Fe^{3+}/Ni^{2+} and Fe^{3+}/Mg^{2+} with carbonate as intercalated counterion and Fe^{3+}/Ni^{2+} with sulfate. Layered double hydroxides such as the $[Fe^{III}_xNi^{II}_{1-x}(OH)_2]^{x+}$ cations form a large group of minerals and synthetic materials, capable of intercalating a variety of oxoanions.[48] Complementarily, hexacyanoferrate(II) can act as the intercalating counterion in layered double hydroxides such as $Mg(OH)_2/Cr(OH)_3$, $Mg(OH)_2/Al(OH)_3$, and $Cu(OH)_2/Al(OH)_3$.[49]

3.1.2 Ferrites

'Ferrites' has become a generic term for all magnetoceramic materials widely used in magnetoelectronic applications.[50] True ferrites contain iron(III) and are classified into two main groups: 'cubic ferrites' (MFe_2O_4) with a spinel structure, which are sometimes called ferrospinels, and 'hexagonal ferrites' ($MFe_{12}O_{19}$) with the magnetoplumbite structure (M = divalent cation, e.g. Mn, Fe, Co, Ni, Cu, Mg). These are generally chemically inert materials, which lose oxygen before melting at high temperatures. The former may be obtained by reacting the well-mixed constituent oxides at temperatures above 1000 °C, or more conveniently for the nickel, cobalt, or manganese compounds by decomposition of the appropriate pyridine adduct of the mixed iron acetate.[51] A less controllable, but often used, procedure is coprecipitation of the mixed oxalates followed by thermal decomposition.[52] Lattice constants and magnetic properties of several cubic ferrites are given in Table 4.

3.2 Sulfides

Metallic iron reacts with sulfur when heated to give high-spin iron(II) sulfide. This is also formed when iron(II) is precipitated from solution by addition of sulfide ion, and while it is normally dark gray/brown, when pure it is almost colorless. Rarely is the iron/sulfur ratio unity, and at different times a variety of formulae have been assigned to these nonstoichiometric ferrimagnetic phases.[53] Several minerals contain an approximately octahedral environment of sulfur atoms around iron. Troilite, high-spin stoichiometric FeS, is hexagonal with Fe–S bond lengths ranging from 2.38 Å–2.72 Å. Pyrrhotite ($Fe_{1-x}S$) exists as hexagonal and monoclinic forms, with bond lengths in the range 2.37 Å–2.67 Å. The cubic low-spin iron(II) disulfide FeS_2 has a FeS_6 octahedron with Fe–S bond lengths of 2.26 Å; the tetragonal FeS_2 polymorph, marcasite, has an octahedral geometry distorted by elongation along the c-axis. Iron pyrites, FeS_2, occurs naturally as brass-yellow crystals, sometimes formed in the presence of organic matter such as in coal seams. Iron(III) sulfide may be obtained from aqueous solutions of an Fe^{3+} salt and sodium sulfide at 0 °C. It is unstable, and not easily stored. A tricyclic iron(III) polysulfide anion $[Fe_2S_{12}]^{2-}$ has been characterized.[54]

Table 4 Lattice constants and magnetic properties of some cubic ferrites

Ferrite	Lattice Constant (Å)	Magnetic Transition (°C)	BM/formula(0K)
$MgFe_2O_4$	8.384	440	1.1–1.4
$MnFe_2O_4$	8.512	300	4.5
$CoFe_2O_4$	8.388	520	3.7
$NiFe_2O_4$	8.338	585	2.1
$ZnFe_2O_4$	8.437	264	

3.3 Nitrides

Nitrogen dissolves in iron to form a solid solution and several nitride phases – the phase diagram is complex. Specific nitrides are best obtained via reaction of iron with ammonia. At 400–500 °C, gray orthorhombic Fe_2N is obtained, which when heated at about 500 °C in vacuo, loses nitrogen to give face-centered cubic Fe_4N.

3.4 Carbides

The addition of small amounts of carbon to iron dramatically changes its physical properties. By occupying interstitial sites, carbon can be thought of as locking together the structure, thus reducing ductility and increasing hardness. Thus, physical properties markedly depend on the amount of carbon present. Cast iron contains at least 4% carbon, which is present as graphite, in solid solution, or as cementite (Fe_3C). It is very brittle, whereas mild steel contains less than 1.5% carbon and is much more ductile. Commercially, careful control of carbon content is very important. However, the properties of a particular steel depend not only on carbon content, but also on the amount of other low-level additives, as well as grain size, (which depends on thermal history) and surface treatments. In the irregular structure of cementite, carbon is located in a very distorted trigonal prism of six iron atoms at distances 1.89 Å–2.15 Å, with an additional two iron atoms at 2.31 Å. Other iron carbides are also known. The reaction of cementite with dilute hydrochloric acid has been reported to be complex, forming hydrogen, and a range of liquid and gaseous hydrocarbons. The reasons for this are not clear, for its structure suggests methane would be the major product. This is, however, in accord with the behavior of iron as a Fischer–Tropsch catalyst.[55]

3.5 Phosphides

The iron–phosphorus phase diagram is well established. The phases FeP and FeP_2 are well characterized; Fe_3P is also known, and there are three distinct FeP_4 structures. Hexagonal Fe_2P is formed in the reaction of iron with red phosphorus. It is ferromagnetic (magnetization 2.94 BM/Fe_2P with a Curie temperature of 210K) and contains two iron sites, one in a tetrahedron of P atoms, and the other in a pyramid of five P atoms. Orthorhombic iron monophosphide ($a = 5.19$ Å, $b = 3.099$ Å, $c = 5.79$ Å) may be obtained by electrolysis of iron(III) and sodium metaphosphate at 925 °C in the form of needles with a metallic luster. FeP is antiferromagnetic with a Néel temperature $T_N = 123$ K, and is stable in air, water, and acids at room temperature.[56] FeP is the major constituent of recently characterized nanowires generated by thermal decomposition of (η^4-cyclohexadiene)irontricarbonyl in the presence of tri-*n*-octylphosphine.[57] FeP_2 is orthorhombic.

3.6 Borides

Metal borides have high melting points and considerable hardness, in many ways they resemble nitrides and carbides. Usually, their stoichiometry does not reveal their often-complex structures. Thus, iron boride (FeB, density 7.15 g cm^{-3}) contains infinite zigzag chains of boron atoms (B–B distance 1.77 Å) with each boron atom being surrounded by six iron atoms (Fe–B distances 2.12 to 2.18 Å) located at the apices of a trigonal prism. Fe_2B has a layer structure in which each boron atom has eight iron neighbors with the two near boron atoms, but there are no B–B bonds. The discrete compound FeB_{49} has the iron atom in a rhombohedral boron environment.[58]

4 SIMPLE SALTS

4.1 Halides

4.1.1 Fluorides

Anhydrous iron(II) fluoride, FeF_2 (ferrous fluoride), is an off-white powder obtained by reacting iron with HF, dehydration of the tetrahydrate, displacement of chlorine in $FeCl_2$ by HF, or reduction of FeF_3. It is monomeric in the gas phase, and the solid has the rutile structure in which FeF_6 octahedra are tetragonally distorted with two Fe–F distances of 1.99 Å and four of 2.12 Å. Above 100 K, FeF_2 has a spin-free magnetic moment of 5.56 BM. White iron(II) difluoride tetrahydrate is oxidized in air and becomes brown. It can be made by dissolving iron in warm hydrofluoric acid followed by precipitation with ethanol. Its structure contains discrete $[FeF_2(H_2O)_4]$ octahedra with H_2O and F^- randomly distributed over 12 possible sites, each being occupied by an average of $^1/_3$ O and $^1/_6$ F^-. On standing in air, a saturated aqueous solution of iron(II) fluoride forms a precipitate of yellow $Fe_2F_5{\cdot}7H_2O$, which may be dehydrated at 100 °C under nitrogen to give $Fe_2F_5{\cdot}2H_2O$, and at 180 °C to a gray salt, Fe_2F_5, that has distinct Fe(II) and Fe(III) centers.[59] Iron(III) fluoride, FeF_3 (ferric fluoride), is prepared from the elements, or $FeCl_3$ with ClF_3, or $FeCl_3$ and HF at an elevated temperature. It is antiferromagnetic with a Néel temperature of $T_N = 394$ K. Although only slightly soluble in water, it dissolves in dilute HF. The pale pink trihydrate $FeF_3{\cdot}3H_2O$ may be crystallized from 40% HF in two forms. Low-temperature crystallization favors a form isostructural with α-$AlF_3{\cdot}3H_2O$, while the higher-temperature form has bridging fluorides and one water molecule of hydration in the unit cell.[60] The affinity of iron(III) for fluoride ion is high. Formation constants for aqua fluoride species are several orders of magnitude larger than those for chloride.[61] In the solid state, salts containing $[FeF_6]^{3-}$ are known, but in aqueous solution, only species with less than six fluorides exist.

4.1.2 Chlorides

Iron(II) chloride, $FeCl_2$ (ferrous chloride), occurs as the mineral lawrencite. It is a hygroscopic white/pale green solid, readily soluble in water and ethanol, with a melting point of 677 °C and a boiling point of 1074 °C. When a saturated aqueous solution is cooled to 0 °C, pale green monoclinic crystals of the tetrahydrate are deposited. When this is heated in a partial vacuum above 72.6 °C, a very pale green dihydrate is obtained, and at 120 °C, a monohydrate is obtained.[62] The anhydrous compound is prepared by the action of HCl on iron at red heat (or under milder conditions in THF or methanol, which affords solvates), or by reduction of iron(III) chloride with hydrogen at 200 °C. Anhydrous iron(II) chloride may also be obtained as a tan colored solid by boiling iron(III) chloride in chlorobenzene.[63] When heated at 300 °C in vacuo, $FeCl_3$ decomposes to $FeCl_2$, and this facilitates purification of $FeCl_2$ by vacuum sublimation. Depending on the temperature, the vapor of iron(II) chloride contains monomeric or dimeric species, while the crystalline solid has the $CdCl_2$ structure with the packing of $FeCl_6$ octahedra depending on the method of crystallization; the structure is also pressure sensitive. The anhydrous salt has a magnetic moment of 5.87 BM. Pale green $FeCl_2{\cdot}4H_2O$ is easily oxidized both in the solid and solution forms. In the presence of an excess chloride ion and suitably large cations, salts of tetrahedral $[FeCl_4]^{2-}$ are readily obtained. Thus, mixing ethanolic solutions of $FeCl_2{\cdot}2H_2O$ and NEt_4Cl gives[64] a cream precipitate of $(NEt_4)_2[FeCl_4]$. Recrystallization of iron(II) chloride from pyridine gives yellow *trans*-$[FeCl_2(py)_4]$, which has the advantages of being somewhat less easily oxidized by air than simple iron(II) salts, and soluble in common organic solvents. It is therefore often used in the preparation of other iron(II) compounds.

Anhydrous iron(III) trichloride, $FeCl_3$ (ferric chloride), is soluble in water and organic solvents. It is manufactured by reaction of excess chlorine with iron at 500–700 °C as an almost black crystalline solid with a metallic luster (density 2.89 g cm^{-3}), which sublimes at about 305 °C, and boils at 332 °C with some decomposition. In the gas phase, it is dimeric up to about 400 °C when increasingly significant amounts of monomer are present; at these temperatures in vacuo, it decomposes to the dichloride. The anhydrous solid has a layer structure, and is very hygroscopic; it forms a series of hydrates when exposed to moist air. The common hydrate is yellow $FeCl_3{\cdot}6H_2O$ (mp about 37 °C), which contains $[FeCl_2(H_2O)_4]^+$. This is very soluble in water, and gives a strongly acidic solution, which when partially neutralized forms a series of polymeric species. The addition of more alkali gives, depending on conditions, brown colloidal β-FeO(OH) or a precipitate of iron(III) hydroxide. With hydrochloric acid, or another source of chloride ion, tetrachloroferrates $[FeCl_4]^-$ and $[FeCl_4(H_2O)_2]^-$ are formed. Salts of the $[FeCl_6]^{3-}$ anion can be obtained in the solid state through the use of large cations such as $[Co(NH_3)_6]^{3+}$ and $[Co(pn)_3]^{3+}$ (pn = 1,2-propanediamine), which provide lattice stabilization.[65] $FeCl_3$ is sometimes used as a catalyst in Friedel–Crafts reactions, and it is also occasionally used as a chlorinating agent. Fe(III) is oxidizing, and many metals dissolve in aqueous $FeCl_3$ solutions (e.g. copper when preparing printed circuit boards, and in the bacterial extraction of ores). When heated strongly in air, chlorine and iron(III) oxides are formed.

The largest consumption of iron(III) chloride is in water treatment where it is used to condition some potable waters. Dilute solutions, adjusted to the appropriate pH, flocculate, and precipitate finely divided solids, colloids, and heavy metals, via adsorption on extremely insoluble iron(III) hydroxide. Very large quantities are employed in sewage plants to coprecipitate, and thus remove from clarified water, oils, polymers, heavy metals, sulfides, and phosphates, which would otherwise be extremely difficult to degrade. Iron(III) chloride was the first inorganic contrast agent in magnetic resonance imaging (MRI) in a human, administered orally for gastrointestinal tract imaging.[66] Iron compounds are now returning (the currently widely used gadolinium complexes are significantly toxic) to favor with iron(III) ammonium citrate (the main ingredient in Geritol, an iron supplement for anemia), iron(II) sulfate, and iron oxide nanoparticles assessed as contrast agents.[67]

4.1.3 Bromides

Iron(II) bromide, $FeBr_2$ (ferrous bromide), is a pale yellow/brown hygroscopic solid soluble in water and donor organic solvents. It may be prepared from iron and bromine at 200 °C, or iron and HBr in methanol, hydrobromination of iron(III) oxide at 200–350 °C, or dehydration of $[FeBr_2(H_2O)_4]$. The anhydrous compound is readily purified from $FeBr_3$ by sublimation under nitrogen or in vacuo. It was used in the early determinations of the atomic weight of iron via quantitative precipitation of silver bromide.[68] It has a layer lattice of the CdI_2 type, and has a magnetic moment of 5.71 BM at 295 K. It readily forms complexes with a wide range of ligands, and a series of hydrates can be crystallized from water. At room temperature, a hexahydrate is obtained, above 49 °C, a tetrahydrate, and above 83 °C, a dihydrate. With excess bromide ion and a suitably large cation, salts of $[FeBr_4]^{2-}$ are readily obtained. Thus, mixing ethanolic solutions of $FeBr_2$ and NEt_4Br precipitates[69] pale brown $(NEt_4)_2[FeBr_4]$. Dark red hygroscopic iron(III) bromide, $FeBr_3$ (ferric bromide) can be obtained from the elements below 200 °C. It dissolves freely in water, and in coordinating organic solvents. Several hydrates are known. Structures have been reported for $Ba[FeBr_4]_2$[70] and for its parent $FeBr_3$, which has the BiI_3 structure with pairs of bromide ligands bridging the Fe^{3+} ions, all of which are octahedrally coordinated.[71]

4.1.4 Iodides

Iron(III) iodide, FeI_3 (ferric iodide), was first isolated in the pure state as recently as 1988 as a black, fairly stable solid, though it is unstable in solution.[72] It reacts with iodide to give the previously characterized complex $[FeI_4]^-$.[73] Iron(II) iodide, FeI_2 (ferrous iodide), is a red–black hygroscopic solid having the CdI_2 structure, and a magnetic moment of 5.75 BM at 295 K. It is readily prepared from finely divided iron and iodine, and is soluble in water, ethanol, and ether. A series of hydrates are known, and at room temperature, a green tetrahydrate crystallizes. Complexes are formed with a range of ligands. There are few applications for FeI_2 although it is used in some discharge lamps.[74]

4.2 Sulfates

Pale green iron(II) sulfate heptahydrate, $FeSO_4{\cdot}7H_2O$ (ferrous sulfate), formerly known as green vitriol (mp 64 °C), is produced by dissolving iron in dilute sulfuric acid, or by the oxidation of moist pyrites (FeS_2) in air. Iron(II) sulfate is a readily available by-product, for example, from steel pickling (see Section 2.4.3), or processes such as traditional titania manufacture, which involves digestion in sulfuric acid. It is readily soluble in water, the heptahydrate crystallizing as green monoclinic crystals. On gentle heating (60–70 °C), water is lost to give a tetrahydrate, and in the absence of oxygen at about 300 °C, a monohydrate is obtained which decomposes at about 480 °C. When heated in air, the monohydrate is oxidized to an iron(III) sulfate. In air, solid $FeSO_4{\cdot}7H_2O$ is gradually oxidized at room temperature; the easily purified Mohr's salt, iron(II) ammonium sulfate $FeSO_4{\cdot}(NH_4)_2SO_4{\cdot}6H_2O$, is more stable, and is preferred in analytical work. Similar double salts are formed with other univalent cations. In acid solution, iron(II) sulfate reduces nitrate and nitrite ions to nitric oxide, which complexes with iron(II) to give the intensely colored

cation $[Fe(H_2O)_5NO]^{2+}$, the basis of the Brown Ring Test for these anions (see Section 8.1.1).

Anhydrous iron(III) sulfate, $Fe_2(SO_4)_3$ (ferric sulfate), is a pale yellow solid, which when strongly heated gives iron(III) oxide and sulfur trioxide. It dissolves in water with hydrolysis to give a yellow/brown solution, and when boiled, this forms a precipitate of basic iron(III) sulfate. The related basic complex $K_5[Fe_3O(SO_4)_6(H_2O)_3]$ is structurally similar to basic iron(III) acetate:[75] it contains a planar Fe_3O core via which magnetic exchange takes place, and each pair of iron atoms is bridged by two bidentate sulfate groups. Solutions of iron(III) sulfate are prepared by oxidation of iron(II) sulfate in sulfuric acid, or by dissolving iron(III) oxide in warm sulfuric acid. With alkali metal sulfates, alums $MFe(SO_4)_2{\cdot}12H_2O$ (M = alkali metal cation) are formed, which have the violet tinge characteristic of $[Fe(H_2O)_6]^{3+}$ but are otherwise almost colorless. Iron(III) sulfate is used as a sludge coagulant in sewage plants, in tanning, and in the production of iron pigments.

4.3 Nitrates

Green rhombohedral crystals of iron(II) nitrate hexahydrate, $Fe(NO_3)_2{\cdot}6H_2O$ (ferrous nitrate), with a melting point 60.5 °C, are obtained from solutions made by dissolving iron in dilute nitric acid. With more concentrated acid, oxidation takes place, and monoclinic pale violet iron(III) nitrate nonahydrate, $Fe(NO_3)_3{\cdot}9H_2O$ (ferric nitrate), melting point 47 °C, may be crystallized. A colorless hexahydrate can also separate as cubic crystals. Various basic iron(III) nitrates have been described. The eight-coordinate iron(III) anion $[Fe(NO_3)_4]^-$ has an essentially dodecahedral symmetry with four almost symmetrical bidentate nitrate groups.[76]

4.4 Phosphates

Insoluble iron(II) orthophosphate, $Fe_3(PO_4)_2$ (ferrous phosphate), occurs as a monoclinic mineral, $Fe_3(PO_4)_2{\cdot}8H_2O$ (Vivianite). When pure it is white, but most samples are greenish-blue due to slight oxidation. Mixing solutions of an iron(III) salt and sodium phosphate gives insoluble yellowish-white iron(III) orthophosphate, $FePO_4{\cdot}2H_2O$ (ferric phosphate), which occurs naturally as various hydrates and from which anhydrous $FePO_4$ may be obtained.[77] Both iron(II) and iron(III) salts of hydrogen phosphates are known,[78] as well as pyrophosphates. The iron(II) compounds are sensitive toward oxidation. Studies of three-dimensional phosphate networks have been extended to iron arsenate analogues, along with their two- and one-dimensional precursors.[79]

4.5 Cyanides

Iron(II) cyanide is obtained as very air-sensitive pale green crystals by carefully heating $(NH_4)_4[Fe(CN)_6]$ to 320 °C in vacuo. Mixing solutions of KCN and iron(II) sulfate (in excess) gives an orange precipitate of uncertain composition. There appears to be no authentic report of iron(III) cyanide; mixing solutions of iron(III) chloride and KCN yields iron(III) hydroxide and HCN. In contrast to the difficulty of obtaining simple iron cyanide salts, the literature on low-spin iron penta and hexacyano complexes is vast (see Section 7).

4.6 Thiocyanates and Azides

Addition of thiocyanate ion to a solution of an iron(III) salt produces a deep bloodred color of $[Fe(H_2O)_5(NCS)]^{2+}$, which is used as a test for iron(III). This reaction has been extensively studied by fast reaction techniques.[80] Dark red crystals of $Fe(NCS)_3$ may be obtained by evaporation of ether after extraction of an aqueous solution containing iron(III) and thiocyanate ion; with a large excess of thiocyanate, salts of $[Fe(NCS)_4]^-$ can also be extracted into ether. Recrystallization of $Fe(NCS)_3$ from water affords very soluble red $Fe(NCS)_3{\cdot}3H_2O$. Bright red salts of $[Fe(NCS)_6]^{3-}$ are known, for example, $Na_3[Fe(NCS)_6].12H_2O$, which is soluble in ethanol. Dark red iron(III) azide has a color similar to that of the thiocyanate, and is also a freely soluble salt.

4.7 Formates

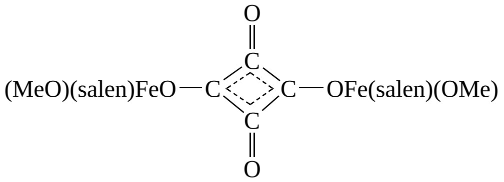
Iron(II) formate crystallizes from water as a pale green dihydrate, which loses water in the range 140–150 °C, and undergoes gradual decomposition above 200 °C. It is best prepared by dissolving iron in formic acid, which proceeds smoothly when the mixture is boiled.[81]

4.8 Acetates

Anhydrous iron(II) acetate can be obtained by dissolving iron in acetic acid, or in a purer form by reaction of $Fe(CO)_5$ with acetic acid and acetic anhydride in dimethyl formamide. Reaction with pyridine affords[82] yellow high-spin $[Fe(O_2CCH_3)_2(py)_2]$. Iron(II) trifluoroacetate can be prepared by photolysis of $Fe(CO)_5$ in $CF_3CO_2H/(CF_3CO_2)_2O$. It presumably contains bridging trifluoroacetate ligands like its manganese analogue.[83] Iron(III) forms a series of basic acetates. The complexes $[Fe_3O(O_2CCH_3)_6(L)_3]X$ (L = H_2O, CH_3OH, py, DMF etc, and X = anion) are well characterized, and have a central oxygen atom with a triangular cluster of iron(III) atoms.[84] They are easily reduced to $Fe^{II}Fe_2{}^{III}$ analogs (see Sections 5.5 and 10.3). Commercially, iron(III) acetate is prepared by reacting iron with acetic acid, followed by air oxidation. When boiled, a brown–red basic acetate precipitates, which is used as a mordant in dyeing, for weighting silk and felt, and as a leather colorant.

4.9 Oxalates

Sparingly soluble iron(II) oxalate, $Fe(C_2O_4).2H_2O$ (ferrous oxalate) is precipitated as a yellowish powder on mixing an iron(II) salt solution with one containing an excess of oxalate ion. Its structure is undoubtedly complex, and when heated in the absence of air, pyrophoric iron(II) oxide and/or iron are formed depending on the temperature. Well-characterized iron(II) complexes such as $K_2Fe(C_2O_4)_2{\cdot}2H_2O$ can also be obtained. Pure iron(III) oxalate is difficult to prepare as iron(II) tends to be formed as a result of reduction by oxalate. However, stable iron(III) oxalato complexes are well known – calcium oxalate will dissolve in an iron(III) chloride solution! Green crystals of $K_3[Fe(C_2O_4)_3]{\cdot}3H_2O$ are obtained by hydrogen peroxide oxidation of iron(II) oxalate in the presence of potassium oxalate, or by adding barium oxalate to a solution of potassium oxalate and iron(III) sulfate, followed by filtration to remove barium sulfate, and evaporation.[85] The structure of this six-coordinate anion shows slight trigonal distortion from octahedral symmetry, and as expected, its room temperature–magnetic moment (5.96 BM) is close to the high-spin value. It readily undergoes photochemical reduction with the oxalate ligand being oxidized to carbon dioxide, and is used as a photochemical standard.[86] It loses water to give the anhydrous salt when heated at 120 °C. Fe–O distances in *catena*-$[Fe(\mu$-oxalate)(bipy)$]_n$ are 2.092(3)–2.162(4) Å,[87] very similar to those in $[Fe(bipy)_3][Fe_2(oxalate)_3]$, where Fe–O = 2.122(2), 2.128(2) Å.[88] Bridging oxalate, and squarate, are particularly effective in transmitting antiferromagnetic coupling between Fe^{3+} ions as much as 5 Å apart. The intramolecular Fe–Fe distance in (**1**) is 7.8 Å, but the nearest intermolecular Fe···Fe distances are 6.6 Å.[89] The bis(ethylenedithio)tetrathiafulvalene compound $[bedt\text{-}ttf][Fe(C_2O_4)_3(H_2O)].PhCN$ was the first molecular superconductor containing a paramagnetic metal ion. It contains alternate layers of bedt-ttf cations and $[Fe(C_2O_4)_3]^{3-}$ anions with associated water and PhCN.[90] The tetrathiafulvalene derivatives $(ttf)_7[Fe(C_2O_4)_3]_2{\cdot}4H_2O$ and $(ttf)_5[Fe(CO_4)_3]{\cdot}2C_6H_5Me{\cdot}2H_2O$ are semiconductors with stacked structures.[91]



(**1**)

4.10 Citrates

Iron(II) and iron(III) citrates are known but have a poorly defined composition, though octa-iron[92] and nona-iron[93] citrate complexes have been characterized; in solution, complex species exist.[94,95] Brown and green hydrated iron(III) ammonium citrates are commercially available for use as iron supplements in foods. Iron(III) citrate and iron(III) ammonium citrate (Geritol) are used for administering supplementary iron to iron-deficient patients, for inducing iron overload in rats or other creatures prior to testing the efficacy of iron chelators, or for introducing the isotope ^{59}Fe for metabolic tracer studies. There has been a qualitative study of the incorporation of iron into transferrin from iron citrate,[96] which reacts relatively slowly with the aluminium(III)-transferrin complex to give the thermodynamically strongly favored combination of iron(III)-transferrin with aluminium(III) citrate.[97]

4.11 Other Carboxylates

Succinate, fumarate, and gluconate salts and complexes are, like citrates, used in iron supplements.[98] Iron-gluconate complexes are sufficiently stable not to cause iron toxicity (in contrast to Fe^{2+} aq, Fe^{3+} aq, and complexes of low stability) and are safe and effective in hemodialysis;[99] there is information on iron transfer between gluconate and transferrin.[100]

Alkali metal salts of tris-maleato ferrate(III) are high spin; the isomer shifts of their Mössbauer spectra reflect the electronegativity and polarizing power of the cations.[101] Tetraaquabis(hydrogen-maleato)iron(II) is stable to air oxidation as a solid and in aqueous solution.[102] X-Ray diffraction and EXAFS studies of $[Fe^{III}(O_2CCH_2COCH_2CO_2)(H_2O)_2X]$, X = Cl, Br, show the oxodiacetate to be terdentate and planar, giving a *mer* complex with the central ether-O trans to X^-.[103] Humic acid binds Fe^{3+} predominantly or exclusively through carboxylate groups, though there may be a very small amount of ligation by phenolate. Some qualitative observations on stabilities and complex formation and dissociation reactivities are available for humic acid[104] and for fulvic acid.[105] By use of appropriate sterically demanding carboxylates, it is possible to generate four-, five-, and six-coordinated mononuclear iron(III) complexes. Ligand flexibility and electronic properties provide fine-tuning. These complexes are subunits of the models for di-iron(II) sites in metalloproteins.[106]

4.12 Silicates

Iron(II) silicates are widely distributed in nature. Most of the iron in the primary magmatic rocks is in the form of Fe(II) silicates (olivines, pyroxenes, amphiboles, and biotites). When exposed on the Earth's surface, they undergo oxidative hydrolytic weathering to give iron(III) hydroxyoxides such as goethite, the overall stoichiometry being described by equation (1). This form of iron is very insoluble, but subsequent microbial reduction to iron(II) makes it available to the biosphere.

$$Fe_2SiO_4 + \tfrac{1}{2}O_2 + 3H_2O \longrightarrow 2FeO(OH) + H_4SiO_4 \qquad (1)$$

5 OXIDATION STATES AND COORDINATION GEOMETRIES

Compounds of iron in oxidation states from −II (d^{10}) through +VI (d^2) are known though several oxidation states, for example, −I, +I, +V, are rare. This range, and the coordination geometries displayed, are illustrated in Table 5. The most well known are the +II (d^6) and +III (d^5) oxidation states, often referred to as ferrous and ferric iron respectively. The effects of ligand type on the iron(II)/iron(III) redox potential are shown in Figure 4. Although the vast majority of coordination complexes of iron contain the metal in oxidation states two or three, the lower oxidation states of one and zero are not uncommon, especially in areas bordering on organometallic chemistry. Oxidation state four is of relevance to bioinorganic electron transfer systems; oxidation state six is represented by the ferrate(VI) anion, well known but rather little studied. There are many important mixed valence and fractional formal oxidation state compounds (e.g. Fe_3O_4) and complexes of iron.

5.1 Low-oxidation States

Low-oxidation state iron compounds are stabilized by electron acceptor ligands, especially carbon monoxide, isocyanide, and phosphorus donors. The most common coordination geometry encountered in iron compounds is octahedral, but tetrahedral, trigonal bipyramidal, and square pyramidal are also represented. There are only a few compounds with iron in the −II state, although reduction of $[Fe(CO)_5]$ with sodium amalgam in THF affords pale yellow $Na_2[Fe(CO)_4]$, in which the anion is tetrahedral.[107] The stabilities of iron(−I) in water and in liquid ammonia have been assessed based on an electrostatic model.[108]

Reduction of common iron(II) coordination complexes that have ligands which can accommodate some electron density from the metal can give moderately stable low-oxidation state compounds. For example, reduction of red $[Fe(bipy)_3]^{2+}$ with alkali metal gives black $[Fe(bipy)_3]$, but without full characterization, care is needed when assigning oxidation states in complexes that involve ligands which can exist as coordinated radical species. With extensively delocalized ligands, particularly diimines, and macrocycles like phthalocyanines and porphyrins, reduction at the ligand can take place as well as at the metal center, and thus there is often ambiguity in assigning oxidation states for complexes of ligands with strong π-interactions. Thus, the substitution-inertness of the 1-, 2-, and 3-electron reduction products of $[Fe(diimine)_3]^{2+}$, diimine = bipy (**2**), phen (**3**), or bipym (**4**), and their spectroscopic properties, argue for their representation as iron(II) complexes containing one, two, or three anion radical ligands rather than as complexes of iron(I), iron(0), and iron(−I).[109] Similar comments apply to the $[Fe(bmpphen)_2]^+$ and $[Fe(bmpphen)_2]^0$ species from electroreduction of $[Fe(bmpphen)_2]^{2+}$, bmpphen = 2,9-bis(2-methoxyphenyl)-1,10-phenanthroline, (**5**).[110] In similar vein, it is now apparent that for the iron complex produced in the long-established 'Brown Ring Test', the formulation Fe^{III}-NO^- is to be preferred to Fe^{I}-NO^+ (see Section 44.3.8).

The iron(0) complex $[Fe(CN)_4]^{4-}$ has been isolated as its Cs^+ salt.[111] Iron(0) complexes may also be represented

Table 5 The oxidation states and geometries of iron complexes

Oxidation State	Electronic Configuration	Coordination Number	Complex Geometry	Example
−II	d^{10}	4	Tetrahedral	$[Fe(CO)_4]^{2-}$
0	d^8	5	Trigonal bipyramidal	$[Fe(CO)_3(PPh_3)_2]$
I	d^7	5	Square pyramidal	$[Fe(dppe)_2H]$
II	d^6	4	Tetrahedral	$[FeBr_2(PPh_3)_2]$
		5	Trigonal bipyramidal	$[FeBr(Me_6tren)]^+$
		5	Square pyramidal	$[Fe(ClO_4)(OAsMe_3)_4]^+$
		6	Octahedral	$[Fe(phen)_3]^{2+}$
		7	Pentagonal bipyramidal	$[Fe(HPAP)(H_2O)_2]^{2+}$
		8	Dodecahedral	$[Fe(1,8\text{-}naph)_4]^{2+}$
III	d^5	3	Trigonal	$[Fe\{N(SiMe_3)_2\}_3]$
		4	Tetrahedral	$[FeCl_4]^-$
		5	Square pyramidal	$[FeCl(dtc)_2]^{2-}$
		5	Trigonal bipyramidal	$[Fe(N_3)_5]^{2-}$
		6	Octahedral	$[Fe(phen)_3]^{3+}$
		7	Pentagonal bipyramidal	$[Fe(edta)(H_2O)]^-$
		8	Dodecahedral	$[Fe(NO_3)_4]^-$
IV	d^4	4	Tetrahedral	$[Fe(1\text{-}norbornyl)_4]$
		6	Octahedral	$[Fe(diars)_2Cl_2]^{2+}$
V	d^3	4	Tetrahedral	FeO_4^{3-}
VI	d^2	4	Tetrahedral	FeO_4^{2-}

by the diazabutadiene complex [Fe(dab)$_2$], dab = (**6**).[112] Iron(I) complexes are not common, though a number of more or less transient species have been generated by electrochemical or radiolysis techniques, and a small number of stable compounds have been characterized. Thus, an iron(I) catenate has been described,[113] and a series of trigonal bipyramidal [FeCl(dppe)$_2$] (dppe = 1,2-bis(diphenylphosphino)ethane) iron(I) complexes have been reported.

Whereas in many metalloprotein redox systems the oxidation states +II, +III, and +IV are involved, horseradish peroxidase catalysis appears to involve five oxidation states. The interest to coordination chemists of this study goes well beyond bioinorganic systems, for here, as in several cases reported earlier, the X-rays used to obtain the high-resolution structures induced chemical changes during structure determination. The X-rays liberate

electrons, which may change the oxidation state of the metal.[114]

5.2 Iron(II) Complexes

The +II oxidation state of iron has a d^6 electronic configuration, and is one of the two most important, iron(III) being the other (d^5). Most iron(II) complexes have an octahedral geometry, although there are examples of four-, five-, and even eight-coordination. The iron(II) $^5D_2$ ground state is split in an octahedral crystal field into $^5T_{2g}$ and ^5E_g states. High-spin octahedral iron(II) complexes have magnetic moments of about 5.2 BM. The one spin-allowed d-d transition is the broad $^5T_{2g}$ to ^5E_g absorption in the visible/near infrared. Thus, $[Fe(H_2O)_6]^{2+}$ is pale green with an absorption at 10 400 cm^{-1} (and a shoulder at about 8300 cm^{-1}, most likely due to a Jahn–Teller effect in the excited state). With high-field ligands such as aromatic nitrogen donors, low-spin iron(II) complexes result, whose spectra are often dominated by an intense metal to ligand charge-transfer band. Their magnetic moments are typically about 1 BM due to a temperature-independent paramagnetic contribution. The magnetism of some six-coordinate complexes, for example, $[Fe(phen)_2X_2]$, is markedly temperature dependent changing sharply from about 1.5 BM to about 5.1 BM. This spin-crossover phenomenon is well documented, and discussed in Section 6.[115]

Tetrahedral iron(II) complexes are high-spin, with magnetic moments rather higher than predicted for four unpaired electrons due to orbital contributions. The ^5E to$^5T_2$ transition normally occurs at about 4000 cm^{-1}, and magnetic moments are usually in the range 5.0–5.2 BM. Iron(II) chloride in the presence of excess chloride ion and a large cation gives salts of the tetrahedral anion $[FeCl_4]^{2-}$. Other tetrahedral complexes include $[Fe(OPPh_3)_4]^{2+}$, $[Fe\{OP(NMe_2)_3\}_4]^{2+}$, and the iron(II) centers in rubredoxins with four sulfur donor ligands. Many tetradentate macrocycles, including phthalocyanines and porphyrins, form square-planar iron(II) complexes, which often have an intermediate spin ($S = 1$) ground state. These complexes readily acquire additional axial ligands to form six-coordinate complexes, which are frequently low spin. The coordination of dioxygen (and carbon monoxide) is of enormous biological importance in respiration, involving heme systems such as hemoglobin and myoglobin. Although once rare, there are now several examples of five-coordinate iron(II) complexes derived from a tetracoordinate macrocycle with the fifth site occupied by a halide ion. Complexes of tripod ligands such as $[Fe(halide)\{N(CH_2CH_2PPh_2)_3\}]^+$ are examples of five-coordinate iron(II) complexes. High- and low-spin complexes are known with such tripod ligands, as well as with some displaying spin-crossover behavior.[116] Coordination numbers higher than six are unusual for iron(II), but seven coordination is known in several macrocyclic complexes, and eight-coordinate red–orange $[Fe(1,8\text{-naphthyridine})_4]^{2+}$ has a distorted dodecahedral geometry.[117]

5.3 Iron(III) Complexes

Most iron(III) complexes are octahedral. In simple complexes, such as red $[Fe(acac)_3]$, the d^5 center is usually high-spin, with magnetic moments close to the expected 5.9 BM (sS). The affinity of iron(III) for amine ligands is not high, but this is not the case for oxygen donors, and often, bridged species are formed, in which there is antiferromagnetic coupling between the iron atoms. In μ-oxo dimers such as $[\{Fe(salen)\}_2O]$ (5-coordinate), $[\{Fe(porphyrin)\}_2O]$ (5-coordinate), and $[(FeCl_3)_2O]^{2-}$ (4-coordinate), it is sufficient for the magnetic susceptibility to be lowered to less than 2 BM/iron atom. This tendency to form bridged complexes extends to sulfur species, many of which are biologically relevant. However, monomeric five-coordinate complexes such as $[Fe(S_2CNR_2)_2X]$ have three unpaired electrons. Little is known about the d-d transitions of iron(III) because their UV/visible spectra are swamped by edges of intense ultraviolet charge-transfer bands, even simple iron(III) salts in water are yellow. Complexes with very high-field ligands are low spin, for example, $[Fe(phen)_3]^{3+}$ and $[Fe(CN)_6]^{3-}$, and they have higher than predicted magnetic moments due to large orbital contributions that decrease at lower temperatures (typically to about 1.9 BM at 77 K). While iron(III) complexes are usually kinetically labile, the low-spin complexes can be quite inert. Several examples of iron(III) species display spin-crossover phenomenon, for instance, a variety of trigonally distorted octahedral dithiocarbamate complex, $[Fe(S_2CNR_2)_3]$, can be high spin or low spin depending on temperature.

5.4 Higher Oxidation States

There are few simple compounds in which iron has an oxidation state higher than three, though a number of species containing iron(IV), iron(V), or iron(VI) have been characterized. There appears to be no example of iron(VII), but iron(VIII) has been claimed[118] as a disproportionation product of ferrate(VI), $FeO_4{}^{2-}$. Oxidizing anions containing the +IV, +V, and +VI oxidation states are known; Fe–O bond distances are 1.889, 1.807, 1.720, and 1.647 Å in the $Fe^{III}O_4{}^{5-}$, $Fe^{IV}O_4{}^{4-}$ $Fe^{V}O_4{}^{3-}$, and $Fe^{VI}O_4{}^{2-}$ anions.[119] Deep red/purple salts containing discrete tetrahedral $Fe^{VI}O_4{}^{2-}$ units are obtained by anodic oxidation of iron, or by hypochlorite oxidation of freshly precipitated iron(III) hydroxide. Potassium ferrate(VI), K_2FeO_4, is water soluble and fairly stable at high pH. It is a more powerful oxidant than permanganate ($E^o \sim 2$V), and has been used in organic oxidations.[120] Strongly heating appropriate hydroxides affords the mixed oxides Sr_2FeO_4 and Ba_2FeO_4, which contain Fe^{IV} but not discrete anions; structural, electronic, and magnetic properties have been established for Ba_2FeO_4 and for Ba_3FeO_5.[121]

Low-spin green/black $[Fe^{IV}(diars)_2X_2]^{2+}$ is obtained by concentrated nitric acid oxidation of $[Fe^{III}(diars)_2X_2]^{+}$. It is a rather unstable d^4 complex with a large temperature-independent Mössbauer quadrupole splitting ($\sim$3.2 mms^{-1}), consistent with a *trans*-structure. Intensely colored $[Fe^{IV}(S_2CNEt_2)_3]^{+}$ is obtained by mild oxidation (with iodine!) of the corresponding iron(III) complex.[122] Mössbauer chemical shifts of 0.1–0.2 mm s^{-1} and quadrupole splittings of 2.0–2.5 mm s^{-1} have been reported for tris-dithiocarbamatoiron(IV) complexes of this type, consistent with a low-spin configuration (3.2–3.4 BM) in a slightly distorted environment. Iron(IV) is also stabilized by, for example, amido-tetraazamacrocyclic[123] and triamidoamine[124] ligands. Both iron(IV) and iron(V) are stabilized by certain porphyrin ligands,[125] for example, octafluoroporphyrin,[126] and by the tetranegative *S,N,N,S*-donor ligand $(^{-}S)C_6H_4(N^{-})CH_2CH_2(N^{-})C_6H_4S^{-}$.[127] Intermediates containing $Fe^V = O$ are believed to be involved in Gif-type hydrocarbon oxidations by O_2 or H_2O_2 catalyzed by iron complexes such as picolinates.[128]

5.5 Mixed Oxidation State Complexes

Mixed oxidation complexes containing iron(II) and iron(III) are fairly common and examples of both localized and delocalized oxidation states are known. Certainly the oldest and perhaps the most extensively studied is $Fe_4{}^{III}[Fe^{II}(CN)_6]_3 \cdot 14H_2O$, Prussian Blue, whose structure has been reported and oxidation state delocalization extensively probed (see Section 7.1). Mixed oxidation state clusters of the type $[Fe_3O(RCO_2)_6L_3]$, with two iron(III) and one iron(II) centers, have sharp transitions between phases composed of electron localized and delocalized complexes, which are affected by molecules of crystallization. The behavior of these complexes is also complicated by numerous phase transitions. Most phases have localized oxidation states at low temperatures that become delocalized at room temperature. Other solid-state mixed oxidation–state complexes include the oxoferrate $Na_9[Fe^{II}O_3][Fe^{III}O_4]$;[129] spinel systems $M_xFe_{3-x}O_4$, which with $x < 0.5$ have magnetite characteristics but those with $x > 0.6$ are semiconductors implying localization of the Fe(II) state.[130] The mixed oxidation state fluoride Fe_2F_5 is referred to in Section 4.1.1. Electrochemical, homogeneous chemical redox reactions, EPR, and Mössbauer spectroscopy established[131] the series Fe(III)Fe(III), Fe(III)Fe(II), and Fe(II)Fe(II) can be derived from the compound $[C_6H_4(CH_2S)_2Fe^{III}(S)_2Fe^{II}(SCH_2)_2C_6H_4]^{3-}$.

6 SPIN STATES AND SPIN CROSSOVER

For iron(II), the two spin states are high-spin ($^5T_2$; $S = 2$) and low-spin ($^1A_1$; $S = 0$), and for iron(III), the common spin states are high-spin ($^6A_1$; $S = {}^5/_2$) and low-spin ($^2T_2$; $S = {}^1/_2$). The intermediate spin state of $^3/_2$ is known for a number of iron(III) complexes, for example, of porphyrins. The mixed spin state $S = {}^3/_2, {}^5/_2$ has been observed,[132] and even $S = 2$ ($S = {}^3/_2, {}^5/_2$ coupled) in a peroxo-μ-oxodi-iron(III) complex.[133] Values of S as high as 10 and 11, for Fe_8 and Fe_{10} complexes, have been reported.[134] Spin-crossover complexes exist both for iron(II) and for iron(III). The spin-crossover phenomenon is of intrinsic interest and potential practical importance. The marked magnetic and optical[135] changes associated with low-spin/high-spin changeover make spin-crossover compounds strong candidates for controlling molecular switching,[136] and thermal hysteresis confers memory possibilities. Applications in temperature sensors, optical switching, information storage and retrieval, and memory devices[137] will be optimized by the use of polymeric species, where interactions and cooperation magnify the desired effects.[138] Density functional calculations for high-spin and low-spin forms of nine iron(II) complexes, including the familiar $[Fe(phen)_2(NCS)_2]$ and several bis-ligand complexes of terdentate ligands such as tris(2-pyridylmethyl)amine and tris(1-pyrazolyl)methane have been reported.[139] A short general review[141] of crystal structures, magnetic properties, and Mössbauer and vibrational spectroscopy of iron(II) spin-crossover complexes,[140] and a review covering the design and synthesis of such complexes, are available.[142] Spin crossover is determined by temperature, pressure, and by ligand field strengths, which can be tuned by ligand variation. A review of structural changes accompanying spin-state transitions summarizes information on a range of Fe^{2+} and Fe^{3+} complexes, after detailing the important case of $[Fe(2\text{-pic})_3]Cl_2 \cdot CH_3OH$ (2-pic = 2-(aminomethyl)pyridine).[143]

Spin-crossover kinetics for Fe(II) complexes have been reviewed,[144] and enthalpies, entropies, and rate constants for a range of Fe(II) and Fe(III) spin-crossover complexes documented.[145] Thermodynamic and kinetic parameters, iron-ligand bond distance and volume changes, and calorimetric data relating to the low-spin/high-spin transition in solution and in the solid state obtained prior to 1991 have been fully documented and discussed.[146] A selection of thermodynamic and kinetic parameters for the spin-crossover complexes of 2-(2-pyridyl)imidazole (pyim) and *N*-(2-pyridylmethyl)picolinamidine (ppa),[147] tetrakis(2-pyridylmethyl)-*trans*-1,2-cyclohexanediamine (tpchxn),[148] 3-(1,10-phenanthrol-2-yl)-5-methyl-1,2,4-oxadiazole (phenmethoxa),[149] and 1,4,7-triazacyclononane (tacn)[150] in various solvents are given in Table 6. Activation parameters are primarily determined by the ease with which the ligands can twist, thus the hexadentate ligands (**7**) cause considerable impediments to the movement required for spin change. The ease of twisting may be determined by solvation effects as much as by intrinsic rigidity of the complex itself.[151] The effect of solvent of crystallization on the ease of spin-state transitions has been explored, by high-resolution deuterium NMR spectroscopy,

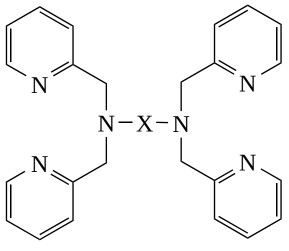
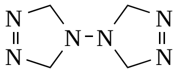
for polymeric $[Fe(1,2,4\text{-triazole})_3](ClO_4)_2.nD_2O$ and its 4-amino derivative.[152] An unusual application of isokinetic relationships has been to spin-crossover systems, especially of Fe(II) complexes.[153]



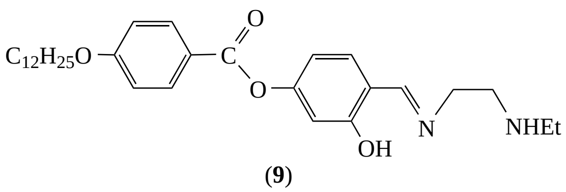
X = CH_2CHMe, CHMeCHMe,

(**7**)



(**8**)

Activation volumes for spin crossover are generally between 0 and $+10\,cm^3\,mol^{-1}$ for low spin → high spin, and close to $+6\,cm^3\,mol^{-1}$ for the reverse, for a range of tris-diimine (e.g. 2-pyridylimidazole), bis-terimine, and hexadentate linked-bis-terimine complexes. The derived volume profiles indicate that transition states are approximately midway between initial and final states.[154] X-ray absorption spectroscopy (XANES) can give useful information on structural changes associated with pressure-induced spin crossover, as was demonstrated for a selection of well-established 'traditional-crossover' systems, such as $[Fe(phen)_2(NCS)_2]$, and other spin-crossover complexes. Increasing the pressure on a high-spin sample of the hydrate or ethanol solvate of $[Fe(pic)_3]Cl_2$ involves iron-ligand and hydrogen-bonding distance changes. Pressure effects sometimes show that a change in spin state is not a single simple process. Thus, increasing the pressure applied to high-spin $[Fe(btrz)_2(NCS)_2]$, where btrz = 4,4′-bis-1,2,4-triazole (**8**), produces a second high-spin modification before the change to the low-spin state.[155] The *cis*-1,2-bis(diphenylphosphino)ethene complexes $[Fe(Ph_2PCH{=}CHPPh_2)_2X_2]$, X = Cl or Br, undergo pressure-induced spin-state transitions at about 8 kbar and about 60 kbar respectively.[156] Several iron complexes are mentioned in a review of pressure effects on spin crossover and associated effects on electronic spectra.[157]



(**9**)

The NO_3^- and PF_6^- salts of the iron(III) complex of the terdentate phenolate anion of the liquid crystal Schiff base (**9**) provide the first example of the coexistence of spin transition and liquid crystal properties in a single compound. The ligand needs to be tuned to increase the spin-crossover transition temperature and decrease the transition temperature to the liquid crystal state.[158]

A unique type of spin-crossover behavior is claimed for the mixed-valence dithiooxalate salt ${}^{n}Pr_4N[Fe^{II}Fe^{III}(dto)_3]$.[159] Here, the spin change is associated with electron transfer, equation (2), with the bridging dithiooxalate favoring Fe^{III}–S bonding at higher temperatures, Fe^{III}–O bonding at lower temperatures:[160]

$$(dto)_2Fe^{II}(S_2C_2O_2)Fe^{III}(dto)_2 \underset{110\,K}{\overset{120\,K}{\rightleftharpoons}} (dto)_2Fe^{III}(S_2C_2O_2)Fe^{II}(dto)_2 \tag{2}$$

7 CYANIDE COMPLEXES

7.1 Hexacyano Complexes

Iron forms exceptionally stable complexes with cyanide ion. Hexacyanoferrate(II), $[Fe(CN)_6]^{4-}$, the ferrocyanide anion, is readily formed[161] ($\Delta H^0 = -358.9\,kJ\,mol^{-1}$) upon the addition of excess cyanide to solutions containing $[Fe(H_2O)_6]^{2+}$. Red hexacyanoferrate(III), $[Fe(CN)_6]^{3-}$, the ferricyanide anion, is readily prepared by oxidation of the corresponding Fe(II) species by chlorine. The iron(III) complex is both more toxic and more labile in terms of ligand substitution than its iron(II) analog. Both $H_4[Fe(CN)_6]$ and $H_3[Fe(CN)_6]$ are known. The Fe–C bond is 0.03 Å shorter in the iron(II) complex (1.92 Å) despite its larger size, due to enhanced π-bonding in the +2 oxidation state ion. The cyanide ion is capable of bridging metal centers, and polymeric transition metal cyanides are well known; many salts of the hexacyanide complexes involve M-N coordination. The Prussian and Turnbull Blues are important examples. Often cited as the first isolated coordination complex,[162] Prussian Blue (PB) is produced (Diesbach, 1704) as a voluminous dark blue precipitate when an excess of an iron(III) salt reacts with $[Fe(CN)_6]^{4-}$. Turnbull's Blue results from the reaction of excess iron(II) with $[Fe(CN)_6]^{3-}$. Only recently was there a claim[163] for the first characterization of authentic Turnbull's Blue, a valence-trapped (Robin and Day Class I[164]) compound. The intense coloration and lightfastness of PB and its family of complexes has led to a long history of exploitation as pigments, the more common examples are listed in Table 7. More recently however, their electrochemical properties in the form of thin films have attracted attention[165] – PB is photoswitchable.[166] The PB family share similar structures in which well-defined octahedral cyanide coordination sites are bridged by cyanide in a cubic array. The individual iron atoms may be iron(II) (low-spin) with Fe–C bonds, or iron(III) (high-spin) with Fe–N bonds, and intense colors arise from electron transfer from the ferrocyanide ground

Table 7 The Prussian Blue family

Trivial Name	Idealized formula	Reference
Soluble Prussian Blue	$KFe^{III}[Fe^{II}(CN)_6]$	*a*
Insoluble Prussian Blue	$Fe_4^{III}[Fe^{II}(CN)_6]_3$	*a*
Prussian Brown and Berlin Green	$Fe^{III}[Fe^{III}(CN)_6]$	*b,c,d*
Prussian Green	$KFe_3{}^{III}[Fe^{II}(CN)_6][Fe^{III}(CN)_6]_2$	*b,c*
Prussian White and Everitt's salt	$K_2Fe^{II}[Fe^{II}(CN)_6]$	*b*

Note: [a]D. Davidson, *J. Chem. Educ.*, 1937, **14**, 277. [b]J. F. De Wet and R. Rolle, *Z. Anorg. Allg. Chem.*, 1965, **336**, 96. [c]P. Ellis, M. Eckhoff and V. D. Neff, *J. Phys. Chem.*, 1981, **85**, 1225. [d]N. V. Sidgwick, ''The Chemical Elements and Their Compounds'', Oxford University Press, London, 1958, 1339.

state. When both iron environments contain only iron(II), the resulting salt is not colored (Prussian White). The oxidation state localization in PB has been studied extensively.[167] Structures, electrochemical behavior (electrodes; batteries), and uses in medicine (treatment of ^{137}Cs and of thallium poisoning) of Prussian Blue are mentioned in a review of cyanide complexes.[168] In cobalt–iron Prussian Blue analogues, $Na_xCo_yFe(CN)_6{\cdot}zH_2O$ electronic and spin states are controlled by temperature and the ligand field strength around the Co^{2+} ions, which in turn is determined by the Co:Fe ratio.[169]

Solubility data (pK_{sp}) for two dozen hexacyanoferrate(II) and hexacyanoferrate(III) salts, and Pourbaix (pe/pH) diagrams for several multicomponent, iron–cyanide-containing systems, are given in a review ostensibly dedicated to hydrometallurgical extraction of gold and silver.[170] Kinetics of hexacyanoferrate(II) reductions and hexacyanoferrate(III) oxidations, and of hexacyanoferrate(II)/(III) electron exchange, have been intensively studied for several decades,[171] often as a probe of medium effects.[172] Pressure effects on the kinetics of the $[Fe(CN)_6]^{3-}$/$[Fe(CN)_6]^{4-}$ reaction have been studied in solution and at electrodes,[173] while factors controlling electron diffusion in electroactive polymer films have been probed by studying the dynamics of incorporated $[Fe(CN)_6]^{3-}$/$[Fe(CN)_6]^{4-}$.[174]

Hexacyanoferrate(II). $K_4[Fe(CN)_6]$ has been used to photosensitize TiO_2.[175] The acidity constants for $H_4[Fe(CN)_6]$ are $pK_1 = 2.54$, $pK_2 = 1.08$, $pK_3 = 2.65$, $pK_4 = 4.19$.[176] Association constants have been published for alkali metal cations ion pairing with hexacyanoferrate(II).[177] Substitution at hexacyanoferrates(II) is very difficult, though it can be catalyzed by metal ions such as Hg^{2+}. Such catalysis can be augmented by surfactants such as sodium dodecyl sulfate (SDS), and indeed SDS-catalysis of Hg^{2+}-catalyzed replacement of cyanides in $[Fe(CN)_6]^{4-}$ by 1,10-phenanthroline has been proposed as an analytical method for the determination of mercury.[178]

Hexacyanoferrates(III). These are of particular interest as pigments and in relation to kinetics and mechanisms of intramolecular electron transfer. The structure of $Bi[Fe(CN)_6]{\cdot}4H_2O$ has been elucidated,[179] and $Ce[Fe(CN)_6]{\cdot}5H_2O$ and $Gd[Fe(CN)_6]{\cdot}4H_2O$ studied by X-ray crystallography and Mössbauer spectroscopy.[180]

7.2 Pentacyano Complexes

A convenient synthesis of the aquapentacyanoferrate(II) ion, $[Fe(CN)_5(H_2O)]^{3-}$, which is a good starting point for many $[Fe(CN)_5L]^{3-}$ complexes, involves reduction of nitroprusside in the presence of ammonia, equation (3), and hydrolysis of the resulting complex at room temperature.[181] The iron(II) complex is best formed in the presence of a small amount of ascorbic acid, which prevents oxidation to iron(III).

$$[Fe(CN)_5NO]^{2-} + 2NH_3 + OH^- \longrightarrow [Fe(CN)_5NH_3]^{3-} + N_2 + H_2O \qquad (3)$$

Photolysis of $[Fe(CN)_6]^{4-}$ in aqueous solutions yields some $[Fe(CN)_5(H_2O)]^{3-}$, but both this synthesis and the route via reduction of nitroprusside ions also result in the formation of dimeric species. Two of the observed species are the complex ions $[Fe_2(CN)_{10}]^{6-}$ and $[Fe_2(CN)_{11}]^{7-}$. The former is thought to contain an aqua ligand and a linear cyanide bridge.[182] There have been numerous studies of the kinetics of ligand replacement in $[Fe(CN)_5L]^{n-}$ complexes. For the most part, these reactions involve dissociative rate limiting ligand loss, which is accompanied by large positive entropies of activation and volumes of activation. Both the strength of the iron-ligand bond and solvation effects are important in these reactions since they contribute significantly to the volume of activation.[183] The electronic spectra of the pentacyano complexes contain a L $\rightarrow$ Fe charge-transfer band, which along with ligand pK_a values has been used to assess the relative contributions of σ- and π-bonding to the linkage. The marked solvatochromism of these charge-transfer bands has been suggested as a probe for selective solvation.[184]

7.3 Carbonyl Cyanides

It has been known since the nineteenth century that hexacyanoferrates(II) react with concentrated sulfuric acid to give carbon monoxide; the concurrent formation of $[Fe(CN)_5(CO)]^{3-}$ was reported[185] in 1913. Conversion of coordinated –CN into –CO probably proceeds through $-CONH_2$.[186] The stereospecific formation of *fac*-$[Fe(CN)_3(CO)_3]^-$ then *cis*-$[Fe(CN)_4(CO)_2]^{2-}$ from $[Fe(CO)_4I_2]$, as well as the stereospecific production of *trans*-$[Fe(CN)_4(CO)_2]^{2-}$ from iron(II) chloride plus cyanide in

an atmosphere of CO, appears to be under kinetic control. *cis*-$[Fe(CN)_4(CO)_2]^{2-}$ decomposes rapidly in aqueous solution, whereas the *trans* isomer, first reported in 2001,[187] decomposes relatively slowly. *fac*-$[Fe(CN)_3(CO)_3]^{-}$ and *cis*-$[Fe(CN)_4(CO)_2]^{2-}$ have infrared-spectra characteristics of their C_{3v} and C_{2v} geometries; their carbonyl stretching frequencies are somewhat solvatochromic.[188] The presence of both cyanide and carbonyl bonded to iron is a feature of iron–nickel and iron-only hydrogenases.[189] The limiting member of the carbonyl cyanide series is the hexacarbonyl anion $[Fe(CO)_6]^{2+}$, long elusive but eventually prepared and characterized as its $[SbF_6]^{-}$ and $[Sb_2F_{11}]^{-}$ salts.[190]

8 COMPLEXES WITH NITROGEN DONORS

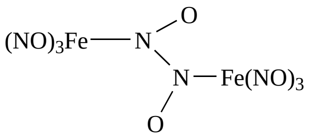
8.1 Monodentate Ligands

Iron(II) and iron(III) form important series of complexes with a variety of nitrogen-donor ligands, ranging from nitric oxide, azide,[191] and ammonia, through mono-, bi-, and polydentate amines, diimines (Section 8.2), and a range of tetraaza-macrocycles to phthalocyanines and porphyrins. However, the tendency of iron(III) to complex with ammonia or simple amines is rather low, while many iron(II) complexes are high-spin and susceptible to oxidation. Relative stabilities of the +2 and +3 oxidation states are markedly ligand-dependent (Figure 4). Ligands with two or more nitrogen-donor sites, such as azide,[192] pyrazine,[193] or 4,4′-bipyridyl can act as bridging ligands, to give binuclear complexes or infinite layers or 3-D structures. Thiocyanate (see Section 4.6) generally prefers to bond to iron through nitrogen, but can bridge pairs of iron atoms, as in the *trans*-1,2-bis(4-pyridyl)ethene complex $[Fe(bpe)_2(NCS)_2]$.MeOH, which is a supramolecular coordination polycatenane consisting of two interpenetrating 2-D networks.[194] Dinitrogen itself is reluctant to complex with iron, though diphosphine ligands help to stabilize iron-dinitrogen complexes, of iron(II), iron(I), and iron(0).[195] Dinitrogen is end-on (σ; η^1) bonded both in the octahedral $[Fe^{II}Cl(N_2)(depe)_2]^{+}$ anion[196] and in the trigonal bipyramidal $[Fe^{0}(N_2)(depe)_2]$.[197] Dinitrogen can also act as a bridging ligand, as in $[(OC)_2(Et_3P)_2Fe^{0}(\mu\text{-}N_2)Fe^{0}(PEt_3)_2(CO)_2]$.[198]

8.1.1 Nitric Oxide Complexes

General. Nitric oxide readily forms complexes with transition metals and is in many ways similar to carbon monoxide. It has a single electron in a π^* antibonding electron, which is easily lost. When NO is not bridging, molecular orbital theory would predict a linear $M\text{-}NO^{+}$ moiety and that $M\text{-}NO^{-}$ would be bent. In principal, this would seem to allow a ready indication of the metal oxidation state from an X-ray structure or even examination of the infrared spectrum of the complex. The reality is frequently more complex and it is difficult to assign a formal oxidation state to many iron nitric oxide complexes. A scheme of corrections to the observed NO stretching frequencies has been proposed and, by taking account of the atomic number and coordination number of the metal, the other ligands present in the complex, and its overall charge, it has been possible to predict the geometry of the M-NO group with more accuracy.[199]

Binary Nitric Oxide Complexes. A binary iron nitrosyl complex is not known, although described in early reports as $[Fe(NO)_4]$, the compound having that stoichiometry is a dimer with an N_2O_2 bridging ligand (**10**).



(**10**)

The chloride dimer $[Fe(NO)_2Cl]_2$ also exists, and can be reduced in THF solution to '$Fe(NO)_2$', which is most likely $[Fe(NO)_2(THF)_n]$. The brown color of the familiar, so-called, Brown Ring Test for nitrate in which the sample is treated with ferrous sulfate and sulfuric acid is due to the formation of the nitric oxide complex $[Fe(H_2O)_5NO]^{2+}$.

Nitroprusside. The action of nitric acid or sodium nitrite on $[Fe(CN)_6]^{4-}$ generates sodium nitroprusside, $Na_2[Fe(CN)_5NO]\cdot 2H_2O$, perhaps the best-known transition metal nitrosyl complex. Barium chloride is added to the hot reaction mixture and HCN removed in a stream of carbon dioxide to give the overall reaction shown in equation (4). The red sodium salt dissolves readily in water and alcohol, and aqueous solutions decompose in light. Several of the low-spin salts show a tendency toward high-spin at very high pressures. The X-ray photoelectron spectrum of the nitroprusside ion indicates a positive charge on NO of +0.35; whilst this is consistent with the Mössbauer spectrum and the short Fe–N bond (1.63 Å), one might expect a higher charge considering the N–O bond length (1.13 Å), Fe–N–O angle of 180° and NO stretching frequency (1947 cm^{-1}). $[Fe(CN)_5NO]^{2-}$ can be reduced, for example, by sodium in liquid ammonia, to form $[Fe(CN)_5NO]^{3-}$. Theoretical calculations predict a *cis*-cyanide will be lost to yield a tetragonal pyramid, $[Fe(CN)_4NO]^{2-}$, and this is indeed observed.[200]

$$2[Fe(CN)_6]^{4-} + 2NO_2^{-} + 3Ba^{2+} + 3CO_2 + H_2O \longrightarrow 2[Fe(CN)_5NO]^{2-} + 2HCN + 3BaCO_3 \quad (4)$$

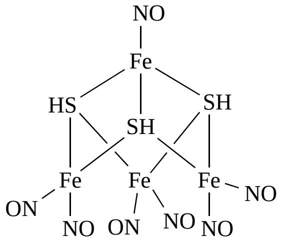
$Na_2[Fe(CN)_5(NO)]$ reacts in methanol at 2 °C with aqueous NaOH to form the yellow nitro complex $Na_4[Fe(CN)_5NO_2]$. This can be hydrolyzed to $[Fe(CN)_5(H_2O)]^{3-}$, which is also the

final product of reactions between nitroprusside and ketones involving highly colored intermediates. The nitroprusside ion is well known for such color reactions, most of which result from a nucleophilic attack on coordinated NO followed either by displacement or the formation of a new ligand. Examples of such reactions abound, for example, the Gmelin test for SH^- (purple/violet) or the identification of mercaptans in mildly basic solution (red/purple) are useful applications. In some cases, these colors develop further and eventually become blue. The chemistry of this color evolution is uncertain but the final color is thought[201] to be due to the $[Fe(CN)_5(NCS)]^{3-}$ ion, which can be obtained directly from nitroprusside and thiocyanate ions (e.g. by photolysis). Solutions of salts of this complex ion vary dramatically in color depending on the solvent. The ammonia complex $[Fe(CN)_5(NH_3)]^{3-}$, is formed by the reaction of nitroprusside with ammonia in both stoichiometric and excess quantities, in the latter case nitrogen is evolved, whilst in the former nitrite ion is the coproduct.

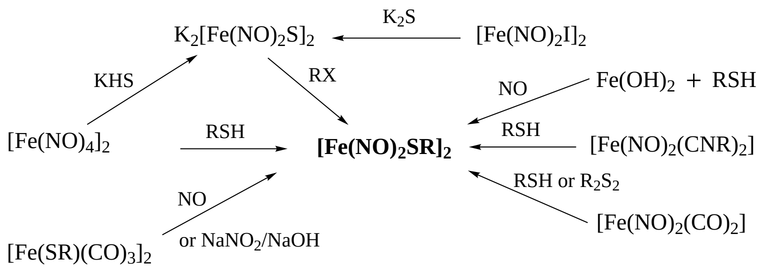
$Na_2[Fe(CN)_5(NO)]$ rapidly lowers blood pressure and has been used in both surgical and emergency applications. Caution has been advised because of the possibility that free cyanide is formed in vivo, although it is possible that its detection may have resulted from photodecomposition during colorimetric determinations.[202] The April 2002 issue of *Chemical Reviews* contains several references to nitroprusside chemistry.

Nitric Oxide Carbonyl Complexes. Whilst binary iron nitrosyls do not appear to exist as discrete complexes, mixed nitrosyl carbonyls do. $[Fe(CO)_2(NO)_2]$ is readily formed in a number of reactions including the treatment of iron carbonyls with nitric oxide or nitrosyl chloride, and the reaction of $[HFe(CO)_4]^-$ with nitrite ion in acidic solution. The complex is a distorted tetrahedron,[203] it forms red, air-sensitive crystals, which melt at 18 °C and can be readily transferred around a vacuum system. In reactions with a variety of ligands, carbon monoxide displacement is observed and both mono and dimeric complexes result. The kinetics of these reactions are second order and the mechanism is thought to be bimolecular with the new ligand forming a five-coordinate transition state.[204] The substitution is catalyzed by hard bases, presumably via attack on a CO carbon atom making a more labile leaving group. Many salts of the $[Fe(CO)_3(NO)]^-$ ion are known, for example, bright yellow $[(Ph_3P)_2N][Fe(CO)_3(NO)]$, which is formed in the reaction between $[Fe(CO)_5]$ and $[(Ph_3P)_2N](NO_2)$ in THF. The anion can be isolated as $[Hg\{Fe(CO)_3(NO)\}_2]$ by reaction with mercurous cyanide in methanol; the structure contains a linear Fe-Hg-Fe grouping with trigonal bipyramidal iron. π-Acceptor ligands readily displace carbon monoxide from this complex with no change to the geometry of the metal atoms to form $[Hg\{Fe(CO)_2(NO)L\}_2]$ ($L = R_3P, R_3As, R_3Sb, (RO)_3P$). Reaction with nitrogen bases however leads to disproportionation, for example, in the case of pyridine to form a mixture of $[Fe(py)_6][Fe(CO)_3NO]$ and $[Fe(py)_2(NO)_2]$.

Nitric Oxide Complexes with Sulfur Donors. First reported in 1858, Roussin's red and black salts are formed in a mixture when iron(III) sulphide reacts with nitric oxide and an alkali metal sulfide. Some more convenient routes to the red salt, $K_2[Fe(NO)_2S]_2$ and the dark red diamagnetic so-called esters are shown in Scheme 1. These are dimeric and have a structure with two iron and two sulfur atoms in a plane. The sulfur atoms bridge an Fe–Fe bond and two NO molecules are coordinated to each iron to give a tetrahedral geometry. The black salts $M[Fe_4S_3(NO)_7]$ (M = Na, K, Cs, $AsPh_4$) may be prepared from iron(II) sulfate, $NaNO_2$, and KHS, or by the nitrosylation of iron carbonyl sulfides. The structure is of a trigonal pyramid of iron atoms with triply bridging sulfur atoms and terminal NO groups (**11**). Bonding comparisons with the cluster $[Fe_4(NO)_4(\mu_3\text{-}S)_4]$ reveal close relationships with both the red and black salts, and suggest a common building block. Preparations and properties of $[Fe_2S_2(NO)_4]^{2-}$, $[Fe_4S_4(NO)_4]$, and $[Fe_4S_3(NO)_7]^-$ have been reviewed,[205] photolysis of these complexes described,[206] and the preparation of $[Fe_5S_4(NO)_8]^-$ and $[Fe_7S_6(NO)_{10}]^-$ reported.[207]



(**11**)



Scheme 1

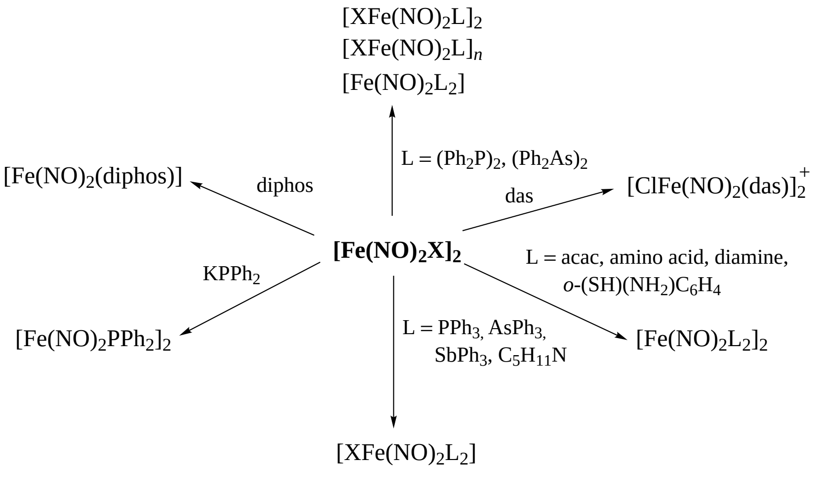
In methanol, nitric oxide and $Na_2S_2CNR_2$ react with iron(II) salts to form the paramagnetic bis-dithiocarbamato iron nitrosyl complexes $[Fe(NO)(S_2CNR_2)_2]$. The structure is a square pyramid with iron at the apex and the N–O bond is almost linear (Fe–N–O = 174° when R = Et). The EPR and Mössbauer spectra of a number of these complexes support their description as formally d^7 iron(I) complexes, in which the unpaired electron resides in the iron d_{z^2} orbital. The nitrosyl-iron group is also stabilized by dithiolenes and the resulting $[Fe(NO)(S_2C_2R_2)_2]^z$ complexes ($z = 0, -1, -2, -3$) have the same square-pyramidal geometry. These complexes undergo a series of sequential one-electron transfer reactions, which can be demonstrated voltametrically.[208] The ease of electron transfer, as measured by the half-wave potential for each step, correlates strongly with the ligand R groups as a function of their electron-withdrawing ability. When $[Fe(NO)(S_2C_2Ph_2)_2]$ is formed by the reaction between nitric oxide and $[Fe(S_2C_2Ph_2)_2]_n$ in chloroform, purple $[Fe_2(NO)_2(S_2C_2Ph_2)_3].CHCl_3$ may also be isolated and a green monoanionic form can be obtained by reaction of the complex with $NaBH_4$.

Nitric Oxide Halide Complexes. The dimeric diamagnetic halides $[Fe(NO)_2X]_2$ have essentially tetrahedrally coordinated iron atoms with bridging halides. The trinitrosyl halides $[Fe(NO)_3X]$ are comparatively much less stable; they can be prepared by the reaction of $[Fe(CO)_2X]_2$ with iron and nitric oxide. The complexes $[Fe(NO)X_3]$ and $[Fe(NO)_2X_2]$ are known but much more work has been done on the reactivity of the dimeric dinitrosyl, and some of its reactions are illustrated in Scheme 2.

Nitric Oxide Adducts of Other Complexes. Simple nitrosyl complexes containing σ-N donor ligands are rare, as these 'hard' bases do not allow the appreciable d-π interaction required to stabilize the Fe–NO group. As a result, nitric oxide forms adducts with complexes whose ligands can offer a π-acceptor character. In particular planar macrocycles with N-donors such as phthalocyanine, tetraphenylporphyrin and tetraazacyclotetradecane form five-coordinate mono-nitrosyl iron complexes. Nitrosylhemoglobin and nitrosylmyoglobin have been described, as has [Fe(salen)(NO)] [salen = N,N′-ethylenebis(salicylideniminato)]. This black complex exhibits a sharp $S = 3/2$ to $S = 1/2$ spin crossover at 175 K, interestingly when the ligand is 5-Cl-salen, the crossover is not sharp but the complex shows a steady decrease in its magnetic moment from 3.8 to 0.5 BM between 4 and 100 K. These $S = 3/2$ to $S = 1/2$ spin equilibria are a general feature of iron nitrosyl complexes of quadridentate Schiff bases and similar ligands.[209]

8.1.2 *Ammonia*

Iron(III) ammine complexes appear not to exist in aqueous solution, and when solutions of ammonia and an iron(III) salt are mixed, a highly insoluble hydrated oxide is precipitated. In comparison, iron(II) hydroxide is relatively soluble (solubility product ca. 3×10^{-14}). Initially, when ammonia is added to an iron(II) salt solution, the hydroxide is precipitated but the addition of further ammonia causes it to dissolve, due in part to ammine complex formation. Anhydrous iron(III) halides are reported to form only moderately stable adducts with ammonia ($FeCl_3 \cdot 6NH_3$, decomposes at 100 °C) that are unstable in the presence of water, whereas many anhydrous iron(II) salts readily absorb ammonia to form ammine complexes up to the hexammine. Thus, saturating a solution of freshly prepared iron(II) bromide with ammonia in the presence of hydrogen gives a hydroxide precipitate that is converted[210] to light blue–gray crystals of moderately stable $[Fe(NH_3)_6]Br_2$, which has an Fe–N stretching frequency in the infrared at 315 cm^{-1}. $[Fe(NCS)_2(NH_3)_2]$ is the product of the evolution of ammonia, at room temperature, from the various ammines of iron(II) thiocyanate, $Fe(NCS)_2 \cdot nNH_3$ (n = 5, 7, or 8).[211]

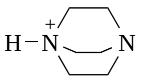


Scheme 2

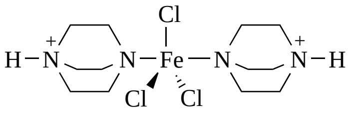
$[Fe(NH_3)_6]^{2+}$ and $[Fe(en)_3]^{2+}$ have proved useful counterions for crystallization of salts of, for example, the $[AgAsS_4]^{2-}$, $[AgSbS_4]^{2-}$, and $[Sb_2Se_5]^{4-}$ anions.[212]

8.1.3 *Aliphatic Amines*

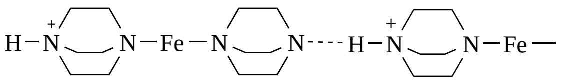
Iron(II) chloride reacts directly with excess anhydrous primary amines to give complexes of the type $[Fe(NH_2R)_2Cl_2]$, which are thought to have a distorted tetrahedral geometry. Under similar conditions, iron(III) chloride is reduced and the same product is obtained. Iron pentacarbonyl reacts[213] with anhydrous primary and secondary amines to give an adduct first, which, whilst it can involve two amine molecules, goes on to give $[Fe(CO)_4(amine)]$. Iron(II) forms some interesting complexes with tertiary amines. The monodentate monoprotonated ditertiary ligand $dabcoH^+$ (**12**) in anhydrous ethanol reacts with iron(II) halides to give unusual high-spin (5.1–5.2 BM) trigonal bipyramidal five-coordinate complexes, $[FeX_3(dabcoH^+)_2]X$ (**13**) with X = Cl, Br. Under slightly different conditions, the bridged complex $[FeCl_3(dabco)(dabcoH^+)]$ (**14**), is the product, and when heated, this loses dabco to give tetrahedral $[FeCl_3(dabcoH^+)]$. The less stable complexes $[FeX_3(dabcoMe^+)(L)]$ containing methylated dabco (X = Cl, Br; L = NH_3, H_2O) can be obtained. In contrast with iron(II) iodide, only the tetrahedral complex $[FeI_3(dabcoH^+)]$ is detected. The related monotertiary amine quinuclidine (**15**) in which electrostatic and hydrogen-bonding effects are absent simply forms a four-coordinate (pseudotetrahedral) complex $[FeCl_2(quinuclidine)_2]$.



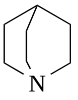
(**12**)



(**13**)



(**14**)



(**15**)

8.1.4 *Aromatic Amines*

Iron(II) sulfate forms compounds of the type $[Fe(SO_4)(L)_2]$ by direct reaction with aniline and *para*-toluidine. In solution, the affinity of iron(II) for pyridine is very low ($\log \beta_2 \sim 0.9$). In the presence of a large excess of pyridine, neutral complexes of the type $[FeX_2(py)_4]$ can be prepared. Yellow *trans*-$[FeCl_2(py)_4]$ (5.34 BM) is precipitated when a saturated solution of $FeCl_2{\cdot}4H_2O$ is added to pyridine. It is more stable toward oxidation than simple iron(II) salts, and has the advantage of being moderately soluble in organic solvents. When heated in the absence of air, successive pyridine molecules are lost with the formation of three polymeric complexes.[214] The related complexes $[FeCl_2(4\text{-}Mepy)_4]$ and $[Fe(NCS)_2(py)_4]$ each form only a single well-defined intermediate with two pyridine ligands when heated. The complexes *trans*-$[FeI_2(py)_4]$.2py (5.64 BM) and *trans*-$[Fe(NCO)_2(py)_4]{\cdot}2py$ (5.13 BM) do not contain $[Fe(py)_6]^{2+}$. They show infrared bands due to free and coordinated pyridine, and have other spectroscopic properties in accordance with the given formulation. The complex $[Fe(NCS)_2(py)_4]$ can be obtained in yellow and black forms, once thought to be *cis* and *trans* isomers. However, X-ray crystallography showed[215] the yellow complex to be *trans*-$[Fe(NCS)_2(py)_4]$, and the black complex has effectively the same Mössbauer and magnetic properties. It appears both forms have the same structure, but the black form contains small amounts of iron(III) and its black color is due to charge transfer. Thus yellow *trans*-$[Fe(NCS)_2(py)_4]$ does not darken under oxygen-free conditions, and the dark violet solutions formed by exposure to air are converted to yellow by sulfur dioxide. The cation $[Fe(py)_6]^{2+}$ can be prepared by reaction of pyridine with iron pentacarbonyl. The product $[Fe(py)_6][Fe_4(CO)_{13}]$ has a high-spin iron(II) center (5.47 BM), and in $[Fe(py)_6]^{2+}$ the ligands are in three mutually perpendicular planes with each pair of *trans* pyridines being coplanar.[216]

8.2 Bidentate Amines

8.2.1 *Aliphatic Diamines and Polyamines*

The $[Fe(en)_3]^{2+}$ structure[217] was recently redetermined; the average Fe–N bond distance is 2.192 Å. In aqueous solution, ethylenediamine (en) forms mono, bis, and tris complexes with iron(II), having successive enthalpies of formations of 21.1, 43.5, and 66.3 kJ mol^{-1} respectively, and data for many other polydentate amines have been reported.[218] Slow addition of en to iron(III) chloride in ethanol affords low-spin $[Fe(en)_3]Cl_3$ (2.45 BM), which has only a small Mössbauer quadrupole splitting (1.09 mm s^{-1}) compared with the 1,4-diimine complexes discussed below, consistent with a small distortion from octahedral symmetry. However, the corresponding iron(II) complex can result if reaction conditions are changed. Thus, anhydrous en or propylenediamine react with iron(III) chloride to give tris-ligand iron(II) complexes, while bis(2-dimethylaminoethyl)methylamine reacts with iron(II) chloride to give the very air-sensitive, high-spin, five-coordinate $[Fe\{(Me_2NEt)_2NMe\}Cl_2]$, and the bulky ligand N,N,N',N'-tetramethylethylenediamine gives tetrahedral $[Fe(tmen)I_2]$.[219] Related iron(II) complexes have been isolated with tri- and tetradentate amines. For instance, $[Fe(Me_6tren)Br]Br$ has trigonal bipyramidal geometry, although it appears that in solution, six-coordinate species are present. A problem with these reactions can be precipitation of iron hydroxide rather than complex formation, and with 3,3′,3″-triaminotripropylamine, an iron(II) complex could not be obtained for this reason. An interesting feature of the iron(II)

tetraethylenepentamine (tetren) complex is that it forms[220] a mono carbon monoxide adduct, $[Fe(tetren)CO]^{+}$.

8.2.2 1,4-Diimine Ligands

Historical. Fritz Blau obtained[221] the stable intensely red cation $[Fe(bipy)_3]^{2+}$ in 1888. He used the sensitive color reaction to monitor the presence of 2,2′-bipyridine (bipy) in its synthesis from the pyrolysis of copper(II) picolinate. Ten years later he reported[222] the synthesis of 1,10-phenanthroline (phen) and its red tris-ligand iron(II) complex. In 1912, Werner[223] demonstrated the octahedral geometry of $[Fe(phen)_3]^{2+}$ by resolving its optical isomers. Later, this complex was shown to be a high-potential redox indicator, and it also became much used in the colorimetric determination of iron.[224] Several tris-iron complexes of this type have significant antibacterial activity, but they appear never to have been introduced commercially. Resin-supported $[Fe(bipy)_3]^{2+}$ has recently been proposed as a catalyst for photochemical degradation of organic pollutants by molecular oxygen.[225] A wide variety of 1,4-diimine ligands have been synthesized and properties of their iron complexes investigated. Here, the primary focus is on complexes of the prototype ligands bipy and phen, and a final section outlines the reactivity differences of iron complexes with other 1,4-diimines.

Tris Complexes. In the absence of steric effects, 1,4-diimines in iron complexes are high-field ligands due to back donation of t_{2g} metal electron density into unfilled ligand orbitals. Many octahedral iron(II) tris-diimine complexes are low spin, often with a small temperature-independent paramagnetism of about 1 BM. Strong, metal to ligand charge-transfer bonds cause[226] the complexes to be intensely colored (Table 8). Crystal structures of some iron(II) and iron(III) tris-diimine complexes have been reported: in $[Fe(phen)_3]^{2+}$, the small bite of the ligand results in some compression along the pseudo threefold axis as well as some twist from an exactly octahedral geometry.[227] The mean Fe–N bond distances in the iron(II) and iron(III) complexes are the same, 1.97 Å.[228]

Many tris-(1,4-diimine)iron(II) complexes may be made by adding ligands in acetone, ethanol, or methanol to an aqueous solution of an iron(II) salt. The deeply colored cations are indefinitely stable in neutral solutions and they may be precipitated by addition of large cations such as perchlorate, iodide, thiocyanate, or nitroprusside, followed by recrystallization from an organic solvent (with caution in the case of the potentially explosive perchlorate salts). When the anion concerned is a good ligand, the product obtained on recrystallization is often the neutral bis complex, for instance, $[Fe(bipy)_2Cl_2]$ (see below). Reaction of Fe^{3+} with excess 1,4-diimine gives brown oxo-bridged dinuclear complexes, and not tris complexes.[229] These have an infrared – Fe–O–Fe-stretching vibration at 840–860 cm^{-1}, and temperature-dependent magnetic susceptibilities of about 1.9 BM per iron atom resulting from antiferromagnetic superexchange between the two high-spin centers, via the oxo bridge. Mössbauer spectroscopy confirms this assignment. $[Fe(bipy)_3]^{3+}$ and related complexes are readily obtained by oxidation of the corresponding iron(II) species by, for example, Ce(IV) or PbO_2 in dilute sulfuric acid.[230] These blue cations are less intensely colored than their red iron(II) counterparts and they can also be precipitated as perchlorate salts. They are surprisingly stable in acidic solution, even in concentrated sulfuric acid, probably because the activity of water is so low in this medium.[231] Optically active $[Fe(phen)_3]^{2+}$ is readily obtained via crystallization as the antimony *d*-tartrate salt. Low-temperature oxidation in acid affords optically active $[Fe(phen)_3]^{3+}$, which racemizes slowly in the solid, whereas in solution, racemization is complete in a few minutes.[232] The corresponding iron(II) complexes racemize relatively slowly in solution and very slowly in the solid. The volume of activation for racemization of crystalline $[Fe(phen)_3](ClO_4)_2$ is $-0.9 \pm 0.1\,cm^{-3}\,mol^{-1}$. In solution, it is $14.2 \pm 0.3\,cm^{-3}\,mol^{-1}$, which is similar to that for dissociative acid aquation. However, the racemization rate is

Table 8 Absorption maxima, extinction coefficients, stability constants, and standard electrode potentials for selected Tris-(1,4-diimine)iron(II) complexes in water

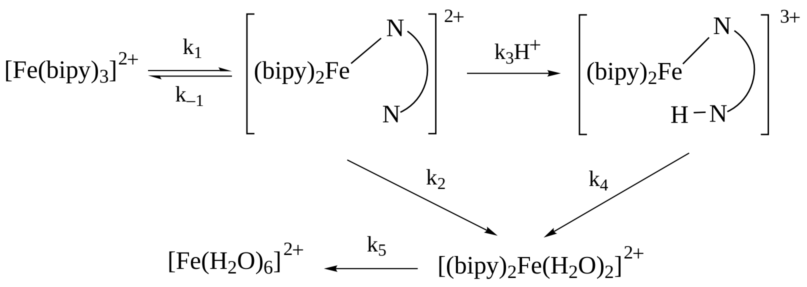


Scheme 3

almost an order of magnitude faster than that for dissociation, suggesting racemization involves an additional intramolecular twist process.[233]

There is a simple dissociative mechanism for $[Fe(phen)_3]^{2+}$ dissociation in acid, which is independent of acid concentration. However, when the ligand is the more flexible bipy, a monodentate protonated intermediate is kinetically significant. Here, the observed rate of dissociation increases with increasing acid concentration up to about $2\,mol\,l^{-1}$, as shown in Scheme 3, and the reaction rate is given by equation (5).

$$\frac{-d[Fe(bipy)_3{}^{2+}]}{dt} = \frac{[Fe(bipy)_3{}^{2+}]k_1(k_2 + k_3[H^+])}{(k_{-1} + k_2 + k_3[H^+])} \quad (5)$$

Reactions of tris(1,4-diimine)iron(II) complexes with hydroxide and cyanide ions take place via first and second-order processes typified by the rate law, equation (6). With hydroxide, the initial product is iron(II) hydroxide which is oxidized by adventitious oxygen to give very insoluble iron(III) hydroxide, the formation of which is the driving force for the overall reaction, equation (7). With cyanide ion, the product[234] is low-spin $[Fe(phen)_2(CN)_2]$. Over a prolonged period in the presence of sufficient cyanide ion, this goes on to give $[Fe(phen)(CN)_4]^{2-}$ and finally $[Fe(CN)_6]^{4-}$, equation (8). There remains controversy about the mechanistic origin of the second-order reactions of tris(diimine)iron(II) complexes. These have large positive volumes of activation normally considered characteristic of a dissociative rather than an associative mechanism. This dichotomy could have its origin in strong transition state desolvation.[235]

$$\frac{d[Fe(phen)_3{}^{2+}]}{dt} = [Fe(phen)_3{}^{2+}]\{k_1 + k_2[\text{nucleophile}]\} \quad (6)$$

$$[Fe(phen)_3]^{2+} + \frac{OH^-}{O_2} \longrightarrow Fe(OH)_3 + 3phen \quad (7)$$

$$[Fe(phen)_3]^{2+} \longrightarrow [Fe(phen)_2(CN)_2] \longrightarrow [Fe(phen)(CN)_4]^{2-} \longrightarrow [Fe(CN)_6]^{4-} \quad (8)$$

Kinetic parameters, including activation volumes, for base hydrolysis of a variety of iron(II)-diimine complexes provide useful indicators of ligand, substituent, and medium effects on reactivity.[236]

The redox potential for tris- 1,4-diimine iron complexes is about 1 V (Table 8), and the iron(III) complexes will oxidize a variety of organic substrates. The addition of a base causes their rapid reduction to iron(II) via an involved process with a hydroxide ion concentration term in the rate equation.[237] Lower oxidation state tris-diimine iron complexes are known. Reduction of $[Fe(bipy)_3]^{2+}$ with Li_2bipy gives black paramagnetic crystalline $[Fe(bipy)_3]$, as in equation (9). This can also be prepared directly from an iron chloride and Li_2bipy in THF, for example, as in equation (10). Solutions in unreactive organic solvents are red–violet but in protic solvents, oxidation to $[Fe(bipy)_3]^{2+}$ takes place and hydrogen gas is evolved. When heated to 145 °C in vacuo, $[Fe(bipy)_3]$ decomposes to metallic iron and the free ligand. In the presence of excess reducing agents, $[Fe(bipy)_3]^{2+}$ affords $[Fe(bipy)_3]^-$ according to equation (11). This complex is best described[238] as an iron(0) complex with a $(bipy)^-$ ligand. The electrochemical reduction of $[Fe(bipy)_3]^{2+}$, and related complexes, to iron(I) and iron(0) species is well characterized. The nature of more highly reduced species is however, not well defined.

$$Li_2bipy + [Fe(bipy)_3]^{2+} \longrightarrow [Fe(bipy)_3] + bipy + 2Li^+ \quad (9)$$

$$2FeCl_2 + 4bipy + 2Li_2bipy \longrightarrow 2[Fe(bipy)_3] + 4LiCl \quad (10)$$

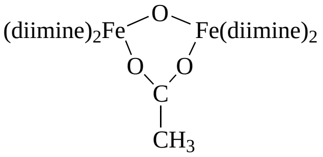
$$3Na(bipy) + [Fe(bipy)_3]^{2+} \longrightarrow Na[Fe(bipy)_3] + bipy + 2Na^+ \quad (11)$$

Bis Complexes. The dicyano complexes $[Fe(CN)_2(diimine)_2]$ are protonated in strong acid to give stable mono and diprotonated species. Protonation is associated with major color changes, typically dark violet to yellow, and these complexes have been used as acid-base indicators in nonaqueous titrations.[239] They also show strong solvatochromatic charge-transfer bands. For example, the absorbance maximum of $[Fe(CN)_2(bipy)_2]$ in water is 515 nm and in pyridine, 629 nm. The solvatochromism of a variety of $[Fe(diimine)_2(CN)_2]$ and $[Fe(diimine)(CN)_4]^{2-}$ complexes has been established,[240]

and used to monitor solvation in ranges of single and mixed solvents, and in micelles and microemulsions[241] – indeed a few complexes self-aggregate.[242] Appropriate tailoring of the diimine ligands gives complexes with significant solubility in almost all known solvents.[243] Solubility data[244] and partial molar volumes[245] are available for several diimine-cyanide complexes; transfer chemical potentials (from solubilities) can indicate preferential solvation in mixed solvents.[246] $[Fe(diimine)_2(CN)_2]$ complexes have been used to probe connections between solvatochromism, electronic absorption spectra, and color perception parameters.[247] There are also correspondingly marked changes in extinction coefficient.[248] Oxidation of these complexes gives iron(III) salts, which can be isolated, for example, *cis*-$[Fe(CN)_2(bipy)_2]X$ ($X = ClO_4^-$, NO_3^-). These are low spin, with magnetic and Mössbauer properties similar to the iron(III)-tris-1,4-diimine complexes discussed above. The reaction of iron(III) chloride with 1,10-phenanthroline in acetone gives a compound of empirical formula $Fe(phen)Cl_3$. This is in fact *cis*-$[FeCl_2(phen)_2][FeCl_4]$, in which the cation is high-spin,[249] and the Fe–N bonds are significantly longer than in $[Fe(phen)_3]^{3+}$. Iron(II) complexes of the type $[FeX_2(NN)_2]$ (NN = bipy, phen; X^- not CN^-) are obtained from the corresponding $[Fe(NN)_3]X_2$ salts by extraction with hot organic solvent, or dissociating one diimine ligand at an elevated temperature (140–200 °C) under vacuum over a prolonged period.[250] Most of them are somewhat air sensitive and high spin. For example, $[FeCl_2(bipy)_2]$ has a magnetic susceptibility of 5.3 BM. In the presence of water, the more stable low-spin complex is formed, presumably according to equation (12). With $X^- = NO_2^-$ and NCO^-, the complexes are low spin; when $X^- = 1/2$ oxalate or F^-, the complexes are claimed to have intermediate spin. Of special interest are those complexes with $X^- = NCS^-$ and $NCSe^-$, which display the spin-crossover phenomenon,[251] a change in magnetic and spectral properties over quite a narrow temperature range. Room temperature magnetic moments of $[FeX_2(diimine)_2]$ ($X^- = NCS^-$, $NCSe^-$; diimine = phen, bipy) are in the range 4.9–5.2 BM, but at lower temperatures these abruptly decrease, and at the temperature of liquid nitrogen, become characteristic of low-spin complexes. In some instances, the existence of more than one polymorph is a complication but spectroscopic studies, and in particular, Mössbauer results, confirm a change from the $^5T_2$ to the $^1A_1$ state is involved. Crossover phenomena of this kind have been the subject of several reviews.[252]

$$3[FeCl_2(bipy)_2] \longrightarrow 2[Fe(bipy)_3]^{2+} + Fe^{2+} + 6Cl^- \qquad (12)$$

It has long been known that whereas oxidation of $[Fe(phen)_3]^{2+}$ in solution gives blue $[Fe(phen)_3]^{3+}$, reaction of an iron(III) solution with 1,10-phenanthroline gives a brown solution. In 1936, this was, based on analysis and on conductimetric and magnetic measurements, proposed[253] to be a dihydroxy-bridged species $[(phen)_2Fe(\mu\text{-}OH)_2Fe(phen)_2]^{4+}$. Later X-ray diffraction studies indicated this and related cations contained a bridging oxide rather than a hydroxide, as in $[(phen)_2ClFe(\mu\text{-}O)FeCl(phen)_2]Cl\cdot nH_2O$,[254] $[(H_2O)(phen)_2Fe(\mu\text{-}O)Fe(phen)_2(H_2O)](NO_3)_4\cdot 5H_2O$,[255] and $[(H_2O)_3(phen)Fe(\mu\text{-}O)Fe(phen)(H_2O)_3](NO_3)_4\cdot H_2O$.[256] Simple μ-oxo-di-iron complexes,[257] of which the bis-iron(III) complexes $[Fe_2(\mu\text{-}O)(diimine)_4(H_2O)_2]^{4+}$ provide examples, can act as models for the structure and catalytic activity of di-iron sites in proteins (e.g. in methane monooxygenase), and also as catalysts for oxygen transfer to hydrocarbons or sulfur. $[Fe_2(\mu\text{-}O)(phen)_4(H_2O)_2]^{4+}$ was obtained as a result of an electrochemical study of $[Fe(phen)_3]^{2+/3+}$ in aqueous solution.[258] Subsequently, the other members of the group $[Fe_2(\mu\text{-}O)(diimine)_4L_2]^{n+}$, where diimine = phen, bipy, or 4,4′-bipy and L = H_2O, Cl^-, or $CF_3CO_2^-$, and the slightly different acetate complex $[Fe_2(\mu\text{-}O)(\mu\text{-}O_2CCH_3)(diimine)_4L_2]^{n+}$ (**16**), were synthesized, characterized, and assessed as alkane oxidation catalysts.[259]



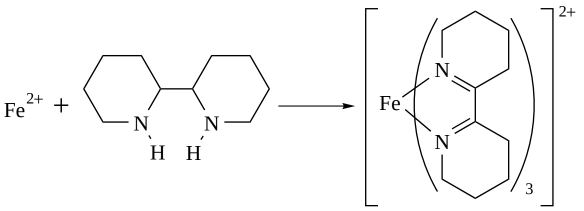
(**16**)

Mono Complexes. The product from the reaction of iron(III) chloride and 1,10-phenanthroline in acetone, originally formulated as $[FeCl_3(phen)]$, is *cis*-$[FeCl_2(phen)_2][FeCl_4]$ (see above). Under the conditions of kinetic experiments, the formation of $[Fe(phen)(H_2O)_4]^{2+}$ from Fe^{2+} and phen is rapid with an unfavorable entropy of activation.[260] It can be produced in significant concentrations when an excess of an iron(II) salt is added to an acid solution of the ligand. The reaction of $[FeF_2(py)_4]$ with 1,10-phenanthroline in pyridine affords polymeric violet $[FeF_2(phen)]$, which has a magnetic susceptibility of 4.4 BM. Other iron(II) dihalide complexes are obtained from extended pyrolysis of the corresponding tris-(1,4-diimine)iron(II) salts. Two isomers of $[FeCl_2(bipy)]$ obtained from $[Fe(bipy)_3]Cl_2$ have been identified.[261] An orange isomer, which was originally thought to be monomeric (and perhaps tetrahedral), is first obtained from $[FeCl_2(bipy)_2]$; on further heating, this is converted into a red polymeric form which is similar to that prepared from iron(II) chloride and 2,2′-bipyridine in hydrochloric acid. The latter form has octahedral iron(II) centers with bridging chloride ligands. It has been proposed that the orange isomer may contain a chain of five-coordinate iron(II) centers with single bridging chlorides. The mono complex with 5,5′-dimethyl-2,2′-bipyridine may also contain the five-coordinate iron(II). The low-spin complexes $[Fe(CN)_4(diimine)]^{2-}$ are obtained after a prolonged reaction of $[Fe(diimine)_3]^{2+}$ with cyanide ion (via the neutral intermediate $[Fe(CN)_2(diimine)_2]$), or better[262] from the reaction

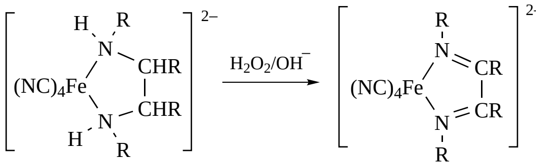
of $[Fe(CN)_6]^{4-}$ with free ligands in the presence of a small amount of Hg^{2+}, as illustrated in equation (13).

$$[Fe(CN)_6]^{4-} + \xrightarrow[Hg^{2+}]{bipy} [Fe(CN)_4(bipy)]^{2-} + 2CN^- \qquad (13)$$

Complexes with other Bidentate 1,4-Diimines. The thermodynamic stability of the five-membered iron(II) 1,4-diimine chelate ring in low-spin complexes is illustrated by the facile autoxidation of saturated amine complexes to the corresponding colored 1,4-diimine complexes. The first example[263] of this oxidative dehydrogenation is shown in equation (14), and the more recently studied[264] reaction (15) is known to involve iron(III) species and radical intermediates. Interestingly, the complex $[Fe(CN)_4(HN{=}CHCH{=}NH)]^{2-}$ can be obtained by oxidizing $[Fe(CN)_4(en)]^{2-}$, whereas the tris-ligand complex of this smallest diimine ligand has yet to be prepared.

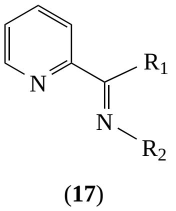


(14)

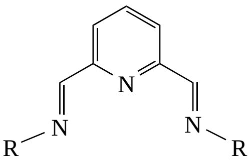


(15)

Similar iron(II) complexes can be formed in template reactions. For example, glyoxal and biacetyl react with amines in the presence of Fe^{2+} to give tris complexes of derivatives of the unsaturated ligand in equation (15). Although such ligands are not particularly stable, the complexes are very stable toward dissociation. Other Schiff bases can be formed in this way, and a wide range of complexes have been prepared from 2-pyridine aldehydes or ketones and amines (**17**). The related tridentate ligands (**18**) as well as the corresponding hydrazones form stable low-spin iron(II) complexes.[265] In some instances, the ligand can be removed, thus forming a convenient metal mediated synthesis.[266]

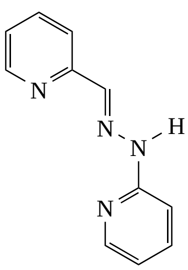


(**17**)

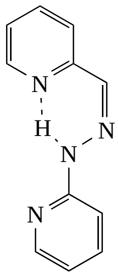


(**18**)

The *cis*- (**19**) and *trans*-isomers (**20**) of the Schiff base from pyridine 2-aldehyde and 2-pyridylhydrazone have been isolated, and both form iron(II) complexes. The tris complex $[Fe(\mathbf{20})_3]^{2+}$ is yellow, and when heated, this is converted to the very stable ($\log \beta_2 = 16.2$) purple colored $[Fe(\mathbf{19})_2]^{2+}$ that can be deprotonated in alkaline solution to give the neutral bis complex.[267]

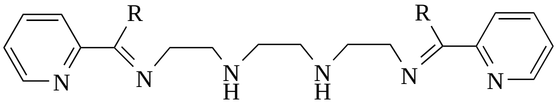


(**19**)



(**20**)

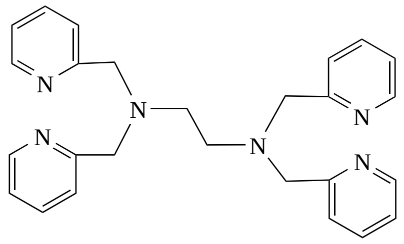
Hexadentate Schiff-base iron(II) complexes have been reported with linear,[268] tripodal,[269] or encapsulating (see below) tris-diimine ligands. Of particular interest are hexadentate ligands which have unsaturated segments and only two 1,4-diimine units (**21**) but still form low-spin complexes. Here, oxidative dehydrogenation does not take place and it appears the additional stability afforded by the chelate effect is significant. This complex, like most of the others described here, behaves in many ways like $[Fe(bipy)_3]^{2+}$. Thus, the rate of acid dissociation of $[Fe(\mathbf{21})]^{2+}$ is slow and depends on acid concentration, while reactions with hydroxide and cyanide are second order. Reaction with cyanide ion gives $[Fe(CN)_4(\mathbf{21})]^{2-}$. Synthesis of suitably designed tripodal ligands containing three bipy moieties can lead to dissteroselective synthesis of the respective iron(II) complexes.[270]



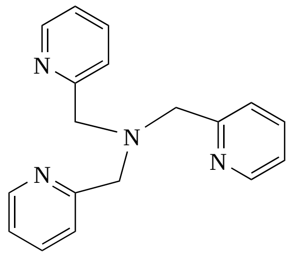
(**21**)

By careful ligand design involving a balance of chelate, electron acceptor, and other effects, it is possible to prepare iron(II) complexes displaying a range of spin-crossover phenomena induced by heat or light, for example, with ligands (**22**) and (**23**) and related derivatives. Even $[Fe(2\text{-(aminomethyl)pyridine})_3]^{2+}$ displays low-temperature spin crossover, and there is evidence that long-range cooperative interactions are present.[271]

In the absence of a reducing agent, $[Fe(dmg)_2]$ (dmg = dimethylglyoximate) is readily oxidized to iron(III) species. However, in the presence of good axial ligands, stable low-spin complexes result. For example, the structure of $[Fe(dmg)_2(imidazole)_2]$ has two planar dmg ligands with the

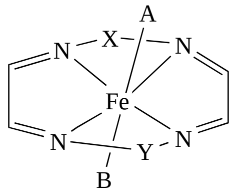


(**22**)



(**23**)

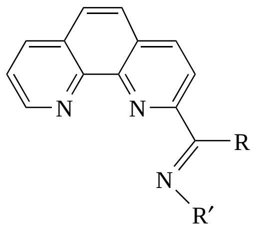
expected tetragonal distortion of the six nitrogen atoms bound to the iron(II) center. A variety of ring closure approaches have been used to provide related macrocyclic systems, which are illustrated in structure (**24**). Encapsulating hexadentate ligands result when three dmg ligands are capped by two species such as ≡BOR. The iron(II) complexes are low spin and have structures approaching trigonal prismatic geometry. Related complexes can be prepared with cyclohexane caps in place of borate.[272]



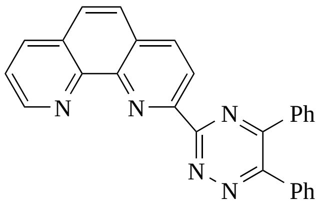
X = Y = O--HO (dmg)
X = $(CH_2)_n$ Y = O--HO
X = Y = $(CH_2)_n$

(**24**)

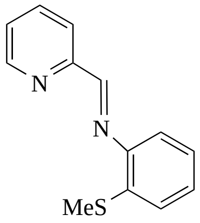
Ter- and Polydentate Ligands. Low-spin iron(II) complexes of polydentate aromatic nitrogen-donor ligands are significantly more stable than the corresponding iron(III) compounds and this dominates their chemistry in the absence of macrocyclic effects. Thus addition of 2,2′:6′,2″-terpyridine (terpy) to a solution of an iron(III) salt results in formation of $[Fe(terpy)_2]^{2+}$. This can be oxidized (redox potential ca 1.1 V) to the corresponding iron(III) complex and isolated as the perchlorate salt. Under appropriate conditions in the presence of halide or thiocyanate, it appears that high-spin $[FeX_3(terpy)]$ is formed which may have a distorted square-pyramidal structure, and in the presence of nitrate the product is a μ-oxo dimer.[273] The iron(II) complex originally formulated as $[FeCl_2(terpy)]$ is in fact $[Fe(terpy)_2][FeCl_4]$, which is in accord with its magnetic moment of 4.60 BM, that is, below the spin-only value. $[Fe(terpy)_2]^{2+}$ is very stable (log $\beta_2 = 20.4$; $\Delta H = -113\,\text{kJ mol}^{-1}$, $\Delta S = -13\,\text{J K}^{-1}\,\text{mol}^{-1}$). It dissociates only slowly in acid solution, second-order base hydrolysis is faster. It reacts with cyanide ion to form $[Fe(CN)_3(terpy)]^-$ via second-order kinetics and the product is strongly solvatochromic.[274] Controlled reduction of $[Fe(terpy)_2]^{2+}$ gives[275] species with iron in the formal oxidation states of +I and 0. Numerous iron(II) complexes containing other polydentate aromatic, and related nitrogen-donor ligands systems have been reported. Many of these are derivatives of the prototype bipy and phen ligands, while others are based on Schiff bases of pyridines, and so on, as illustrated in structures (**25**), (**26**), (**27**), and (**28**). The chemistry of these iron complexes resembles that described here for terpy, usually modified by their being less stable than those discussed in this and previous sections. However, in some instances, for example complexes of hexadentate ligands, they are surprisingly stable even though they may contain two or more aliphatic nitrogen donors.



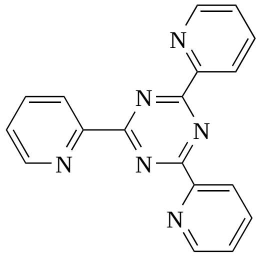
(**25**)



(**26**)



(**27**)



(**28**)

9 LIGANDS WITH PHOSPHORUS DONORS

9.1 Introduction

Phosphorus(III), with its high propensity for accepting π-electron density from coordinated iron, stabilizes complexes in lower oxidation states, but higher oxidation state complexes are also known. For example, $[FeCl_3(PPh_3)]$ is obtained from $Fe_3(CO)_{12}$ and PPh_3 in chloroform. The reaction of iron(III) salts with tertiary phosphines yields an iron(II) bis-phosphine complex. Iron(III) complexes of bidentate phosphines are better known[276] and are typically four coordinate and of the form $[FeX_2(P\text{-}P')]^+$. The lower

oxidation state iron complexes containing phosphorus ligands are considered in this Encyclopedia in the sections on the 'organometallic' chemistry of iron. The structure of *cis*-,*mer*-$[Fe(H)_2(\eta^2\text{-}H_2)(PEtPh_2)_3]$ was established by neutron diffraction techniques.[277]

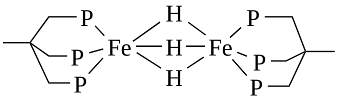
9.2 Iron (II) Complexes

9.2.1 Monodentate Phosphorus Ligands

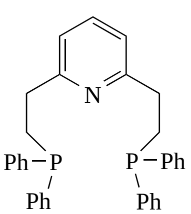
Many simple iron(II) phosphine complexes are unstable and dissociate in solution, whereas complexes of phosphites are more stable. Anhydrous iron(II) halides react with tertiary phenylphosphines in refluxing benzene to yield $[FeX_2(PR_3)_2]$, which are high-spin and have a tetrahedral structure. With secondary phosphines in anhydrous alcohol, five-coordinate paramagnetic violet/red complexes $[FeX(HPR_2)_4]^+$ are formed, which can be isolated as the BF_4^- or PF_6^- salts. Carbon monoxide displaces a phosphine to form yellow six-coordinate complexes $[FeX(CO)_2(HPR_2)_3]^+$ in which the CO ligands are evidently *trans* in solution. Penta-coordinate complexes $[Fe(HPR_2)_5]^{2+}$ are formed[278] in the reaction between excess secondary phosphine and the iron(II) salts of PF_6^- and BF_4^-. They too react with CO to form a six-coordinate *trans* dicarbonyl complex. Many low-spin complexes of phosphines or phosphites with the stoichiometry $[FeX_2(CO)_2(P)_2]$ are known. Trimethylphosphite, $P(OMe)_3$, is a particularly successful ligand because it has both strong σ-donor and strong π-acceptor capabilities associated with rather small steric hindrances.

9.2.2 Polydentate Phosphorus Ligands

The reaction of metallic iron with *o*-phenylenebis(diethylphosphine) in hydrogen at 200 °C gives a small amount of the complex *trans*-$[FeH_2\{C_6H_4(PEt_2)_2\}_2]$. A monohydride complex *trans*-[FeHCl(depe)$_2$] is known (depe = 1,2-bis(diethylphosphino)ethane), which reacts with sodium tetraphenylboride under nitrogen to yield *trans*-$[FeH(N_2)(depe)_2]^+$, which can be isolated[279] as the BPh_4^- salt. The bidentate phosphines 1,2-dialkylphosphinoethane (P-P) form octahedral low-spin complexes *trans*-$[FeCl_2(P\text{-}P)_2]$ with ease. Typically, these complexes have Fe–P bond lengths of the order of 2.2 Å. This contrasts with other complexes where a bidentate phosphine ligand forces a high-spin configuration (for example, octahedral $[FeCl_2\{Ph_2PCH_2(CH_2)_2PPh\}_2]$ where the ligand acts in a bidentate fashion and average Fe–P bond lengths of 2.7 Å are observed). The tripod-like ligand $MeC(CH_2PPh_2)_3$ forms, on reaction with iron(II) salts in the presence of borohydride, an unusual diamagnetic dimeric complex having three bridging hydrides (**29**). Tetradentate phosphines can form both five- and six-coordinate complexes of the type $[FeX_2L]$, the complex geometry appears to depend on the flexibility of the hydrocarbon chain, which forms the chelate 'bite', and on the extent of Fe–P overlap. A mixed tridentate P_2N donor ligand (**30**) forms complexes [Fe(**30**)XY] with iron(II) halides. When X = Y = Cl, Br, the complexes are yellow and display normal high-spin behavior. When X = Y = I or X = I, Y = NCS, however, the complexes are brown and their magnetic moments decrease suddenly[280] at low temperatures although a completely low-spin state is not achieved. This anomalous behavior, which could be due to the existence of a spin equilibrium between a singlet ground state and a low lying triplet state, is found in a number of similar iron(II) phosphine halide complexes.



(**29**)



(**30**)

9.3 Iron(I) Complexes

The unusual iron(I) oxidation state is stabilized in some well-characterized phosphorus complexes. In particular, much work has been done on complexes of 1,2-bis(diphenylphosphino)ethane, (dppe). The iron(II) complex [FeHCl(dppe)$_2$] is reduced[281] by treatment with sodium in benzene under anaerobic conditions to form the iron(I) hydride [FeH(dppe)$_2$]. This deep red complex is paramagnetic, has a sharp EPR signal at $g = 2.085$, and reacts with a large excess of HCl in ethanol at 80 °C to form $[FeCl_2(dppe)_2]$. This can be reduced by sodium in the presence of dppe to yield [FeCl(dppe)$_2$], which is also red and has a strong EPR signal with some resolvable hyperfine structure at $g = 2.075$. The hydride complex reacts with trityl salts under nitrogen to give $[FeH(N_2)(dppe)_2]^+$. Four-coordinate iron(I) is stabilized by dppe according to equation (16) and the resulting complex $[Fe(dppe)_2]^+$ reacts[282] with a variety of ligands (C_2H_4, CO, N_2, MeCN) to give the corresponding five-coordinate iron(I) species.

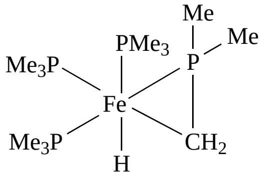
$$[Fe^0(dppe)_2] + AlClR_2 \longrightarrow [Fe^I(dppe)_2]^+[AlCl_2R_2]^- \qquad (16)$$

Two quasi-synthetic techniques have been used to investigate the chemistry of iron(I), pulse radiolysis[283] and cyclic voltammetry.[284] In the former, electrons produced by the γ-ray radiolysis of protic solvents have been shown to reduce iron(II) species to iron(I) and a complex set of equilibria are established. Reversible one-electron reductions of a variety of iron(II) phosphine complexes have been shown spectroscopically to generate iron(I). In some instances, the complexes can be useful synthetic precursors, for example, $[Fe(CO)_3(PPh_3)_2]^+$ that can be

obtained from *trans*-$[Fe(CO)_3(PPh_3)_2]$. Iron(I) complexes are stabilized by the presence of an imidazolidinylidine ligand, which promotes more effective charge delocalization and a number of monodentate phosphine and phosphite complexes of iron(I) have been generated[285] in association with this ligand.

9.4 Iron(0) Complexes

The thermal or photochemical reaction of $[Fe(CO)_5]$ or other iron carbonyls with PR_3 gives a mixture of $[Fe(CO)_3(PR_3)_2]$ and $[Fe(CO)_4PR_3]$. Where the R groups are bulky, the latter complex tends to be formed. The bis-phosphine complexes have a trigonal bipyramidal structure and only the *trans* isomer is known. Bidentate phosphines can yield analogous complexes with either one or both phosphorus atoms coordinated, or dimeric complexes with the phosphine acting as a bridging group. Higher levels of substitution by phosphorus ligands can be obtained in iron(0) complexes by reducing an appropriate carbonyl halide in the presence of a ligand or by metal vapor synthesis.[286] Thus, reduction of $[Fe(P(OMe)_3)_3Cl_2]$ by sodium amalgam in the presence of excess $P(OMe)_3$ gives[287] the air-sensitive complex $[Fe(P(OMe)_3)_5]$. The corresponding reaction with $[Fe(PMe_3)_3Cl_2]$ yields $[Fe(PMe_3)_4]$, however, this is not a four-coordinate but a six-coordinate species, in which oxidative addition has taken place (hydride transfer) to give the iron(II) complex (**31**).[288] The pentakis-phosphite complex reacts with CO to generate members of the series $[Fe(CO)_x(P(OMe)_3)_{5-x}]$, which cannot be obtained by direct substitution from $[Fe(CO)_5]$. The full series of complexes $[Fe(CO)_x(PF_3)_{5-x}]$ can be obtained from $[Fe(CO)_5]$ and PF_3. Direct synthesis from PF_3 and iron atoms[289] is, however, necessary to obtain the unusual dimer $[(PF_3)_3Fe(PF_2)_2Fe(PF_3)_3]$.



(31)

10 OXYGEN DONORS

10.1 Introduction

In the same way that iron(II) has a particularly strong affinity for nitrogen-donor ligands, so does iron(III) for oxygen donors. Most iron(II) complexes with simple oxygen donor ligands are high-spin and easily oxidized in air to iron(III) species, which are often polynuclear with metallic centers linked by oxygen bridges. Some of the most important and intensively studied species contain mixed nitrogen and oxygen donors and in particular, there is a substantial body of work on complexes of planar nitrogen macrocycles, which bind dioxygen. Because of their biological significance, these are dealt with elsewhere in the Encyclopedia. The numerous mono-, bi-, and polynuclear iron(III) complexes with carbohydrates are also of considerable biochemical importance.[290]

10.2 Water

Metallic iron dissolves in dilute mineral acids to yield $[Fe(H_2O)_6]^{2+}$, which oxidizes slowly in contact with air. In alkaline solutions, iron(II) is strongly reducing and there is some evidence that it will reduce dinitrogen.[291] Solutions of $[Fe(H_2O)_6]^{2+}$ are only mildly acidic such that addition of Na_2CO_3 merely precipitates iron(II) carbonate with no evolution of CO_2. The octahedral cation is pale blue–green in solution and is present in many hydrated iron(II) salts. Iron(II) can become present in surface water due to the reducing effect of decomposing matter, which can make purification a problem. In the removal of iron from drinking water, aeration removes CO_2 and iron is oxidized to iron(III) hydroxide which precipitates. Simple hydrated iron(III) salts are assumed to contain the $[Fe(H_2O)_6]^{3+}$ ion, although in practice many contain coordinated anions. The nitrate is an exception, but even here, iron exists crystallographically in two distinct octahedral environments,[292] the mean Fe^{III}–O distance is 0.14 Å shorter than in the corresponding iron(II) cation. Solutions of the simple $[Fe(H_2O)_6]^{3+}$ are pale violet (as is ferric alum), but aqueous solutions of iron(III) salts are frequently more colored due to charge-transfer bands between the anionic ligand and iron. Iron(III) readily undergoes hydrolytic polymerization in an aqueous solution. Examples of the type of complexes that result include $[(H_2O)_5Fe(\mu\text{-}O)Fe(H_2O)_5]^{4+}$ (Ref. 293) and $[(H_2O)_4Fe(\mu\text{-}OH)_2Fe(H_2O)_4]^{4+}$. The latter is the most abundant species at low pH.[294] Each iron atom is octahedrally coordinated to four water molecules and two bridging hydroxyl groups. The Fe_2O_2 group forms a planar ring with bond angles of 79° at Fe and 101° at oxygen, the Fe–Fe distance is 2.91 Å. All such doubly bridged iron(III) complexes show magnetic moments below the value expected for high-spin iron(III) (spin only, 5.92 BM) and they decrease with decreasing temperature. A number of iron(III) salts react with alcohols (and ethers, aldehydes, ketones etc.) to yield complexes whose precise structure can be difficult to determine.

The properties of the aqua-ions $[Fe(H_2O)_6]^{2+}$ and $[Fe(H_2O)_6]^{3+}$ in solution have been placed in context and reviewed in detail.[295] Their structures, established in the solid state in several X-ray diffraction studies of hydrated iron(II) and iron(III) salts, have been investigated in solution by

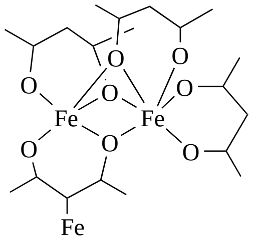
X-ray and neutron diffraction and scattering techniques.[296] The equilibrium between Fe^{3+} aq and $FeOH^{2+}$ aq[297] and the kinetics and mechanisms of their reactions with ligands,[298] including environmentally relevant humic and fulvic acids (see Section 4.11) and pharmacologically relevant desferrioxamine,[299] have been reviewed, as have complex formation reactions of $[Fe^{III}(\mu\text{-}OH)_2Fe^{II}]^{4+}$ (Ref. 300) and of Fe^{2+}aq,[301] for example, with NO,[302] and electron exchange between Fe^{2+}aq and Fe^{3+}aq/$FeOH^{2+}$ aq.[303]

10.3 Oxo Anions

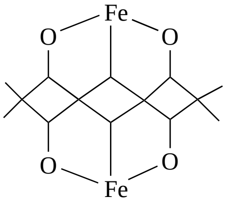
Iron(III) has a strong affinity for carboxylate ligands (see Sections 4.7–4.10 above), which, together with oxide, hydroxide, alkoxide, or phenoxide, readily act as bridging ligands to give numerous bi-[304] and polynuclear complexes. Magnetic and spectroscopic properties of trinuclear $[Fe_3(\mu^3\text{-}O)(O_2CR)_6L_3]^{n\pm}$ complexes have been intensively studied,[305] especially in relation to electron transfer within mixed-valence species ($n = 0$).[306] Many bi- and polynuclear complexes of this type are biomodels, for example, of nonhaem di-iron enzymes[307] of the active site of purple acid phosphatase,[308] of haemerythrin,[309] or of ferritin,[310] while several large polynuclear complexes, containing up to 19 iron atoms, pave the way for molecular magnets.[311] These large complexes may be planar ('ferric wheels'[312]) or incorporate hexagonal prismatic Fe_6O_6[313] or 'butterfly' Fe_4O_4[314] units.

10.4 Diketones

With complete exclusion of air, *trans*-$[FeCl_2(H_2O)_4]$ reacts with acetylacetone to form hydrated bis(2,4-pentanedionato)iron(II). The complex is coordinatively unsaturated and forms[315] an interesting tetrameric structure $[Fe_4(acac)_8]$ in which two asymmetric triply oxygen bridged dimers (**32**) are linked by rather long Fe–C bonds (2.785 Å, **33**). $[Fe(acac)_2]$ forms simple hexacoordinate adducts in reaction with a variety of bases, for example, heterocyclic diimines such as bipyridines. Complexes formed by iron(II) with other β-diketonates are polymeric and highly air sensitive. Iron(III), however, forms a series of stable highly colored



(**32**)



(**33**)

complexes. Neutral $[Fe(acac)_3]$ has a simple, essentially octahedral geometry,[316] it has been reported to have catalytic activity in stereoselective epoxidation reactions. Also neutral and monomeric is the complex $[Fe(acac)_2Cl]$, in which the Fe atom sits slightly above the plane occupied by the four oxygen atoms, the chlorine atom lies above iron at the apex of a square pyramid. A series of corresponding alkoxide complexes exists,[317] although here the structure is dimeric with two OR bridges between the iron atoms in $[Fe(acac)_2OR]_2$.

10.5 Other Oxygen Donors

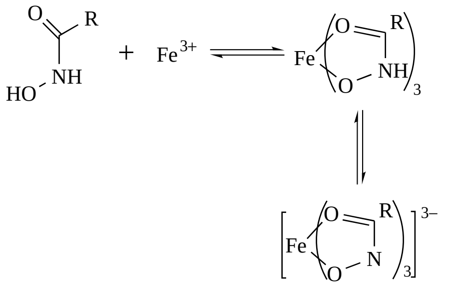
Some *S*-bonded DMSO iron(II) complexes are known, but the explosive pale green complex $[Fe(DMSO)_6](ClO_4)_2$ formed when the hexaqua perchlorate is mixed with dimethylsulfoxide in acetone, appears to be *O*-bonded. Hexaaqua iron(II) reacts with pyridine *N*-oxide to give dark red $[Fe(pyO)_6]^{2+}$, and analogous complexes are formed with a variety of substituted pyridine *N*-oxides.

10.5.1 Phenols, Catechols, and Hydroxamates

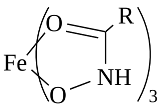
Iron(III) reacts with the phenolic moiety to give characteristic colors, which have long been used analytically. Monodentate phenoxide complexes have been relatively elusive, though tetrakis(2,3,5,6-tetramethylphenolato)iron(III) for example, exists[318] as a red–orange tetraethylammonium salt from reaction of $FeCl_3$ with the phenol in anhydrous alcohol. The complex has a distorted FeO_4 unit with rather short Fe–O bonds (1.85 Å) and a reversible one-electron reduction potential at -1.32 v, demonstrating a particularly strong stabilization of the Fe(III) oxidation state, and an electronic spectrum showing three intense charge-transfer bands.

As mentioned above, iron is largely present in the biosphere as insoluble iron(III) oxide, and so a unique complex chemistry has evolved to allow its transport in biological systems. This involves two classes of oxygen donor chelating ligands: catecholates and hydroxamates. Catechol itself ($catH_2$ = 1,2-dihydroxybenzene) is a poor ligand at low pH, forming a transient complex with iron(III), which decomposes to generate iron(II) and *o*-quinone. In less acid (and anaerobic) conditions, stable tris-catecholate iron(III) complexes are formed. $[Fe(cat)_3]^{3-}$ is a good model for enterobactin (see below).[319] The structure of $K_3[Fe(cat)_3].1.5H_2O$ shows approximate D_3 symmetry with the aromatic rings bent away from the O-M-O plane and an average Fe–O bond distance of 2.015 Å. The weakly acidic hydroxamic acids (LH) form deeply colored complexes[320] with iron(III) at low pH, the colors being characteristic and analytically useful. High-spin $[Fe(L)_3]$ (**34**) is very stable ($\beta_3 \sim 10^{30}$) in contrast to iron(II) derivatives and the reduction of such iron(III) complexes has been

postulated as a mechanism for the release of biological iron following its sequestration by siderophores, which also contain hydroxamate groups. The unexpectedly labile neutral iron(III) hydroxamato complexes can be deprotonated in basic solution to yield the corresponding hydroximato complexes according to equation (17). The predominance of the *cis* configuration is common, but not ubiquitous, for tris-hydroxamato iron(III) complexes.[321]



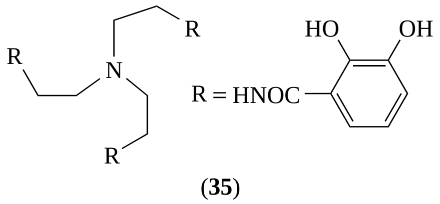
(17)



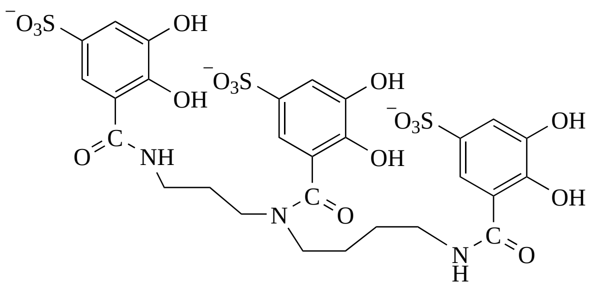
(**34**)

10.5.2 Siderophores and Models

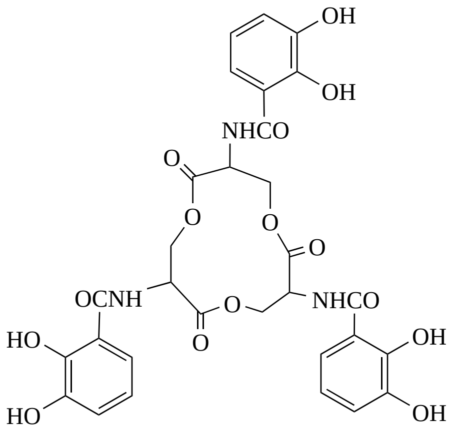
Siderophores,[322] hexadentate tris-catecholate and tris-hydroxamate ligands, are produced by many microorganisms to facilitate iron uptake. Several synthetic models, such as trencam (**35**) and licams (**36**), for the tris-catecholate enterobactin (**37**) do not quite match its affinity for iron(III) (Table 8). Similar tris-hydroxamate ligands model naturally occurring ferrichromes and desferrioxamines (e.g. dfo, (**38**)).



(**35**)



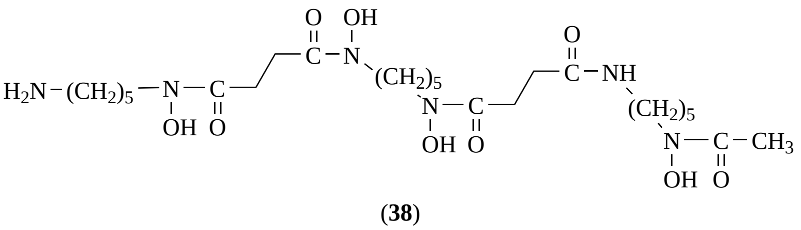
(**36**)



(**37**)

10.5.3 Hydroxypyranones and Hydroxypyridinones

The anionic forms of 3-hydroxypyran-4-ones such as maltol (**39**) or kojic acid (**40**) and of 3-hydroxypyridin-4-ones such as (**41**) – and of their 1-hydroxy-pyridin-2-one isomers – form stable complexes ($\beta_3 \approx 10^{30}$) with iron(III). Several 3-hydroxypyridin-4-ones were originally developed as analytical reagents, for iron and for a number of other metals.[323] In recent years, the main interest[324] in these ligands has been as the most promising potential replacements[325] for desferrioxamine, for many years, the only available but very unsatisfactory agent[326] for the treatment of iron overload in the body, and as agents for the introduction of iron in cases of severe anemia.[327] The facile synthesis[328] of a wide range of hydroxypyridinones, bidentate and hexadentate, with the possibility of tailoring[329] various relevant properties, including solvation[330] to facilitate both administration and trans-membrane transport, has led to their



(**38**)

Table 9 Stability constants and redox potentials for iron(III) and iron(II) complexes of hexadentate ligands

	$\log_{10}K_1$ ($Fe^{III}L$)	E°/mV	$\log_{10}K_1$ ($Fe^{II}L$)

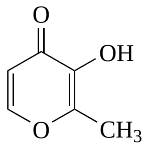
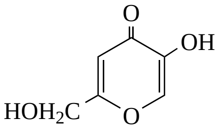
transferrin	20		

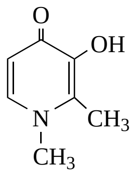
intensive investigation. Deferiprone, (**41**), has been studied[331] and clinically assessed,[332] the most though it is claimed that 2-ethyl derivatives might prove preferable.[333] Interestingly, hexadentate analogues[334] have proved to lack the expected (chelate effect) stability advantage over bidentate ligands, presumably due to steric difficulties.[335]



(**39**)



(**40**)



(**41**)

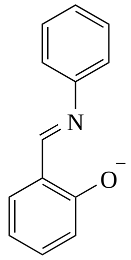
10.5.4 Stability Constants and Redox Potentials

The markedly negative redox potentials of tris-catecholate and tris-hydroxamate iron complexes (Figure 4) may be ascribed to the high stabilities of the iron(III) complexes and the rather low stabilities of their iron(II) analogues.[336] Table 9 details the relevant data (interconnected by a thermochemical cycle earlier applied to amino acid pentacyanoferrate complexes[337]), and documents the remarkably higher stabilities of tris-catecholate than of tris-hydroxamate complexes of iron(III).

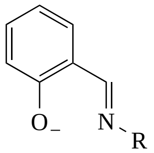
10.6 Ligands Containing Oxygen and Nitrogen Donors

10.6.1 Schiff-base complexes

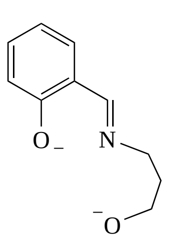
Condensation of an aldehyde or ketone with a primary amine yields a Schiff base, a class of compounds that have been widely studied as chelating ligands. *N*,*N*′-Diimine ligands, resulting from condensation with pyridine-2-aldehyde or 2-pyridyl ketones, are discussed in Section 8.2.2, and *N*,*O*-ligands are discussed here. The condensation products of salicylaldehyde are important mixed *N*,*O* donor ligands. Those resulting from the condensation of salicylaldehyde and aniline (**42**) form very stable complexes with iron(II). In general, the *N*-substituted salicylaldimines (**43**) form high-spin complexes $[Fe(salNR)_2X]$ (X = Cl or Br) with iron(III). The X-ray structure[338] (R = *n*-propyl, X = Cl) shows five coordination with an intermediate geometry between trigonal bipyramidal and square planar. When R is large, different crystalline modifications can be observed and the magnetic moment can be significantly reduced at lower temperatures. The tridentate base (**44**) forms an iron(III) complex, which is five coordinate and dimeric [Fe(**44**)Cl]$_2$. The iron atoms participate in a four-membered ring, bridged by alkoxide oxygen atoms and the chlorine atoms sit at the apex of a square pyramid (**45**).



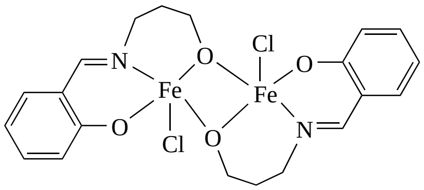
(**42**)



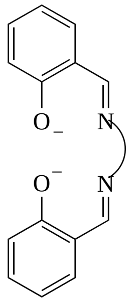
(**43**)



(**44**)



(**45**)



(**46**)

An extremely well-known tetradentate Schiff-base results from the condensation of two molecules of salicylaldehyde with a diprimary amine. Where this is 1,2-diaminoethane, (ethylenediamine, en) the ligand ‘salen’ results (**46**). [Fe(salen)Cl] may be isolated in both mono- and dimeric forms.[339] The monomer has a distorted square-planar geometry with the iron atom sitting 0.46 Å proud of the plane formed by the salen donor group along the same axis as the apical Cl atom. The dimer has an octahedral geometry at iron, each salen ligand sharing one oxygen atom with two monomer moieties. The *trans*-Fe–O bond in the dimer is 0.26 Å longer than the Fe–O bonds in the salen ligand plane. The isomers, which exist for a wide variety of analogous complexes, can be distinguished by their differing magnetic properties. The monomer exhibits classic behavior with the magnetic moment close to the spin-only value; the dimers, however, have low room

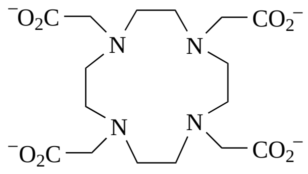
temperature moments, which reduce when the temperature is lowered. The differences are emphasized by divergent IR and Mössbauer properties. The air-sensitive neutral iron(II) complex [Fe(salen)] is obtained[340] from [Fe(salen)CH_2Ph]. It can be reduced by sodium in THF to yield the unusual d^7 iron(I) complex Na[Fe(salen)]. Also assigned a d^7 electronic configuration is the NO adduct [Fe(salen)NO]. This complex has a $S = 3/2$ to $S = 1/2$ spin-crossover near 175 K, its geometry is square pyramidal and the N–O bond is bent, both features remain unchanged as the spin-state changes.[341] The Fe(salen) group also forms dimeric complexes with a single oxygen atom bridge, $[(Fe(salen))_2O]$ having square-pyramidal geometry at the iron atoms. The geometry is distorted, however; crystals from different solvents were shown to have Fe–O–Fe angles of 139° and 142°. The bulky isopropyl groups in the Schiff-base ligand derived from salicaldehyde and isopropylamine impose tetrahedral coordination geometry on the iron(II) in its bis-ligand complex; oxidation in air yields an oxo-bridged di-iron(III) product.[342]

10.6.2 Complexes of Other Mixed Oxygen–Nitrogen Donors

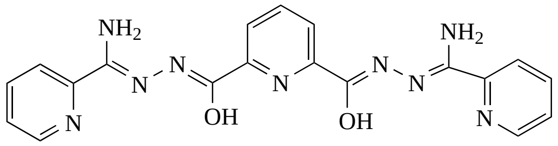
A variety of cyclic and acyclic ligands with mixed oxygen and nitrogen-donor atoms form complexes with iron(II) and iron(III), which have five, six, or seven coordination. A series of complexes is also formed[343] in which amino acids act as N and O donors; typically hexacoordinate, these can have extended carboxylate bridged structures. The structure and reactivity of such complexes have been examined as model systems in the search for explanations of the biological activation and transport of oxygen. The oxygen carrying proteins hemerythrins contain active centers[344] in which two iron atoms are linked by both μ-oxo and carboxylate bridges provided by amino acid groups – these are discussed elsewhere in this Encyclopedia.

Polyaminocarboxylate ligands are important in iron(III) chemistry. The classic mixed hexadentate O and N donor ligand edta forms complexes of the type $X[Fe(edta)(H_2O)]\cdot nH_2O$ (X = Li, Rb), in which the coordinated water molecule provides the seventh donor to give a pentagonal bipyramid. Base hydrolysis yields[345] the complex ion $[Fe_2(edta)_2O]^{4-}$, in which a μ-oxo link joins the iron atoms. Related ligands, of which a wide range is now available, assist the buildup of polynuclear μ-oxo-μ-hydroxo-bridged species such as $[Fe_6(\mu\text{-O})(\mu\text{-OH})_5(hpdta)_3]^{4-}$.[346] The formation constant for iron(III) edta complexation is high and this ligand is often used to reduce the level of free iron and other metal ions in solution. A wide range of related ligands is now available. The addition of carboxylate-bearing pendant arms to tetraaza-macrocycles, as in dota, (**47**), gives ligands with high affinities for 3+ metal ions, including Fe^{3+} (log $K_1 = 29.4$).[347]

The diimine-hydroxyl ligand poap, (**48**), undergoes self-assembly in the presence of Fe^{3+} to give Fe_5^{III} and Fe_9^{III} species; the latter has a square-grid structure.[348]



(**47**)



(**48**)

11 COMPLEXES WITH SULFUR DONORS

11.1 Introduction

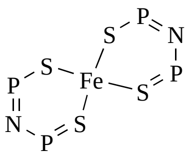
There is a large body of knowledge[349] on the coordination chemistry of iron–sulfur complexes and iron clusters particularly directed at the modeling and understanding of the action of nonheme proteins whose active sites contain iron–sulfur units. These topics are discussed in detail elsewhere in this Encyclopedia; here, the emphasis is on the basic coordination chemistry.

11.2 Sulfide and Thiolate Complexes

11.2.1 Mononuclear Complexes

Tetrahedral mononuclear iron sulfide units lie at the heart of a number of electron transfer proteins. The active site of the rubredoxins, for example, consists[350] of iron coordinated in a somewhat distorted tetrahedral geometry by the sulfur atoms of four cysteinyl residues. One-electron transfer flips one of the irons between oxidation states II and III. A number of synthetic complexes containing an FeS_4 core have been identified. A simple example is provided by $Ba[Fe(SCH_2CH_2OH)_4]$, whose preparation, structure, and EPR and Mössbauer spectra have been reported.[351] Trimethylarsine sulphide forms both $[Fe(SAsMe_3)_4](ClO_4)_2$ and $[FeX_2(SAsMe_3)_2]$ (X = Cl, Br). The iron(II) complex $[Fe(SPMe_2NPMe_2S)_2]$ (**49**) has Fe–S bond lengths between 2.339 Å and 2.380 Å and S–Fe–S angles of between 100.5° and 114.9°. $[Fe(SPh)_4]^{2-}$ can be prepared from PhS^-. The best example, however, is obtained[352] from the reaction between $[FeCl_4]^{2-}$ and excess *o*-xylyldithiol (*o*-xyl$(SH)_2$) to give the orange complex $[Fe(S_2\text{-}o\text{-xyl})_2]^{2-}$. Careful aerobic oxididation of this iron(II) species yields the corresponding iron(III) complex, which can be isolated as the Et_4N^+ salt. The Fe(II)–S bond length of 2.356 Å is 0.09 Å longer than that of its iron(III) counterpart. If a lower ligand

to metal ratio is used in the synthesis, the dimer $[Fe_2(S_2\text{-}o\text{-xyl})_3]^{2-}$ results, which can be converted into the monomeric complex with excess thiol. The oxidation state of the iron in the monomer is reversible in cyclic voltammetry experiments in dimethylformide. Sterically hindered sulfur ligands seem to stabilize the FeS_4 unit.



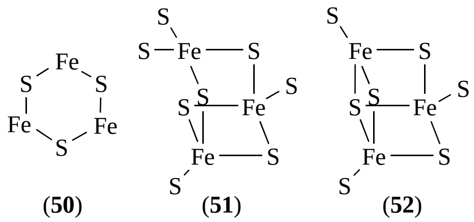
(**49**)

11.2.2 Dinuclear Complexes

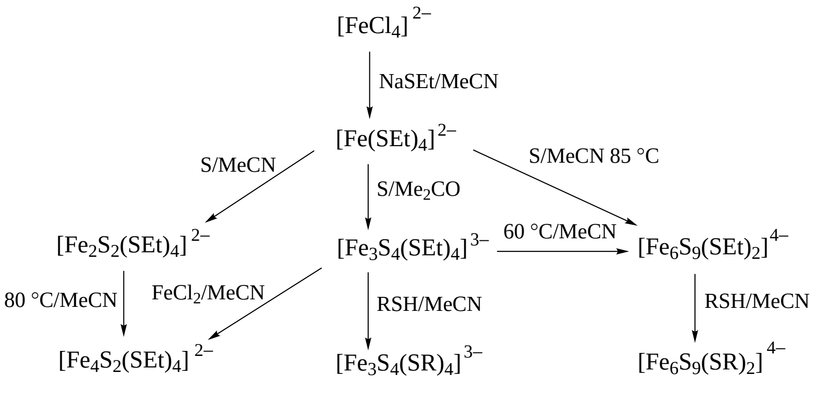
The Fe_2S_2 core is most commonly found in biological systems in the two-iron-ferredoxin proteins and several model complexes of the type $[Fe_2S_2(SR)_4]^{2-}$ have been synthesized. Simple reaction of $FeCl_3$ with NaSH and NaOMe is not a viable route since only Fe_4 units are formed. By selecting a dithiolate with a chelate bite approximately equal to the distance between coordination sites in the stable Fe_4 units, a dimeric iron(III) complex is obtained, namely, $[Fe_2S_2(S_2\text{-}o\text{-xyl})_2]^{2-}$. A successful synthetic route[353] to this and analogous complexes involve the reaction of $FeCl_3$ with elemental sulfur and the thiolate in methanol in the presence of the tetraalkylammonium ion (which appears to prevent the formation of Fe_4S_4 units). These dimeric complexes share many properties with the oxidized forms of the two iron ferredoxin proteins. These include optical spectra and magnetic properties; Mössbauer parameters are also similar. One-electron reduction of the synthetic analogue yields inhomogeneous iron centers on the Mössbauer timescale and the chemical shifts suggest the presence of both high-spin iron(II) and iron(III) that are antiferromagnetically coupled. This behavior is mirrored in the mixed oxidation state form of the protein. The observation in the synthetic analogue confirms that it is not an intrinsic property of the protein but rather an intrinsic property of the Fe_2S_2 system.[354] The stability of the iron–sulfur cores is exemplified in their substitutional chemistry. Thus, aryl thiolate (SAr) readily substitutes S_2-*o*-xyl in the above complexes to yield $[Fe_2S_2(SAr)_4]^{2-}$, which itself reacts with benzoyl chloride to form $[Fe_2S_2Cl_4]^{2-}$. The X-ray structure of $(NEt_4)_2[Fe_2S_2Cl_4]$ shows the transformations have essentially had no effect on the structure of the Fe_2S_2 core. As a result of this inherent stability, ligand substitution can be used as a structural probe for removing the metal core of iron–sulfur proteins (the so-called core extrusion technique).

11.2.3 Trinuclear Complexes

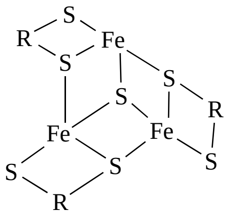
Of more recent discovery[355] are a group of ferredoxins having [3Fe-3S] cores. Structural and spectroscopic investigation suggested structures (**50**), (**51**), and (**52**) as possible core units. There are a number of synthetic cluster complexes with cores containing three iron atoms, notably with two structural types. The first has[356] a pyramidal structure in which a μ^3-sulfur atom caps a ring of three sulfur and three iron atoms (**53**), and is typified by $[Fe_3S(S_2\text{-}o\text{-xyl})_3]^{3-}$. Once again, there is evidence for magnetic coupling and a reversible one-electron redox process. One further synthetic type of trinuclear iron–sulfur core[357] has three linearly arranged iron atoms with two pairs of sulfide bridges (**54**). Complexes of this type, $[Fe_3S_4(SR)_4]^{3-}$, are prepared by the action of sulfur in acetone on $[Fe(SEt)_4]^{2-}$, a strongly reducing complex that has been very useful in the preparation of a variety of cluster complexes (Scheme 4).



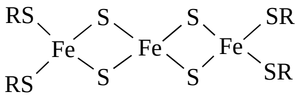
(**50**) (**51**) (**52**)



Scheme 4



(**53**)



(**54**)

11.2.4 Tetranuclear Complexes

The basic geometry of the important Fe_4S_4 unit found in natural and synthetic systems consists of a tetrahedron of four iron atoms inside a slightly larger tetrahedron of four sulfur atoms forming a distorted cube. Each sulfur atom is coordinated to three iron atoms and each iron atom has a terminal SR ligand. In the case of a protein, this is a cysteinyl residue. In either case, the cube is compressed in the direction of D_{2d} symmetry. The synthetic systems are isoelectronic with their protein analogues, and formally contain two iron(II) and two iron(III) centers, which are antiferromagnetically coupled. $[Fe_4S_4(SR)_4]^{2-}$ complexes undergo reversible one-electron reduction and oxidation reactions in electrochemical studies but the protein-encased natural complexes have slightly different redox potentials. Whilst early explanations of this phenomenon concentrated on the protein, it appears solvent effects are rather crucial. No localized individual atoms in the +2 or +3 oxidation state are observable in these systems.[358]

Preparatively, the synthetic complexes are relatively easy to obtain. $FeCl_3$ reacts with NaSR to give[359] a dark green polymeric sulfide, which, when treated with NaHS and NaOMe gives the corresponding disulfide and the mixed oxidation state cluster $Na_2[Fe_4S_4(SR)_4]$. The reaction is illustrated in equation (18). As with the dimeric complexes, thiolate ligand exchange reactions are facile and have been studied in some detail. Exchange takes place, for example, as in equation (19). Solvent effects can be important from the formation of these complexes as is illustrated in the synthesis of $[Fe_4S_4(SPh)_4]^{2-}$ from $FeCl_3$ and PhS^-. Under appropriate conditions of stoichiometry and solvation in this preparation, $[Fe_4(SPh)_{10}]^{2-}$, $[Fe(SPh)_4]^{2-}$, and $[Fe_2S_2(SPh)_4]^{2-}$ can also be isolated. $FeCl_2$ may also be used as a starting material, in which case rather less thiolate is required since it is not consumed in reducing iron(III) and forming disulfide. If these syntheses are carried out[360] with MoS_4^{2-}, RS^-, and $FeCl_3$ in methanol containing R_4N^+, a series of novel bridged cluster complexes result. The tungsten analogues[361] are also known. Ligands other than – SR can coordinate to $[Fe_4S_4]$ cores, including dithiocarbamates[362] (see Section 11.4), phosphines,[363] or halides.[364]

$$4FeCl_3 + 6NaSR + 4NaSH + 4NaOMe \longrightarrow Na_2[Fe_4S_4(SR)_4] + RSSR + 4MeOH + 12NaCl \qquad (18)$$

$$[Fe_nS_n(SR)_4]^{2-} + mR'SH \longrightarrow [Fe_nS_n(SR)_{4-m}(SR')_m]^{2-} + mRSH \quad n = 2, 4;\ m = 0-4 \qquad (19)$$

11.2.5 Higher Nuclearity Complexes

Several clusters of the type $[Fe_6S_6L_6]$ are known,[365] as are a few nonbiological complexes with an $[Fe_8S_8]$ core, and at least one with an $[Fe_{16}S_{16}]$ core.[366]

11.3 Complexes with Nitrosyl Ligands

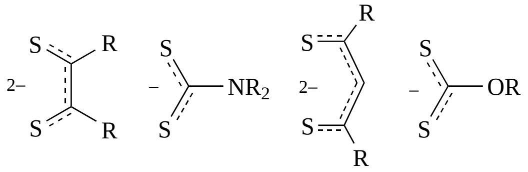
The isolation of $[Fe_2(SMe)_2(NO)_4]$ from certain preserved vegetables[367] and its implication in diet-related carcinogenesis, underlines the similarities between the iron–sulfur nitrosyl systems and the complexes discussed above. The prototypic iron–sulfur nitrosyl complexes are Roussin's salts[368] (Section 'Nitric Oxide Complexes with Sulfur Donors'). $[Fe_2(SR)_2(NO)_4]$ complexes are known with a wide range of R groups. They can be synthesized directly from iron(II) salts, as shown in equation (20), or a variety of other mononuclear iron complex precursors including $[Fe(NO)(S_2CNMe_2)_2]$ (with excess RS^-), $[Fe(CO)_3NO]$, and $[Fe(NO)_2(SR)_2]^-$.

$$4FeSO_4 + 8KOH + 2RSH + 4NO \longrightarrow [Fe_2(SR)_2(NO)_4] + Fe_2O_3 + 4K_2SO_4 + 5H_2O \qquad (20)$$

Dinuclear and tetranuclear complexes are also suitable starting materials, and much of the synthetic and substitutional chemistry of these species reflects the ability of the systems to sustain monomeric solvated dinitrosyl species such as $[Fe(NO)_2(solvent)_2]^+$ or $[Fe(NO)_2(SR)(solvent)]$. The latter tend to be formed in solvents having poor and the former in ones having good π-acceptor capabilities. A review[369] of nitrosyl complexes of iron–sulfur complexes is available.

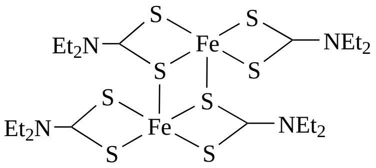
11.4 Dithio Complexes

There are a number of dithio ligands, which readily form complexes with iron, the principal of which are dithiolates (**55**), dithiocarbamates[370] (**56**), dithioacetylacetonates (**57**), xanthates (**58**), and dithiophosphates.

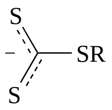


(**55**) (**56**) (**57**) (**58**)

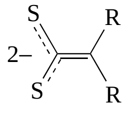
Iron(II) dithiocarbamates $[Fe(R_2dtc)_2]$ have Mössbauer spectra indicating a dimeric structure (**59**) and this is borne out[371] by X-ray investigation. These complexes are air sensitive and are rapidly oxidized to the monomeric tris-dtc species $[Fe(R_2dtc)_3]$, which exhibit spin crossover.[372] The position of the $^6A_1 \rightleftharpoons {}^2T_2$ equilibrium is sensitive to the nature of the NR_2 substituent. It has been argued that this effect is largely steric in origin since an increase in the R–N–R angle



(**59**)



(**60**)



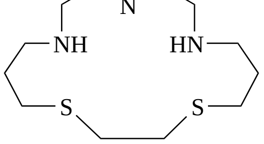
(**61**)

resulting from larger substituents would imply an increasing polarization of charge and therefore an increasing ligand field. This has been disputed, however, and the effect also correlates with the pK_a of the secondary amine. In systems where the CS_2 and NR_2 are coplanar, the electron-releasing ability of the NR_2 group seems to be the important factor. It can be predicted that the transition to the low-spin state would be accompanied by a contraction in the FeS_6 coordination sphere of [Fe(R_2dtc)$_3$], and that there will therefore be a pressure dependance of the spin equilibrium. This effect has been confirmed experimentally and a typical Fe–S bond contraction of around 0.1 Å observed.[373] The spin transition is also affected by the nature of solvent molecules included in the lattice, solvents capable of hydrogen bonding typically shifting the equilibrium toward the high-spin state. [Fe(dtc)$_3$] complexes undergo quasi-reversible one-electron redox reactions in polar solvents to yield low-spin d^4 iron(IV) and yellow, air-sensitive, high-spin iron(II) species. $[Fe(S_2CNR_2)_3]^+$ complexes are the most stable iron(IV) species and can be isolated as the BF_4^- salts (R = Me, Et, ^{i}Pr, cyclohexyl) by oxidation of the tris-iron(III) complex. The perchlorate and hexafluorophosphate salts have also been prepared. As would be predicted from the higher charge on the iron and the removal of electron density in an antibonding e_g orbital, the Fe–S bond lengths are observed[374] to be shorter in the iron(IV) complexes than in the iron(III) complexes by ca. 0.11 Å. The corresponding iron(III) xanthate complexes are almost always low spin in the 90–300 K range, whilst the thioxanthates (**60**) exhibit[375] spin-crossover equilibria. Iron(III) xanthates react with pyridine to form high-spin iron(II) $[Fe(S_2COR)_2(py)_2]$. The iron(II) xanthates $[Fe(S_2COEt)_2]$ and $[Fe(S_2COEt)_3]^-$ are known. The iron(II) thioxanthate complex $[Fe(S_2CSEt)_3]^-$ is formed in the reaction of *trans*-$[FeCl_2(H_2O)_4]$ with KS_2CSEt in MeOH or THF. Dithiolate ligands favor oxidation states higher than +2. *n,n*-Dithiolates such as $(1,1\text{-}S_2CH{=}CH(CN)_2)^{2-}$ (**61**, R = CN) generate a four-membered chelate ring and form high-spin tris-ligand iron(III) complexes. The isomeric *n,n′*-dithiolates $(1,2\text{-}S_2Et(CN)_2)^{2-}$ (**55**, R = CN) yield five-membered chelate rings and form both bis and tris complexes. $[PPh_4]_3[Fe(1,2\text{-}S_2CH{=}CH(CN)_2)_3]$ is six-coordinate low spin but $[NBu_4]_2[Fe(1,2\text{-}S_2CH{=}CH(CN)_2)_2]$ is dimeric in the solid state, the iron atom having a square-pyramidal geometry, in which the base consists of four sulfur atoms from the bidentate dithiolene ligands and the apex of a bridging sulfur from a second FeS_4 unit.[376] The PPh_4^+ salt of this dimer forms parallel stacks.[377]

Dithioacetylacetonate (SacSac) forms [Fe(SacSac)$_3$] by the reaction of iron(II) salts with acac in alcohol at low pH in the presence of H_2S. In this low-spin complex, the metal chelate rings are essentially planar, although one such unit has a larger S–Fe–S angle than the other two leading to a slightly distorted octahedral structure. Attempts to prepare this complex from iron(III) salts result in the formation of the $[FeX_4]^{2-}$ salt of the five-membered cyclic 3,5-dimethyl-1,2-dithiolinium cation. This can be reduced with thiosulfate to give the tris-SacSac complex, but when red–brown crystals of this are shaken further with thiosulfate in chloroform under anaerobic conditions, the bis-SacSac iron(II) complex results. An elegant example of the effect of sulfur as a donor atom on spin-pairing in iron complexes is given by the iron(III) series [Fe(acac)$_3$], [Fe(Sacac)$_3$], and [Fe(SacSac)$_3$] (Sacac = monothioacetylacetonate) in which the first is high-spin, the last low spin and the second either, depending on the ligand substituents.[378]

11.5 Ligands With Sulfur and Other Donor Atoms

Many complexes of iron(II) with ligands having mixed sulfur and nitrogen-donor atoms are known and a wide variety of coordination geometries and magnetic properties have been observed. The familiar Schiff-base condensation reaction can yield mixed-donor atom ligands containing sulfur. Thus, the condensation of 2,6-diacetylpyridine with 4,7-dithiadecane-1,10-diamine gives (**62**) with two sulfur and three nitrogen-donor atoms. Six-coordinate complexes $[Fe(\mathbf{62})X]^+$ are formed, which are high-spin for X = Cl, Br; but low spin for X = I. When X = NCS, $[Fe(\mathbf{62})(NCS)]^+$ is low spin but a complex having the stoichiometry $[Fe(\mathbf{62})(NCS)_2]$ is also known, which appears to exhibit three solid-state modifications, two of which are high and the other low spin.[379] Many iron–sulfur clusters are supported in nature by the thiolate group of cysteinyl residues in proteins. A variety of complex species have been observed in reactions of iron(II) with cysteine, some involving bonding through the carboxylate oxygen and some through bridging thiolate groups. The monothiocarbamates form a series of complexes with iron(III) in a similar way to the dithiocarbamates, these also exhibit the spin-crossover phenomenon.[380] The S_2N_2-donor ligand $(^-S)C_6H_4(N^-)CH_2CH_2(N^-)C_6H_4(S^-)$ stabilizes the +4 and the +5 oxidation states of iron (see Section 5.4).



(**62**)

12 HALIDE COMPLEXES

Tetrachloro-, tetrabromo-, and tetraiodo-iron(III) and -iron(II) anions have already been mentioned in Section 4.1 alongside their respective binary halide parents. Metal-halide bond distances for about 300 species of various oxidation states and coordination numbers of iron,[381] and solution diffraction structural studies on bromoiron(II) and chloroiron(III), have been documented.[382] Tetrachloroiron(III) is a useful counterion for the preparation of salts in a suitable form for X-ray diffraction structural determinations. The redox potential for the $[FeCl_4]^{2-/-}$ couple has ben reported,[383] as have the preparation and characterization of salts of $[FeCl_4(H_2O)_2]^-$ and $[FeCl_5(H_2O)]^{2-}$,[384] along with EXAFS characterization[385] and stability[386] of the latter in solution. The crystal structures and magnetic properties of several salts of $[Fe^{II}Cl_6]^{4-}$ and of $[Fe^{III}Cl_6]^{3-}$ have been determined.[387] The $[Fe^{II}_2Cl_4(H_2O_6)]^{2-}$ anion contains two octahedral Fe^{2+} centers bridged by two chlorides.[388] The $[Fe_2Cl_6]^{2-}$ anion has recently been discovered, in the course of establishing recommended preparations for salts of the well-established $[Fe_2OCl_6]^{2-}$ anion.[389] There are many ternary iron(II) and iron(III) halide complexes containing nitrogen-donor ligands – see Sections 8.1.3 and 8.1.4, for examples. Isomerism is possible for complexes FeX_2L_4 and FeX_3L_3; the discussion[390] of the fine balance between the relative stabilities of the *mer* and *fac* forms of $[FeCl_3L_3]$ complexes provides an entry into this topic.

Glossary

Activated State: form of the enzyme that is capable of effecting substrate turnover
Active site: area in the metalloprotein where catalysis takes place
Diferric: diiron metal binding site in the $Fe^{III}Fe^{III}$ form
Diferrous: diiron metal binding site in the fully reduced $Fe^{II}Fe^{II}$ form
Dinucleating ligand: a ligand that binds two metals
High valent: iron centers in formal oxidation state (IV)
Intermediate: a species that is proposed to be present during the enzymatic catalytic cycle
Mixed valent: containing a diiron site where the oxidation states of the irons are not the same
Resting state: normally the as-isolated form of the enzyme; also a form that is present at the end of the catalytic cycle
Tetrabridged carboxylate: two iron centers that are bonded through four bridging carboxylate groups
Valence delocalized: possessing valence electrons that are exchanged between metal centers
Valence localized: possessing valence electrons that are not exchanged between metal centers

Abbreviations

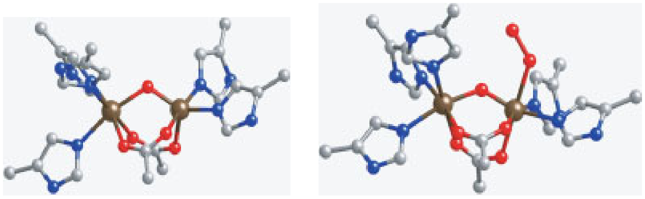
1 INTRODUCTION

The goal of diiron model chemistry is to develop small molecule systems that accurately reproduce spectroscopic, structural, and more ambitiously, reactivity aspects of diiron metalloproteins.[1] Despite being structurally similar, diiron enzymes carry out a variety of catalytic processes (*see* ***Iron Proteins with Dinuclear Active Sites***).[2–5] Advancements in the synthesis and characterization of small molecule mimics for nonheme diiron enzymes have been tremendous in the last decade. Biomimetic studies have been carried out in efforts to reproduce the structural and functional aspects of these biocatalysts.[6–10] Although this has been a challenging endeavor, much information regarding the structural and mechanistic aspects of catalytic intermediates has been obtained.

Metalloenzymes with diiron sites where the metal ions are bridged by carboxylates (i.e. glutamate, aspartate) have emerged as an important class of enzyme (*see* ***Iron Proteins with Dinuclear Active Sites***).[3–5] Several members of this



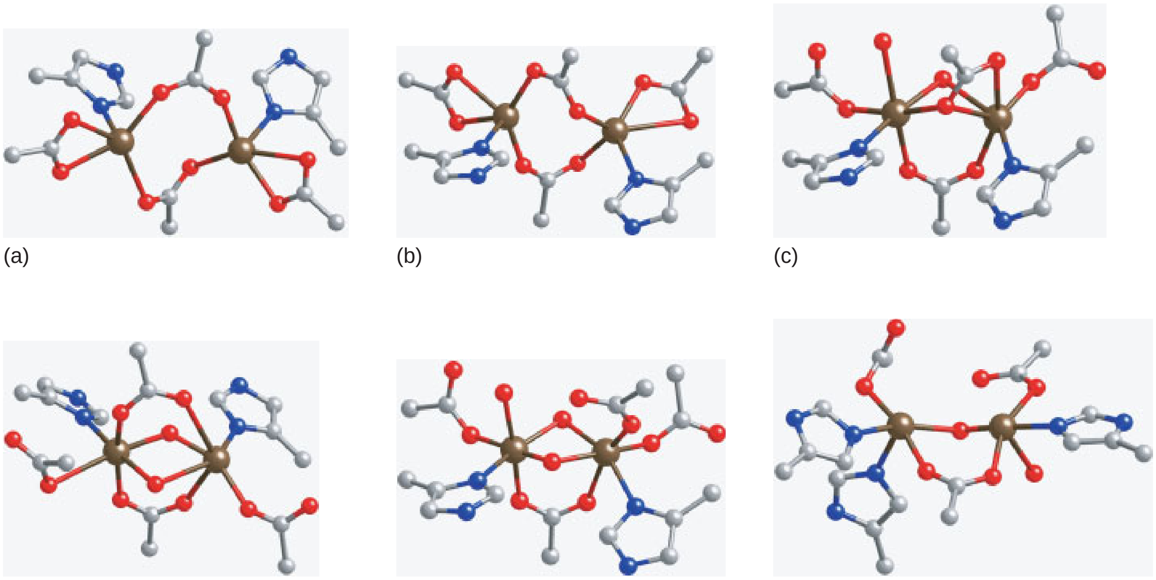
(a) (b)

Figure 1 Structure of diferrous Hr (pdb 1HMD) (a), and oxygenated Hr (pdb 1HMO) (b) Key: iron (brown), oxygen (red), nitrogen (blue), and carbon (gray)

class, isolated from mammals, plants, or bacteria, have been characterized by X-ray crystallography. The first structurally characterized protein in this class was hemerythrin (Hr),[11] which is the O_2 carrier protein in marine invertebrates. Shown below is the diferrous iron site of Hr (Figure 1(a)) and the oxygenated form of Hr (Figure 1(b)). In the reduced state, two Fe(II) centers are bridged by a hydroxo ligand along with two 1,3-μ carboxylates. One iron center additionally is bonded by three histidine nitrogens to make it six-coordinate, while the other iron is bonded by two histidine nitrogen ligands rendering it coordinatively unsaturated. This is where dioxygen binds (Figure 1(b)). Upon binding, the dioxygen molecule is reduced to the peroxide level by acceptance of one electron from each iron. The hydrogen from the bridging hydroxo group is transferred to the peroxide to generate a coordinated hydroperoxo ligand. The dioxygen molecule is transported in this manner until it is released to regenerate the deoxy or reduced form of the oxygen carrying site. Like hemoglobin, some Hr enzymes show cooperativity. Model studies of this metalloprotein have advanced the understanding of dioxygen activation and transport in nonheme diiron centers for aerobic organisms.

Other well known examples of diiron centers are those that bind and activate dioxygen for the purpose of carrying out oxidative transformations. These include the plant soluble stearoyl–acyl carrier protein (ACP) delta 9-desaturases (Δ^9D),[12] ribonucleotide reductase (RNR) from *Escherichia coli* and eukaryotes,[13] and methane monooxygenase (MMO)from methanotrophic bacteria.[14] The enzyme Δ^9D introduces a *cis* double bond at the 9,10 position of stearoyl–ACP to form oleyl–ACP. The X-ray structure of the diferrous active site is shown in Figure 2(a). In this structure, two iron sites are bridged by 1,3-μ-carboxylate groups. In addition, each iron has a chelating carboxylate and histidine nitrogen coordinated to it. It is interesting to note that the histidine groups are situated in a *syn* orientation with respect to each other. This may be important in rapid dioxygen binding.

In the small protein of class I RNR, the diiron center found in the R2 subunit serves to oxidize an endogenous tyrosine to a tyrosyl radical.[15,16] This radical is essential for initiating the conversion of ribonucleotides to deoxyribonucleotides in the rate limiting step of the biosynthesis of DNA. The X-ray structure of the diferrous form of RNR[13] is shown in Figure 2(b). This site possesses two bridging glutamates, one chelating glutamate, one chelating aspartate and two terminal histidines. The phenol side chain of a tyrosine residue is



(a) (b) (c) (d) (e) (f)

Figure 2 Structures of nonheme diiron active sites: reduced Δ^9D (pdb 1AFR) (a), reduced RNR (pdb 1PFR) (b), reduced MMO (pdb 1FYZ) (c), oxidized RNR (pdb 2R2F) (d), oxidized MMO from (pdb 1MHY) (e), and oxidized ROO (pdb 1E5D) (f) Key: iron (brown), oxygen (red), nitrogen (blue), and carbon (gray)

located nearby (within 5.3 Å). Upon reacting with dioxygen, the enzyme becomes activated through the formation of a tyrosyl radical (Scheme 1), and an oxo ligand bridges the two iron(III) atoms. An intermediate species (Intermediate **X**) is generated prior to oxidation of the tyrosine group. This species is believed to be a mixed valent Fe(III)Fe(IV) center. The oxidized (resting) form of RNR is shown in Figure 2(d). In this structure, the diiron unit contains both bridging and terminal carboxylate ligands as well as terminal histidine ligands. Additional bridging oxo and aqua ligands connecting the iron(III) centers are present.[17]

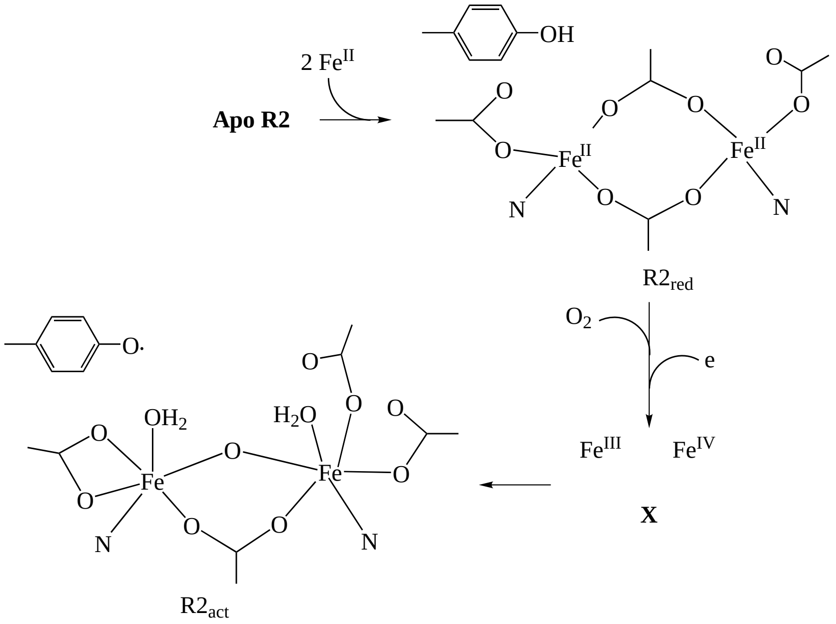
Methane monooxygenases are widely investigated metalloenzymes that catalyze the oxidation of methane to methanol by dioxygen.[18,19] This unique function achieves the first step in the metabolism of methanotrophic bacteria, which consume methane and dioxygen as their sole source of carbon and energy. The diferrous active site of the hydroxylase component (MMOH) of soluble MMO is shown in Figure 2(c). It features a diiron center containing four glutamate and two histidine residues. There is a hydroxo group bridging the two iron(II) centers (Figure 2(c)). The oxidized form or resting state is shown in Figure 2(e). It consists of a diiron(III) unit that usually contains two bridging hydroxo ligands. Scheme 2 depicts the core transformation that occurs during the MMOH catalytic cycle.

The first spectroscopically characterized intermediate in the reaction of the diferrous state (MMO_{red}) with dioxygen is a peroxo species (Intermediate **P**). This intermediate subsequently converts to a high-valent bis(μ-oxo)diiron(IV) component (Intermediate **Q**). Intermediate **Q** reacts with methane releasing methanol and generating a water molecule. The resting state (MMO_{oxd}) is reduced back to the diferrous form to close the cycle. In addition to methane, many other substrates react with MMO. These include long-chain alkanes, alkenes, halogenated and other substituted alkanes, alkynes, sulfides, and others.[20,21]

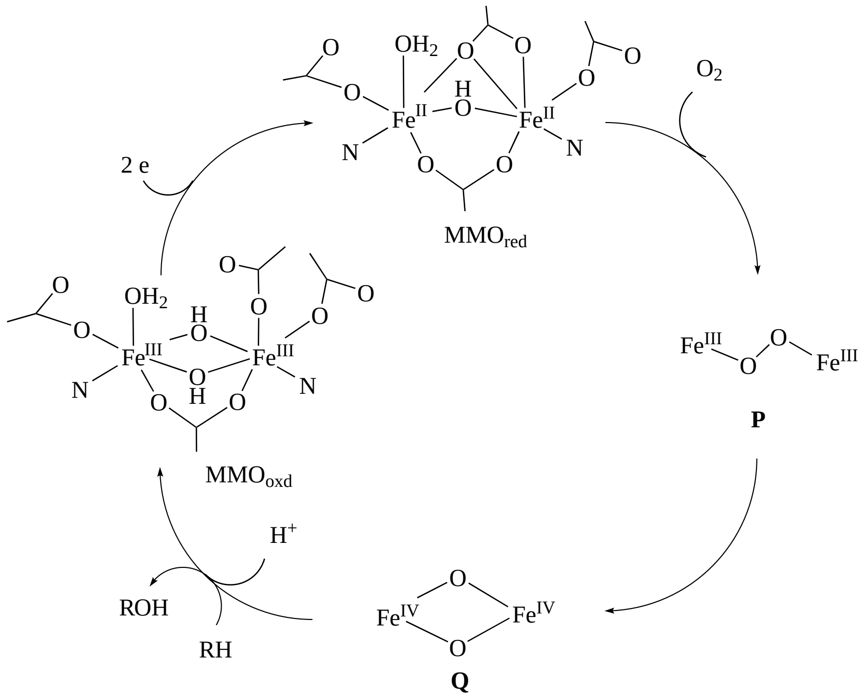
A new member of the family of nonheme diiron enzymes recently discovered is called rubrerythrin. This metalloprotein is formally classified as an oxidoreductase (rubredoxin:oxygen oxidoreductase). The diiron(III,III) active site structure is displayed in Figure 2(f). This biomolecule possesses two histidines coordinated to one iron and one histidine coordinated to the second iron. A carboxylate bridges the two irons and there are carboxylate ligands also coordinated to each iron. The purpose of this enzyme in the strict anaerobe is to safely reduce oxygen to water.[22]

It has recently been suggested from sequence analyses that diiron clusters might be present in a larger number of enzymes, thus indicating a much greater role of these clusters in O_2 activation biochemistry than previously appreciated. A number of related membrane-bound enzymes found in plants and animals have not been structurally characterized but are likely to contain a diiron site in their active sites. Bacterial toluene monooxygenase,[23] phenol hydroxylase[24] and alkene epoxidase[25] show significant homology to MMO. Ferroxidase, an enzyme that catalyzes the oxidation and subsequent storage of iron has also been identified as a diiron enzyme.[26]

Juxtaposition of two iron centers bridged by single oxygens or carboxylate oxygens allows for one- and two-electron redox processes to occur. The redox potentials of the iron centers are carefully modulated by ligands. This fine tuning is seen by the fact that removal of a particular donor and possibly changing a geometry has a dramatic influence on



Scheme 1 Reaction cycle for R2 subunit of ribonucleotide reductase



Scheme 2 Reaction cycle for methane monooxygenase hydroxylase

the active site's catalytic ability. Model chemists have the advantage of probing these effects on a much finer level than is currently possible with biological systems. There has been a multitude of crystal structures for diiron enzymes that have been determined both for the native enzymes and for mutants. The delicate balancing act for these enzymes is seen by the fact that subtle alterations in ligand properties and environment can dramatically change the reactivity.[27] A great deal of work has been carried out in the modeling of diiron enzymes and much structural data has been obtained for not only resting and activated states of the enzymes but also for proposed intermediates in various enzyme catalytic cycles. In the recent past, the increased structural information, together with spectroscopic and kinetic data, allowing the detection and characterization of key intermediates of the catalytic cycle, has clarified the mechanism of reductive oxygen activation by RNR and MMO enzymes. In addition, the employment of low-temperature rapid acquisition techniques for X-ray crystallography has allowed, in some cases, for synthetic models of proposed reactive intermediates to be structurally characterized.

The success of understanding the subtle structural, spectroscopic, and mechanistic aspects of these enzymes has been achieved through the use of specially designed supporting ligands. Several ligand types for modeling these active sites have been employed. They include multidentate dinucleating ligands, multidentate mononucleating ligands, preorganized bridging carboxylate ligands and bulky carboxylate ligands.

For many carboxylate-bridged diiron metalloenzymes, the reduced diiron(II,II) state is the most desirable target. Such compounds rarely assemble spontaneously by mixing of an iron(II) salt with carboxylates and other ligands. Designing and synthesizing suitable organic ligand precursors can therefore be a crucial first step, in which the following considerations must be addressed: (a) the ligands should have bridging potential (preferably through carboxylate ligands and/or oxygen(s)). The redox properties of the ligands should be compatible with diiron species in oxidation states II, III, and IV; (b) Steric properties of the ligand are very important. This is how one can control nuclearity and reactivity in the absence of a protein framework. (Inadequate steric bulk can lead to polynuclear complexes, whereas too much steric bulk will lead to mononuclear complexes.) (c) The coordination number of each iron atom in the resulting compound is also important. Since the Fe(II) complex must react with dioxygen, the Fe site must be coordinatively unsaturated or possess labile ligands such as water or other solvent components. Once a target dinuclear compound is in hand and demonstrated to be a reasonable structural and spectroscopic mimic of a diiron metalloprotein active site, the next objective is to explore its chemical reactivity with an oxidant, preferably dioxygen. Generating an intermediate similar to those encountered with the natural systems will help to characterize these species and may also provide a model with functional properties.[9,28] Structural flexibility is important since rearrangement is inevitable in the catalytic cycle.[14] Intraligand hydrogen bonding may assist in the desired chemical transformation. The model compound should

be in the diferric state after turnover to allow further cycles to ensue. Achieving substrate turnover in a catalytic manner under mild conditions is an important goal for this research.

The following highlights are in the authors' opinion the most significant advances in the area of model chemistry for diiron enzymes. This article endeavors to review recent developments in nonheme model chemistry with emphasis on well defined structurally characterized synthetic models. Their spectroscopic properties will be discussed along with their relevance to the enzyme active sites and the parallels of their reactivities as they relate to these enzymes.

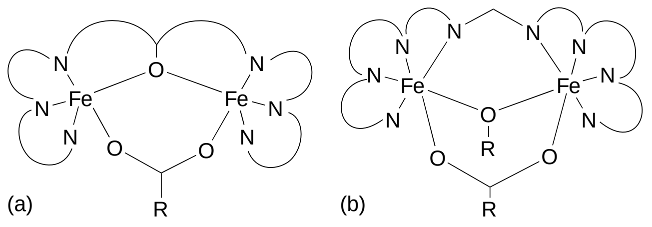


Figure 3 Diiron(II,II) complexes supported by dinucleating ligands

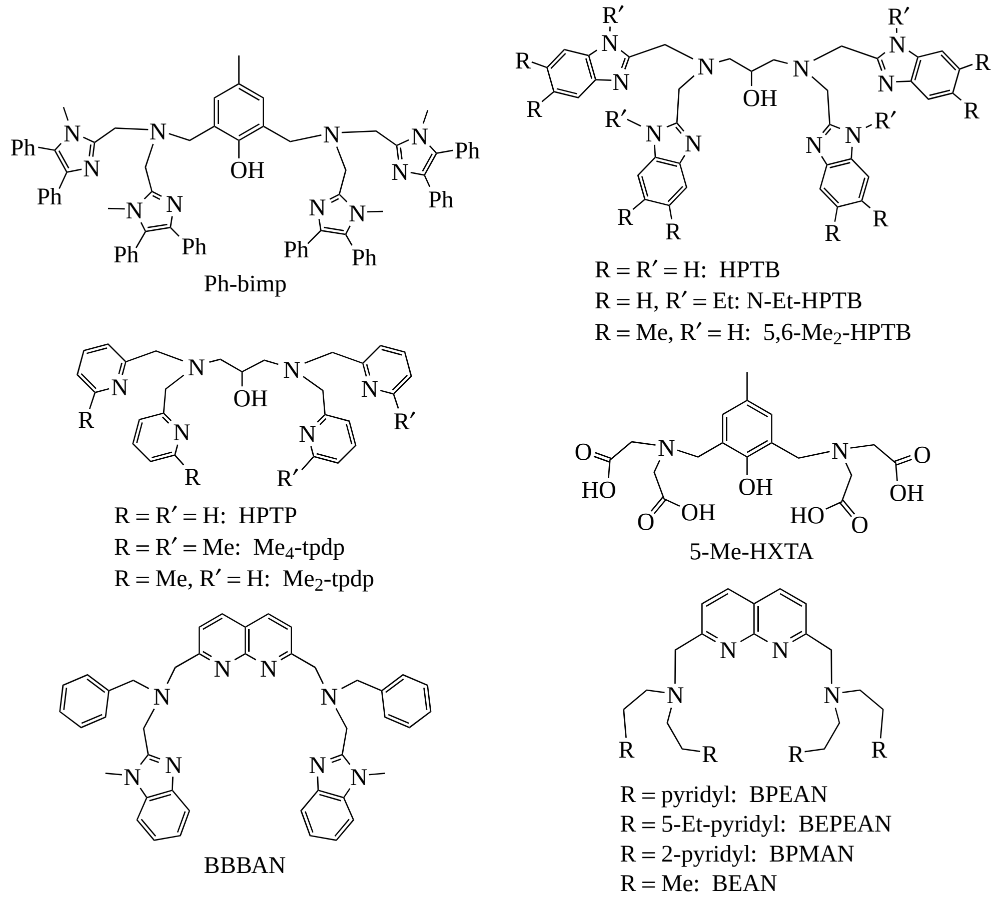
2 SYNTHESIS AND STRUCTURES

2.1 Models Using Multidentate Dinucleating Ligands

Several multidentate dinucleating ligands have been employed to assemble diiron(II) complexes (Scheme 3). The general synthetic strategy for diiron complexes supported by these ligands involves reaction of Fe(II) salts under anaerobic conditions in anhydrous solvent with the ligand in the presence of base and other carboxylate ligand(s).[29–31] Using such an approach, structures such as those shown in Figure 3 can be isolated in crystalline form. These compounds are good models for the diferrous site of hemerythrin since they are nitrogen rich. Recently, diiron compounds supported by naphthyridine-containing dinucleating ligands such as BBBAN (Scheme 3) have been reported. The bridging naphthyridine group is designed to mimic a bridging carboxylate ligand that is almost always present in nonheme diiron enzymes. The advantage of employing this ligand is



Scheme 3 Multidentate dinucleating ligands

that there is less potential for structural rearrangement in the bridging ligand group.

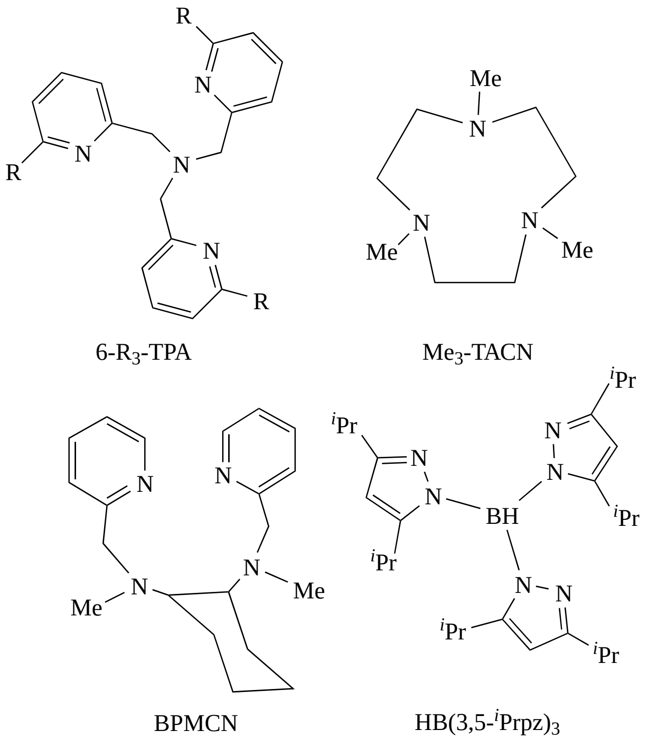
A great deal of structural diversity is seen with these ligands. A carboxylate ligand can be added to the hydroxo- or alkoxo-bridged diiron(II) compound[32,33] to generate a carboxylato bridged species (Figure 3(b)).[32]

Addition of carboxylate ligands to a non hydroxo-bridged analog leads to multiply bridged carboxylate species (Figure 3(a)).[32,33] Phenoxo-bridged diiron(III,III) compounds with two bridging carboxylate ligands have been synthesized using the dinucleating ligand 5-Me-HXTA (Scheme 3).[34] In this method, iron(III) is mixed with deprotonated 5-Me-HXTA in methanol. Acetate is then added to generate $[Fe_2(HXTA)(OAc)_2]^{2+}$.

2.2 Models Using Multidentate Mononucleating Ligands

Approaches to synthesizing diiron units supported by multidentate mononucleating ligands (Scheme 4) have been investigated using capping nitrogen ligands. With ligands such as TPA and its derivatives, structural diversity for diiron compounds is achieved by variation of the bridging ligand(s) or by introducing steric bulk to the pyridine substituents. For example, double-bridged compounds such as $(6\text{-}Me_3TPA)_2Fe_2(\mu\text{-}OH)_2$,[35] and $(TPA)_2Fe_2(\mu\text{-}Cl)_2$[36] differ primarily by the identity of the bridging ligands with each iron coordinated by three pyridine nitrogens and one central amine nitrogen ligand. The dibridged complex $[L_2Fe_2(\mu\text{-}O)(\mu\text{-}OH)]^{3+}$ can be obtained by reaction of Fe(II) with 6-Me_3-TPA in the presence of *t*-BuOOH and water.[37] A $Fe_2(\mu\text{-}O)(\mu\text{-}HCO_2)$ core was unexpectedly constructed by reaction of TPA with Fe(III) in the presence of base.[38] In efforts to model the resting state of the nonheme enzymes, several diiron(III,III) complexes featuring a bridging oxo group have been synthesized (Figure 4). These structures are noted for complexes where L = TPA.[38]

There have also been several examples of valence-delocalized Fe(II)Fe(III), $S = 9/2$ species generated from diiron complexes supported by terminally chelating ligands $[(Me_3\text{-tacn})_2Fe_2(\mu\text{-}OH)_3]^{2+}$ (Me_3-tacn = 1,4,7-trimethyl-1,4,7-triazacyclononane),[39] and $[(C_{24}H_{26}N_4O_2)Fe_2(\mu\text{-}OAc)_2]^{+}$.[40]



Scheme 4 Multidentate mononucleating ligands

2.3 Models Using Preorganized Bridging Carboxylate Ligands

A recent approach to obtain diiron model compounds involves the employment of preorganized carboxylate-bridged ligands (Scheme 5). Addition of nonchelating N donors and carboxylates completes the coordination.[41] The ligand *m*-xylylenediamine bis(Kemp's triacid)imide (H_2XDK) and related ligands H_2PXDK and H_2BXDK (Scheme 5) provides structures shown in Figure 5(a) when two equivalents of N-donor ligand and two equivalents of carboxylate ligand are added.[42,43] The $Fe_2(\mu\text{-}O)(\mu\text{-}RCO_2)_2$ core can also be synthesized using the preorganized XDK^{2-} ligand.[44] Diiron(II,II) compounds can be constructed with the preorganized dibenzofuran-4,6-bis(diphenyl acetic acid) (H_2Ph_4-DBA) (Scheme 5).

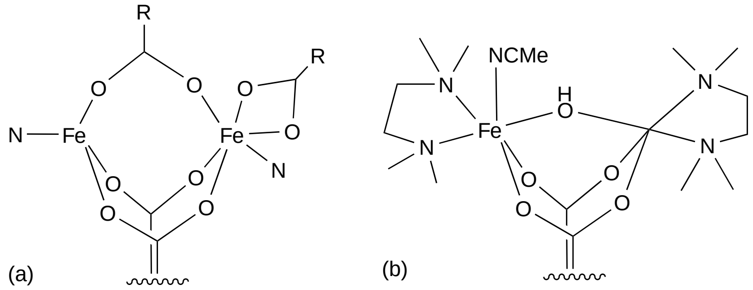

Figure 5 Diiron complexes assembled with XDK^{2-} ligands (a), and Ph_4DBA^{2-} ligand (b)

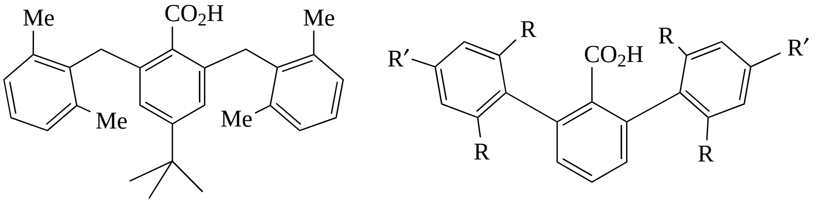
Using H_2Ph_4-DBA, Lippard and coworkers isolated a diiron(II,II) complex that has a donor set (Figure 5(b)) that is identical to that of diferrous hemerythrin.[45]

2.4 Models Using Bulky Carboxylate Ligands

A method that has recently been introduced to the study of diiron model complexes involves self-assembly reactions using bulky carboxylate ligands (Scheme 6). The steric bulk is employed about the carboxylate group to control nuclearity. In this approach, simple nonchelating N-donor ligands are employed as ancillary ligands. This method allows these complexes to 'breathe' structurally thus closely approximating what is seen at the actual nonheme active sites during the catalytic cycles. This approach has been successful in generating several diferrous model complexes that possess the same donor set found in nonheme enzymes (i.e. 4 carboxylates, and two N-donor ligands).[6,9] Utilizing this method, one can obtain di-, tri-, and tetrabridged carboxylate diiron(II,II) compounds with various terminal N-donor ligands.[9,46,47]

The success with this approach is seen by the fact that two groups have successfully synthesized good structural models for the diiron(II,II) centers in reduced RNR (Figure 6(a)).[48,49]



dxlCO_2H

R = Me, R′ = Me: Mes_2ArCO_2H
R = H, R′ = Me: $Ar^{Tol}CO_2H$

Scheme 6 Bulky Carboxylate Ligands

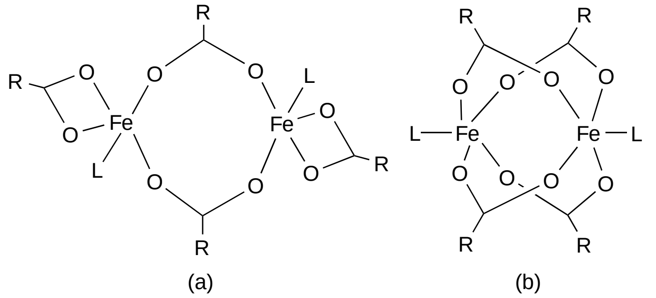


Figure 6 Dibridged (a) and tetrabridged (b) diiron(II,II) carboxylate complexes

The Fe–Fe distances for these complexes are ca. 4.0 Å, which is quite close to the value for RNR. For less sterically hindered carboxylate ligands such as benzoate, pivalate,[50] and 2,6-di(*m*-xylyl)benzoate (Scheme 6),[46] a tetrabridged carboxylate structure is obtained with Fe–Fe distances of ca. 2.8 Å (Figure 6(b)). Interestingly, this tetrabridged carboxylate structure is also obtained when $Ar^{Tol}CO_2H$ (Scheme 6) and 4-*t*-butylpyridine are used to generate the diiron compound thus demonstrating the low-energy barriers between structures in this case. Because of the lability often encountered with high spin iron(II) complexes, the success of these approaches has been primarily due to the use of intramolecular interactions.

The mixed valent diiron(II,III) species has relevance to nonheme enzymes. Recently, structural information on such compounds with bridging and terminal carboxylate ligands has been obtained.[51,52] The structures of one of these compounds is shown in Figure 7. The syntheses for the two species shown are identical. The structural variation in the bridging isopropoxide groups comes about from the conditions for crystallization.[52] The structure in Figure 7(a) has an Fe–Fe distance of 2.7485(5) Å while the structure in Figure 7(b) has a Fe–Fe distance of 2.6241(9) Å. This minor conformational difference results in tuning of the electronic state for these two structures. The structure in Figure 7(a) is valence localized with antiferromagnetically coupled iron sites ($S = 1/2$) while the structure in Figure 7(b) is valence delocalized with ferromagnetically coupled iron sites ($S = 9/2$). The compound $(Mes_2ArCO_2)_3Fe_2(OCHMe_2)$[51,52]

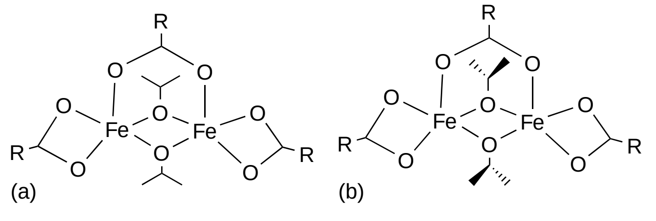

Figure 7 Structure of valence-localized (a), and valence-delocalized Fe(II,III) complex ($R = Mes_2ArCO^{2-}$) (b)

was synthesized by exposing the diferrous starting material $(Mes2_2ArCO_2)_2Fe_2(\mu\text{-}Mes_2ArCO_2)_2$ to dioxygen in the presence of isopropanol. Recently, several valence-delocalized Fe(II,III) complexes have been prepared by Lippard *et al.*[51] These complexes possess a tetracarboxylate-bridged diiron center (Figure 6(b)) with various axial donor ligands (L = THF, Py, 4-*t*-BuPy). The Fe–Fe distances for the THF, Py, and 4-*t*-BuPy complexes are 2.6633(11), 2.6982(13), and 2.713(3) Å, respectively. For these compounds, it is indicated that direct Fe–Fe interaction may provide the exchange mechanism. $[Fe_2(\mu\text{-}O_2CAr^{Tol})_4(Py)_2]^+$ was synthesized by the stoichiometric addition of one equivalent of oxidizing agent (AgOTf, Cp_2FePF_6) to the diferrous starting material $[Fe_2(\mu\text{-}O_2CAr^{Tol})_4(Py)_2]$.

3 SPECTROSCOPIC FEATURES OF DIIRON MODEL COMPLEXES

Carboxylate-rich diiron(II,II) model complexes typically do not have strong absorbances in the visible region. In some cases, charge transfer bands may extend into the visible region leading to compounds that are yellow to beige in color depending on the donor set. These complexes also tend to be high spin and consequently kinetically labile, which is a characteristic found in carboxylate-rich nonheme diiron systems. The d–d transitions of high-spin iron(II) complexes can provide valuable information on the stereochemistry around the iron(II) centers: for six-coordinate complexes of Fe, the electronic transitions from $^5T_2$ to ^5E (in octahedral symmetry) have been shown to split into two bands while for five-coordinate complexes, the splitting is much larger. Diiron(II,II) compounds possessing μ-oxo or μ-hydroxo groups contain visible bands at ~500 nm and 800 nm ($\varepsilon \sim 70\,M^{-1}\,cm^{-1}$).[37,53,54]

The electronic absorption spectra of diiron(III,III) complexes are dominated by ligand-to-metal charge transfer bands. Again, those complexes that accurately mimic the electronic states of nonheme enzymes are high spin. The UV-visible spectra of mixed valent diiron(II,III) complexes are dependent on the electronic characteristics of the complex. For example, in a valence-localized situation ($S = 1/2$), absorption bands in the visible region may correspond to ligand-to-metal charge transfer bands while in a valence-delocalized situation ($S = 9/2$), intervalence charge transfer bands may also be present.

Mössbauer parameters have been instrumental in characterizing diiron sites in model systems. The electronic environment can be assessed by the Mössbauer parameters. At ~4 K, the isomer shift δ for iron(II) centers typically falls between 1.06 and 1.35 $mm\,s^{-1}$, whereas the quadrupole splitting ΔE_Q varies from 1.95 to 3.28 $mm\,s^{-1}$. The isomer shift for diferric species is characteristically small compared to that for diferrous centers. Typical values fall between 0.40

and 0.52 mm s^{-1}. Quadrupole splittings, however, are less informative regarding the oxidation state of the metal since there is much overlap with ferrous parameters. Mixed valent $Fe^{II}Fe^{III}$ and $Fe^{III}Fe^{IV}$ species have Mössbauer spectra that shed light on the electronic state of the complexes. In a valence-localized state, the absorption bands correspond to the individual iron sites in their oxidation states. In a valence-delocalized situation, the spectra become more complicated.[55] In any event, Mössbauer spectroscopy can be instrumental in determining the spin state and electronic properties of the species under study.

4 REACTIVITY OF DIIRON MODEL COMPLEXES

The reaction of the diferrous form of nonheme enzymes with dioxygen initially leads to several types of intermediates depending on the enzyme. For the oxygen carrier protein hemerythrin, dioxygen reversibly binds to the diferrous form generating a coordinated hydroperoxide complex (vide supra). Model studies for this reaction have successfully reproduced this reaction. Using the preorganized dicarboxylate ligand H_2Ph_4DBA (Scheme 5),[45] the diiron(II,II) complex was synthesized, accurately reproducing the coordination of deoxy hemerythrin. When this diferrous compound is exposed to dioxygen at low temperature, in the presence of three equivalents of 1-methylimidazole, spectroscopic evidence indicates that a diiron(III,III) complex is generated with a putative coordinated hydroperoxide ligand. Evidence for the generation of the hydroperoxide adduct was also obtained for a napthyridine based system. The dinucleating ligands BPEAN and BEPEAN (Scheme 3) were employed to synthesize diiron(III,III) complexes, which possessed the structure shown in Figure 3(b).[56] These complexes were reacted with hydrogen peroxide to generate a diiron(III,III) complex with a coordinated hydroperoxide ligand (verified by resonance Raman spectroscopy). The cryoreduced diiron(II,III) complex was characterized by electron paramagnetic resonance (EPR) and ^{1}H electron-nuclear double resonance (ENDOR) spectroscopy.[56]

For nonheme enzymes that further activate dioxygen, it is apparent that the diferrous forms also bind O_2 to eventually generate the active species responsible for the oxidative transformations. In the case of MMO, the first intermediate has been labeled compound **P** (Scheme 2), which subsequently converts to compound **Q**; both are kinetically competent to hydroxylate methane. In the case of RNR, compound **X** (Scheme 1) is responsible for the one-electron oxidation of a tyrosine residue to generate a tyrosyl radical. Based on chemical considerations and its Mössbauer properties, it has been proposed that compound **P** is a diferric peroxide species. To date, three model complexes of compound **P**, with comparable spectroscopic properties, have been structurally characterized (Figure 8).[29,57,58] In two of these models O_2 is bound in a *cis* μ-1,2-peroxo fashion while in a third, it is bound in a *trans* μ-1,2-peroxo manner. As in the enzyme, these compounds were all generated during reaction of diiron(II,II) precursors with molecular oxygen. That O_2 binds to the iron center through an oxidative addition is consistent with the fact that MMO can function with hydrogen peroxide as the oxidant in the absence of electrons and oxygen. In this reaction, compound **P** is also likely to be an intermediate. Many other systems that react with dioxygen in the diferrous state to generate diferric peroxide intermediates have been studied.[35,46,59,60]

In MMO, compound **Q** has been identified as a coupled diiron(IV,IV) species, on the basis of its Mössbauer spectrum. While different structures for compound **Q** are possible, there is now some spectroscopic evidence (X-ray absorption fine structure and Mössbauer spectroscopy) that the diiron center in compound **Q** is a high-valent $Fe_2(\mu\text{-}O)_2$ diamond core (Scheme 2). In the proposed mechanism, reaction

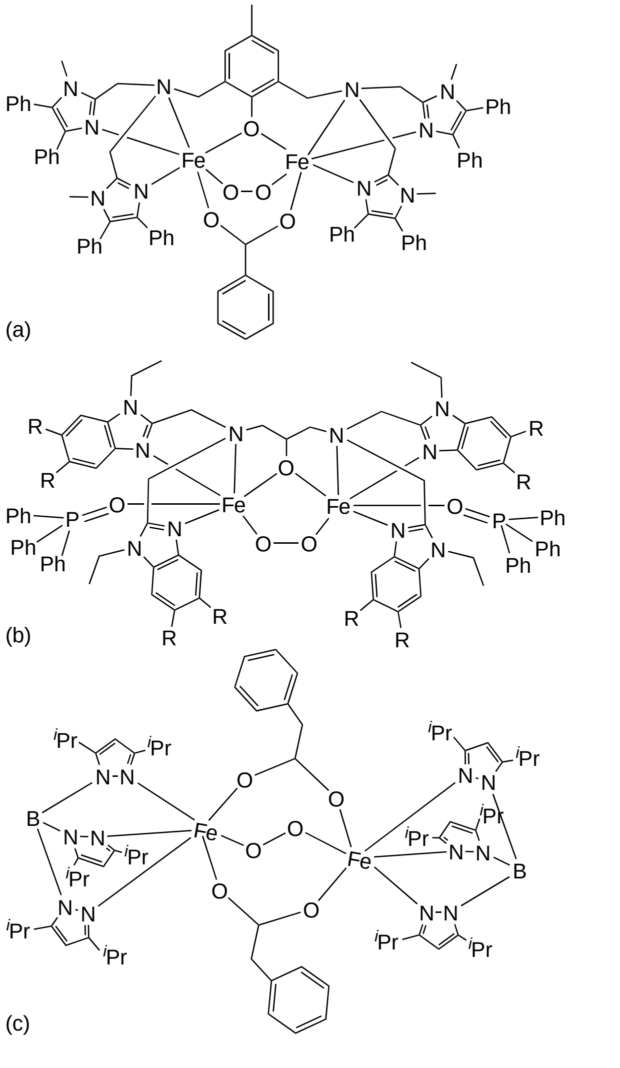

Figure 8 Schematic view of $[Fe_2(Ph\text{-bimp})(PhCO_2)(\mu\text{-}O_2)]^{2+}$ (a), $[Fe_2(N\text{-Et-hptb})(Ph_3PO)_2(O_2)]^{3+}$ (b), and $[Fe_2\{HB(3,5\text{-}i\text{Prpz})_3\}_2(PhCH_2CO_2)_2(\mu\text{-}O_2)]^{2+}$ (c)

products are derived from the two-electron oxidation of the substrate by compound **Q**. Recently, a system employed by Que *et al.* was used to generate a complex evidenced to contain a Fe(IV,IV) unit, which is the first example of a model compound for intermediate **Q**.[61] The supporting ligand is BPMCN (Scheme 4), and the compound was synthesized by treatment of the Fe(II) precursor, namely, $Fe(BPMCN)(OTf)_2$ ($Tf^- = CF_3SO_2{}^-$) with 10 equivalents *t*-BuOOH at $-80\,°C$ in dichloromethane. Initially a Fe^{III}-OO-*t*-Bu species is generated. Upon standing at $-80\,°C$, this species monotonically converts to a species with $S = 1$ spin state. EXAFS measurements support the presence of a $Fe_2(\mu\text{-}O)_2$ core. To explain the spin state, one would have to invoke an exchange coupled low-spin $S_1 = 1/2$, $S_2 = 1/2$ species. This species is capable of alkane oxidation.

Compound **X** from the catalytic cycle of RNR (Scheme 1) is an $S = 1/2$ species, contains only one oxidizing equivalent above the diferric state, and is catalytically competent for oxidizing the tyrosine residue to the tyrosyl radical. While it has first been described as a coupled system consisting of two high-spin Fe(III) plus a ligand radical, recent reanalysis of the ENDOR and Mössbauer experiments now strongly suggests that compound **X** carries a spin-coupled diiron(III,IV) center. A dinuclear $S = 3/2$ diiron(III,IV) complex, containing an $Fe_2(\mu\text{-}O)_2$ core, has been generated during reaction of H_2O_2 with (μ-oxo)diiron(III)(TPA).[62] This complex can carry out oxidation reactions corresponding to those associated with MMO (oxidation of ethylbenzene), desaturase (desaturation of ethylbenzene), or RNR (oxidation of 2,4-di-*tert*-butylphenol to the corresponding phenoxyl radical). In addition, an $S = 1/2$ model containing diiron(III,IV) bridged by a $(\mu\text{-}O)_2$ core, has also been obtained during reaction of H_2O_2 with a bis-(μ-oxo)diiron(III)(5-R_3-TPA) complex (Figure 9; R = Et).[63] This product is dark green and has the formulation for $[Fe_2(\mu\text{-}O)2(5\text{-}Et\text{-}TPA)_2]^{3+}$. Its EPR properties are strikingly similar to those of compound **X**. The fact that no intermediate corresponding to compounds **P** and **Q** could be detected for RNR does not necessarily mean that they are not transiently formed in the enzymatic system. Electron transfer to the metal site may be too fast and prevent accumulation of such species. Nevertheless, two-electron, and not only one-electron, oxidation has been observed in the case of RNR, suggesting the intermediate formation of a compound **Q**-like species, with two oxidizing equivalents above the diiron(III,III) state.

When the precursor to the Fe(III,IV) compound is $[Fe^{III}2(\mu\text{-}O)_2(6\text{-}Me_3\text{-}TPA)_2]^{2+}$, one-electron oxidation affords a Fe^{III}-O-Fe^{IV}=O core structure derived from the isomerization of the $Fe_2(\mu\text{-}O)_2$ diamond core, demonstrating the accessibility of a terminal Fe^{IV}=O unit in a nonheme environment.[64] A different approach to achieve the Fe(III,IV) unit has also been carried out by Lippard *et al.*[65] In this method, a tetracarboxylate-bridged diiron(II,II) complex $(4\text{-}t\text{-}BuPy)_2Fe_2(\mu\text{-}RCO_2)_4$ where $RCO_2{}^-$ is the bulky carboxylate $Ar^{Tol}CO_2{}^-$ (Scheme 6) is exposed to dioxygen at $-79\,°C$. Among the products identified by Mössbauer and EPR spectroscopy is an Fe(III,IV) species.

Much success has been achieved in the modeling of various states for nonheme enzymes. The shortfall so far has been in reproducing the full reactivity found in these enzymes. Oxidation of substrates using molecular oxygen at moderate temperatures is a goal that has yet to be reached. Only a few examples exist in which a substrate can be oxidized in both a stoichiometric and catalytic manner with molecular oxygen as the oxidant. The substrates in this case tend to be easily oxidizable compounds such as phosphines and thioethers.[66–68] Lippard *et al.* have demonstrated the catalytic oxidation of triphenylphosphine with oxygen as the oxidant. They concluded that in their system, the oxidation was not occurring from an intermediate formed but from transfer of a bridging oxo group to the phosphine.[68] In addition, they also studied the oxidative capabilities of the peroxo species derived from the XDK ligands and found that this intermediate was not capable of oxidizing potent acceptors such as triphenylphosphine and that solvent oxidation occurred via radical autoxidation. In a system employed by Tolman *et al.*, it was demonstrated that a peroxo species derived from a carboxylate-bridged diiron complex was capable of stoichiometrically oxidizing triphenylphosphine.[66] The proposed mechanism involves the direct coordination of the triphenylphosphine substrate to the peroxo species.

1 INTRODUCTION

Iron is the most abundant and least expensive of the transition metals, and the level of interest in studying its organometallic chemistry has been, and continues to be, truly staggering. Indeed, the organometallic chemistry of iron has been central to the development of this field of chemistry. In discussing this facet of the chemistry of iron, this article will primarily concentrate on mononuclear species that contain a Fe–C bond. Many of the individual topics covered here have been the subject of reviews, book chapters, and monographs, and the reader will be directed to these for in-depth coverage.

Certain classical coordination complexes (*see Coordination Complexes*) of iron (e.g. Prussian blue) will be dealt with in other articles (*see* ***Iron: Inorganic & Coordination Chemistry*** and ***Cyanide Complexes of the Transition Metals***), as will much of the chemistries of iron carbonyls (*see Metal Carbonyls*) and iron hydrides (*see Hydrides*) (*see* ***Carbonyl Complexes of the Transition Metals***; ***Transition Metal Carbonyls: Infrared Spectra***, and ***Hydride Complexes of the Transition Metals***). The use of organoiron complexes as catalysts (*see Catalysis*) in organic transformations will be mentioned but will primarily be covered elsewhere (*see* ***Asymmetric Synthesis by Homogeneous Catalysis***, and ***Organic Synthesis using Transition Metal Carbonyl Complexes***).

The organometallic chemistry of iron had been frequently reviewed by Kerber between 1984 and 1992,[1] and a thorough review by the same author appeared in *Comprehensive Organometallic Chemistry II*.[2] An extensive review of the application of organoiron complexes to organic synthesis appeared in 1991.[3] A monograph by Pearson was published in 1995, and a more narrowly focused update on recent developments (through 1998) were summarized by Rück-Braun.[4,5] This article will follow a ligand (*see Ligand*)-based classification, depending upon the hapticity (*see Hapticity*) of the ligand of greatest interest.

2 COMMON SYNTHETIC PRECURSORS

By far most of the organometallic chemistry of iron discussed in this article relies on just a handful of commercially available precursors or complexes prepared directly from them. There are three commercially available iron carbonyls: $Fe(CO)_5$ (**1**, iron pentacarbonyl), $Fe_2(CO)_9$ (**2**,

iron nonacarbonyl), and $Fe_3(CO)_{12}$ (**3**, iron dodecacarbonyl).[6] Though toxic, $Fe(CO)_5$ is by far the least expensive of these, and the latter two complexes may be prepared from it. These are used to gain access to many of the η^2-alkene, η^3-allyl, and η^4-diene iron complexes to be described in subsequent sections of this article; (**1**) is also commonly used as a reagent in a variety of organic functional group transformations. Also, reduction of (**1**) with sodium-benzophenone ketyl affords $Na_2Fe(CO)_4$ (**4**, disodium tetracarbonylferrate or 'Collman's reagent' (*see Collman's Reagent*)), which also has a rich chemistry of its own (see Section 3.1.1) and is commercially available as well (as a 1:1.5 complex with dioxane) (equation 1).

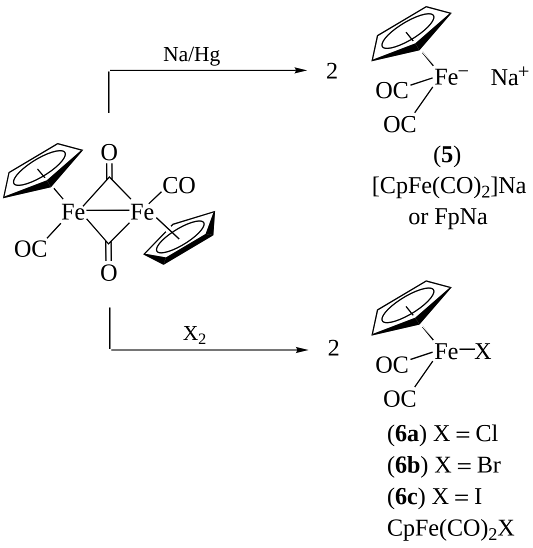
Many other iron complexes (η^1-alkyls, η^1-acyls, η^1-alkynyls, cationic η^2-alkenes, and carbenes) are ultimately derived from either sodium dicarbonyl(cyclopentadienyl) ferrate (**5**) (abbreviated as $[Cp(CO)_2Fe]Na$ or simply FpNa) or one of the dicarbonylcyclopentadienylhalo iron species (**6**), $CpFe(CO)_2X$ (where X = Cl, Br, or I). Iodo analog (**6c**) is commercially available. Both (**5**) and (**6**), in fact, are derived from the commercially available dimer $[Cp(CO)_2Fe]_2$ (Scheme 1), and typically (**5**) is prepared and used *in situ* (*see In Situ Reaction*).

The chemistry of ferrocene and its derivatives form a significant subset of iron organometallic chemistry. Ferrocene is commercially available; its chemistry will be discussed in Section 7.



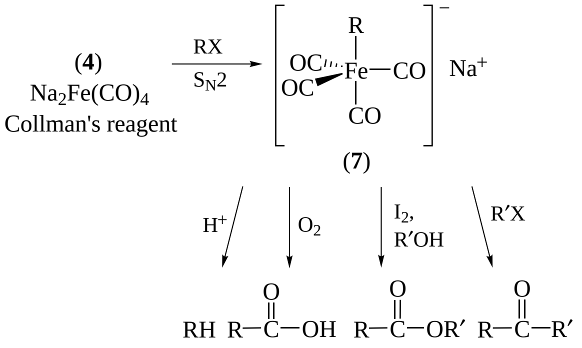
Scheme 1

3 η^1-LIGAND COMPLEXES[7]

3.1 Iron σ-Alkyls

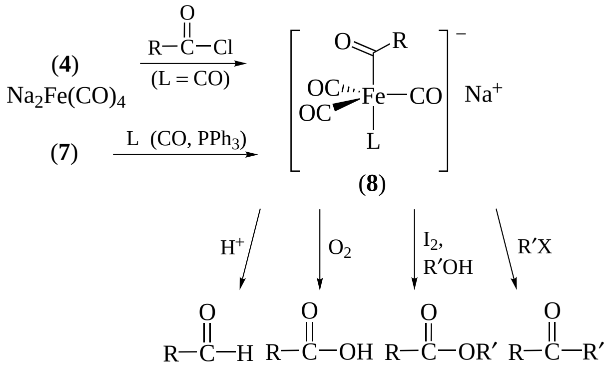
3.1.1 *Preparation of Anionic Complexes and Use in Functional Group Transformations*

Treatment of the d^{10} Fe(−2) Collman's reagent (**4**) with an alkyl halide produces an air-sensitive, coordinatively saturated (*see Coordinative Saturation & Unsaturation*) anionic (*see Anion*) $d^8\sigma$-alkyliron(0) complex (**7**) in situ (Scheme 2) that is readily converted to other organic functionalities.[8] Production of this η^1-alkyliron species follows S_N2 (*see Nucleophile*) reactivity (second-order kinetics, stereochemical (*see Stereochemistry*) inversion, sensitivity to steric hindrance). Because (**4**) is quite basic, the reaction is generally limited to simple primary and some secondary halides, as elimination is competitive. Furthermore, transformations that involve an insertion (*see Insertion*) of CO into the alkyl-iron bond (as in the reaction with R'X to form ketones or with iodination/alcoholysis to form esters) fail if R possesses an adjacent electron-withdrawing group. Alternatively, an acyl-iron anion (**8**) may be generated (Scheme 3) by reaction of (**4**) with acid chlorides or by treatment with additional ligand (via CO migratory insertion

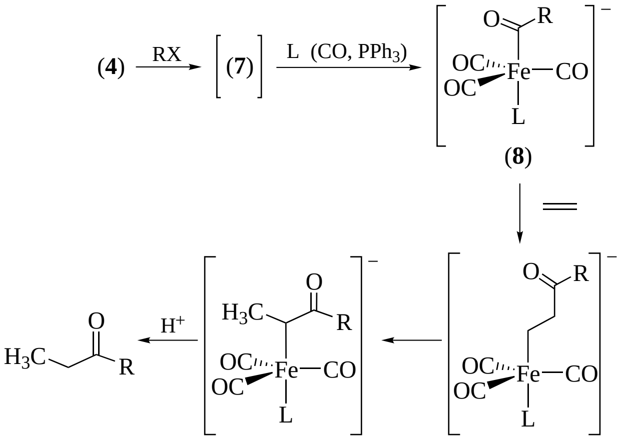


Scheme 2

(*see Migratory Insertion*)). Anion (**8**) may similarly be used to prepare an array of different organic functionality, including aldehydes via protonation (*see Protonation*) with acetic acid. This chemistry has been studied carefully (both (**7**) and (**8**) have been isolated and characterized) and mechanistic details are available.[9] Presumably the formation of the organic products occurs by formation of a six-coordinate d^6 species, followed by reductive elimination (*see Reductive Elimination*).

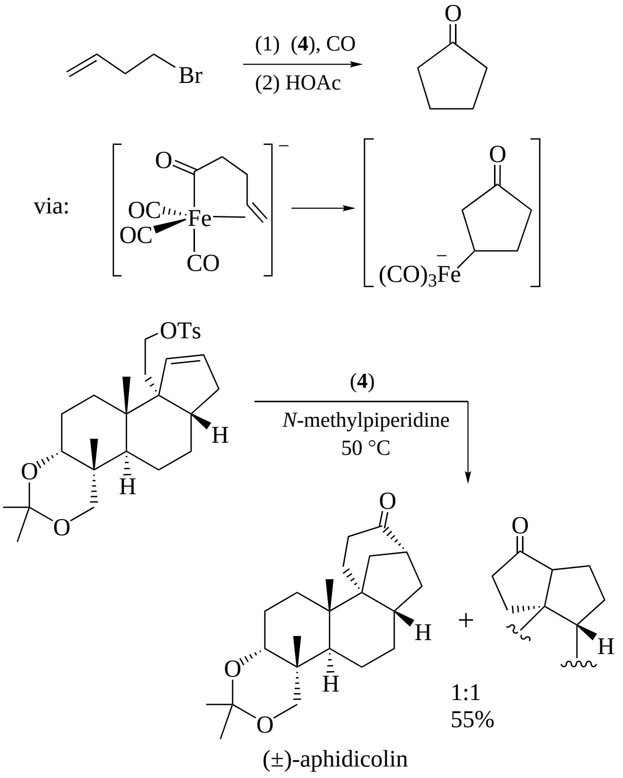


Scheme 3

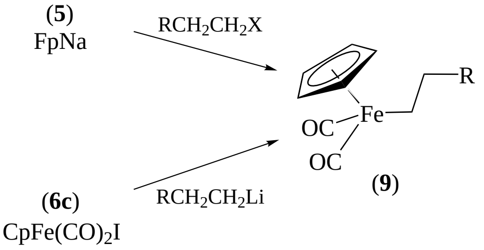


Scheme 4

Anionic acyl-iron complex (**8**) may be intercepted by ethylene, which inserts into the acyl-iron bond to produce a β-metalloketone that rearranges to an α-metalloketone (Scheme 4). Protonation affords the ethyl ketone. Intramolecular (*see Intramolecular*) versions of this process are known as well, and provide an approach to cyclic ketones. That the cyclization is not always regioselective (*see Regioselectivity*) is shown in an example used in the total synthesis of (±)-aphidicolin (Scheme 5).[10,11]



Scheme 5



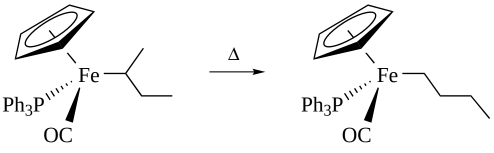
Scheme 6

3.1.2 *Preparation of Neutral Complexes*

Neutral σ-alkyliron complexes are obtained upon reaction of $Na[Cp(CO)_2Fe]$ (**5**) with alkyl halides (**9**) (Scheme 6),[12] and as with Collman's reagent this occurs in an S_N2 fashion with inversion of configuration at the carbon atom. Epoxides also participate in this reaction,[4] but tertiary alkyl halides are poor substrates. Alternatively, complexes (**9**) may be prepared by reaction of an appropriate metal alkyl with $Cp(CO)_2FeX$ (**6**). Typically complexes of this type are prepared in order to gain access to the synthetically useful cationic η^2-alkene iron complexes (Section 4.1.2). Also, nucleophilic addition of (**5**) to heteroatom-substituted alkyl halides (such as methoxymethylchloride or chloromethyl methyl sulfide) affords complexes of type (**9**) that can be converted to cationic

iron carbenes (Section 3.5.2). These processes can be reversed, as (**9**) can be obtained from nucleophilic addition to either cationic carbene complexes or cationic η^2-alkene complexes (*see Alkene Complexes*). The cyclopropyl analog of (**9**) is best obtained by a decarbonylation of the iron acyl complex via low-temperature photolysis (Section 3.5).

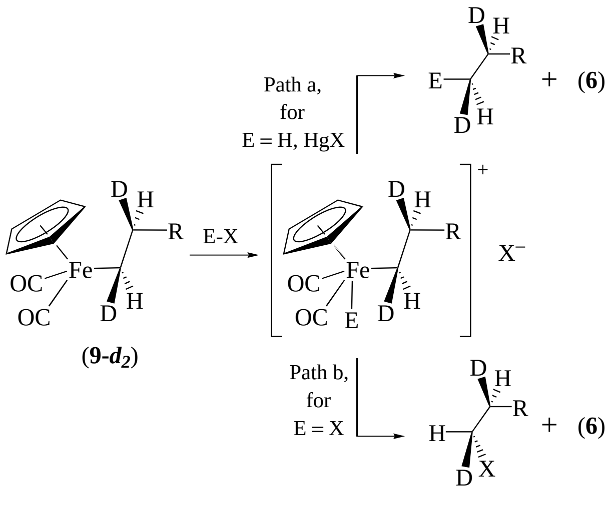
Under ambient conditions σ-alkyl complexes (**9**) are isolable and stable with respect to β-hydride elimination (*see β-Hydride Elimination*), since they are coordinatively saturated. However, it should be noted that related complexes of the type $Cp(CO)(PPh_3)FeCH_2CH_2R$ will thermally decompose in solution (ca. 60 °C) or neat to give the corresponding alkene and an iron hydride $Cp(CO)(PPh_3)FeH$.[13] This is believed to occur via dissociation (*see Dissociation*) of the phosphine ligand to generate a vacant coordination site (*see Vacant Site*), followed by β-hydride elimination to afford an η^2-alkene ironhydride species. Substitution of the alkene ligand by phosphine affords the product hydride. Notably, added phosphine ligand inhibits the decomposition reaction. This mechanism is also believed to be operative in the thermal rearrangement of certain σ-alkyliron complexes (e.g. **10** → **11**) (equation 2).



(**10**) (**11**) (2)

3.1.3 Cleavage Reactions of Neutral Complexes

The iron–σ-alkyl bond in (**9**) may be cleaved by reaction with acid, with halogens, or with mercury(II) halides to afford the corresponding alkanes, alkyl halides, or alkyl mercury(II) halides respectively (Scheme 7).[14] This occurs with retention of configuration at the carbon atom for cleavage with acid[15] and mercury(II) chloride,[16] while reaction with halogens gives inversion of configuration at the carbon atom.[16] If the electrophilic cleavage of iron alkyls, chiral (*see Chiral*) at the metal, is not carried to completion, the recovered iron alkyls are partially epimerized.[17] The stereochemistry along with the order of reactivity for electrophilic cleavage of substituted iron alkyls suggests a reversible attack of the electrophile (*see Electrophile*) at iron to give the square-pyramidal (*see Square Pyramidal*) intermediate shown. Stereochemical nonrigidity in this species would explain epimerization at iron. Reductive elimination occurs with retention of configuration for E = H or HgX (path a); however, in the case of E = halogen, then attack by external halide affords the organic product with inversion of configuration (path b).[17]



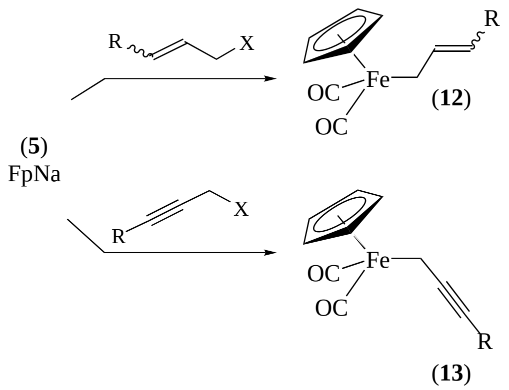
Scheme 7

3.2 η^1-Allyl and Related Complexes[18–20]

3.2.1 Preparation

The first reported and still widely used method for the preparation of (η^1-allyl)$(CO)_2$FeCp complexes (**12**; R = H) (η^1-allyl)Fp involves the nucleophilic substitution of allyl halides or pseudohalides (arenesulfonates, phosphinates[21]) with sodium dicarbonylcyclopentadienylferrate (NaFp, **5**) (Scheme 8). The reaction is successful for halides bearing substituents on vinyl carbon atoms, whereas substituents geminal to the halide result in S_N2' products. Cycloalkenyl chlorides have also been successfully employed, giving the (cycloalkenyl)Fp compounds. The analogous reaction on propargyl halides affords the (η^1-propargyl)Fp complexes (**13**) if the acetylenic carbon is substituted; propargyl bromide itself affords the product of S_N2' displacement.

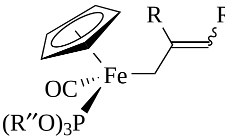
Several alternative methods have been reported for the preparation of (**12**). The addition of $HFe(CO)_2Cp$ to 1,3-dienes results in (η^1-allyl)Fp complexes, although this approach has



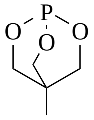
Scheme 8

been employed far less regularly.[22] A much more commonly used route involves proton abstraction of (η^2-alkene)Fp^+ cations (Section 4.3.2). In a similar fashion, an alternative approach to propargyl complex (**13**) involves deprotonation of (η^2-allene)Fp^+ cations (Section 4.3.2).

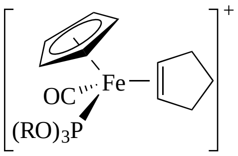
(η^1-Allyl)CpFe(CO)(PR_3) complexes (**14**) have been prepared from the dicarbonyls, by photolysis in the presence of phosphine or phosphite. The substitution is often aided by a trace of $(CpFe(CO)_2)_2$, which is indicative of a radical (*see Radicals*) chain substitution mechanism.[23] Phosphite ligand (as in **15**) has been reported as being a particularly good replacement ligand from the standpoint of thermal stability.[24,25] Nevertheless, neither C-3-substituted (η^1-allyl)Fp complexes (**14b**) nor cyclic allyl complexes (*see Allyl Complexes*) may be made directly by this method; the carbocyclic cases have been prepared by methoxide-induced proton abstraction of alkene cation (**16**) (Section 4.3.2).[24]



(**14a**) R = H, R′ = H
(**14b**) R = H, R′ = H
(**14c**) R = OMe, R = H

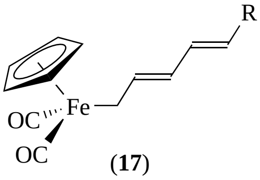


(**15**)

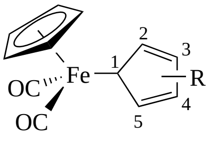


(**16**)

(η^1-Dienyl)Fp (**17**) is known for a limited number of substitution patterns, normally being prepared by the FpNa (**5**) + dienyl chloride route.[26,27] (η^1-Cyclopentadienyl)Fp complex (**18a**) has been prepared by the reaction of NaCp with $Cp(CO)_2FeI$ (**6c**). Substituted versions of these complexes can also be made by this method (compounds **18b,c** and **19**) or in the case of (**20**) by reaction of $Cp'Fe(CO)_2{}^+BF_4{}^-$ with the cyclopentadiene, followed by triethylamine-induced proton abstraction of the intermediate alkene complex (**19,20**). It is also possible to replace one CO ligand of (**18**) by carefully selected phosphite ligands by the photolysis method used for (η^1-allyl)Fp complexes.[23] (η^1-Diynyl)Fp (**21**) has been prepared as well.[27]



(**17**)



(**18a**), R = H
(**18b**), R = 2-Me
(**18c**), R = 3-Me

There exist only a few scattered reports of (η^1-allyl)iron complexes lacking a cyclopentadienyl (*see Cyclopentadienyl*) (or related ligand). Treatment of (η^3-allyl)dicarbonylnitrosyliron complexes (*see Nitrosyl Complexes*) with phosphite or phosphine gives five-coordinate (η^1-allyl) complexes (**22**) of limited stability.[28] The reaction of Fe(t-BuNC)$_5$ with both allyl bromide and chloride gives a product formulated as (**23**).[29] Compounds of the general structure (**24**) were prepared by reaction of $[(CO)_4Fe(SiR_3)]^-$ and $HFe(CO)_4(SiR_3)$ with allyl bromide and isoprene, respectively.[30]

3.2.2 *Properties*

(η^1-Allyl)Fp complexes (**12**) are yellow liquids or low-melting solids that show reasonable air stability when neat, but have greater air sensitivity in solution. The ^{1}H Nuclear magnetic resonance (NMR) spectra show the alkene protons resonate roughly in the normal alkene range, with the protons on C-2 somewhat downfield (5.3–5.95 ppm in acyclic cases, 5.8–6.3 ppm in cyclic cases) from those on C-3 (4.4–5.1 ppm in acyclic cases, 5.35–5.8 ppm in cyclic cases). The protons on the iron-bearing carbon atom (C-1) show a striking difference between acyclic cases (2–2.3 ppm) and cyclic compounds (3.3–3.86 ppm). Coupling constants between the alkene protons are unexceptional. ^{13}C NMR spectra show more distinct differences between the two alkene carbon

atoms: C-2 carbon atoms (135–143 ppm in C_6D_6) resonate considerably downfield from the C-3 carbons (116–125 ppm in C_6D_6), while C-1 is very highly shielded (−2 to +5 ppm acyclic, ≈20 ppm cyclic, C_6D_6).[31,32] The ^{57}Fe NMR spectrum of one (η^1-allyl)Fp complex indicates that the chemical shift (959.1 ppm downfield from $Fe(CO)_5$) is in the midst of known (η^3-allyl)iron complexes.[33]

(η^1-Cyclopentadienyl)Fp (**18**) is one of the classic fluxional molecules (*see Fluxional Molecule*) (*see* ***Stereochemical Nonrigidity of Organometallic Complexes***). At room temperature, all five protons of the (η^1-Cp) ring appear at the same chemical shift (5.7 ppm in CS_2), as do the five ring-carbon atoms in the ^{13}C NMR spectrum (112.0 ppm in CS_2). At ≈−80 °C the proton spectrum shows sharp peaks at 3.5 (H-1), 6.0 (H-3), and 6.3 ppm (H-2), in a 1:2:2 ratio, and the ^{13}C NMR spectrum shows resonances at 28.2 (C-1), 121.6 (C-3), and 145.3 (C-2) ppm. These changes in spectral characteristics are due to rapid 1,2-shifts of the Fe–C σ-bond, which occur with an activation energy of 44.8–46.5 kJ mol^{-1}.[34] Exchanging the η^5-Cp ligand for the more electron-donating η^5-Cp* (C_5Me_5) ligand results in a lowering of this barrier to 40.2 kJ mol^{-1}; in both cases this activation energy is significantly solvent dependent. Substitution of the η^1-Cp ring with an electron-donating methyl group raises the barrier (56.5 kJ mol^{-1}), while an electron-withdrawing group (CONHTs) lowers the barrier; these effects have been interpreted as evidence for ‘some zwitterionic (*see Zwitterion*) character’ ($Fp^{\delta+}$ $Cp^{\delta-}$) in the transition state.[35] This is precisely the same character found for the concerted [1,5]-sigmatropic hydrogen rearrangements in cyclopentadiene itself.[36]

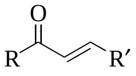
3.2.3 Reactions

The overwhelming majority of reported transformations of η^1-allyliron complexes either produce cationic η^2-alkeneiron complexes or proceed through these intermediates to give other products. This chemistry will be discussed later (Section 4.1.2).

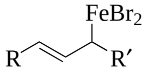
(η^1-Allyl)Fp complexes are also subject to attack, at C-3, by radicals. The mechanism of allylic transposition of (η^1-allyl)Fp complexes, as well as the mechanism of phosphite substitution for CO, has been ascribed to attack by Cp(CO)(L)Fe· on the original Fp–allyl. The reaction of (**12**) with CCl_4 proceeds by a radical chain mechanism, ultimately between $\cdot CCl_3$ and the Fp–allyl.[37] The substitution of α-halo ketones and esters most likely proceeds similarly. A radical cation coupling mechanism has been proposed for the dimerization of (η^1-allyl)Fp and (η^1-propargyl)Fp complexes.[38]

Nitrosylcarbonyliron complexes, $[Fe(CO)_3(NO)]^-$ and $Fe(CO)_2(NO)_2$, are capable of catalyzing the substitution of allylic chlorides, formates, acetates, and carbonates by malonate ion. The attack on substituted substrates goes with retention of double bond stereochemistry, with high retention of stereochemistry at the substituted carbon atom, and with only minor amounts of allylic scrambling. A σ-allyliron intermediate, formulated as (**25**), has been implicated in the substitution.[39]

(**25**)



(**26**)



(**27**)

(η^1-Allyl)iron(III) complexes have been implicated in the enzymatic lipoxygenation of polyunsaturated fatty acids. In the proposed model, concerted allylic deprotonation and electrophilic addition (*see Electrophilic Reaction*) of Fe^{III} gives an iron allyl species, which undergoes Fe–C bond insertion by O_2. In model studies, reaction of allyltributyltin compounds with $FeBr_3$, followed by exposure to oxygen, gives oxidation to the carbonyl compounds (**26**) through presumed intermediates (**27**).

(η^1-Cyclopentadienyl)Fp complexes are relatively reactive dienes for cycloaddition reactions with electron-poor (*see Electron Deficient Compound*) alkenes and alkynes. Alkene addition occurs on the face opposite the iron substituent, giving overall retention of alkene stereochemistry but a mixture of *endo* (*see Exo & Endo Substituents*) and *exo* addition products. Available evidence suggests that the reaction is a concerted [2 + 4] cycloaddition. Less reactive dienophiles (methyl acrylate, acrylonitrile) require the presence of a Lewis acid (*see Lewis Acids & Bases*) (Et_2AlCl) for successful reaction. Oxidative removal of the $Cp(CO)_2Fe$ unit from the product (**28**) allows replacement by either an ester or amine function, Fp(η^1-Cp) therefore being the synthetic equivalent of either (**29a**) or (**29b**).[40] Complexes substituted on the η^1-cyclopentadienyl ring give mixtures of regioisomeric products with substitution away from the bridgehead carbon atoms predominating.[35]

E = CF_3, CO_2Me

(**30**)

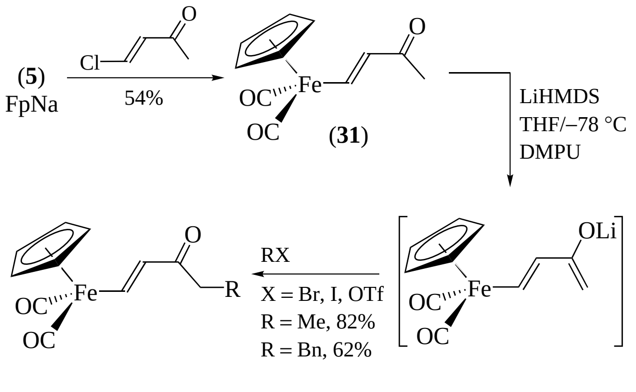
Acyclic (η^1-pentadienyl)Fp complexes also behave as Diels–Alder dienes in some cases, although two other reaction pathways compete. With TCNE and maleic anhydride, (**17**; R = H, Me) undergoes cycloaddition in moderate yields. Highly electron-deficient alkynes, on the other hand, undergo Fe–C bond insertion reactions reminiscent of SO_2 reactions with (η^1-allyl)Fp complexes, to give (**30**). Finally, when the pentadiene is disubstituted at C-5, the Diels–Alder route is effectively blocked, and [3 + 2] cycloadditions result with TCNE at the 2,3-double bond.[41]

3.3 σ-Vinyl Iron Complexes

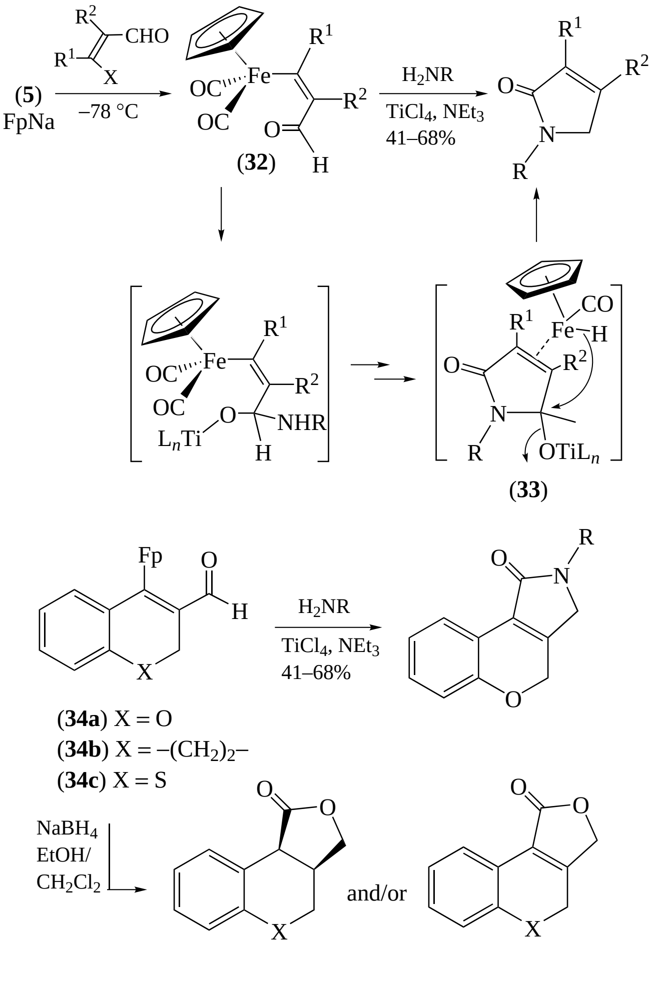
3.3.1 *Preparation and Reactions*

σ-Vinyl iron complexes have been prepared in a number of ways: 1) nucleophilic addition to cationic η^2-alkyne complexes (*see Alkyne Complexes*) (this will be covered in Section 4.5.1), 2) nucleophilic addition to cationic η^2-allenyl complexes (Section 4.3.2), 3) via [3 + 2] cycloaddition of η^1-propargyliron complexes and electron-poor alkenes (Section 4.4), 4) Photolysis of acyliron complexes (Section 3.5), 5) nucleophilic addition to vinylidene complexes (Section 3.7), and 6) the method discussed here, addition-elimination (*see β-Elimination*) of FpNa (**5**) with β-halo-α,β-unsaturated carbonyls.

The synthesis of vinyliron species (**31**) has been described; this has been used to access iron carbenes (Section 3.5) (Scheme 9).[42,43] Analogs of (**31**) are obtained using standard enolate formation with subsequent trapping by an electrophile.[44] Cyclic analogs have also been prepared.[45] More recently related chemistry with acyclic and cyclic enals has been utilized (Scheme 10).[46,47] Kinetically-controlled addition-elimination to (Z)-β-haloenals (*see (E) & (Z) Isomers*) or (Z)-β-(trifluoromethanesulfonyl)enals affords the (Z)-Fp-enals (**32**), and subsequent treatment with primary amines and $TiCl_4$ produces α,β-unsaturated lactams. The key intermediate is believed to be an η^2-alkeneiron hydride complex (**33**) which is formed after intramolecular carbonylation of the amine followed by reductive elimination. Cyclic enals such as (**34a**) behave in an identical manner, and reductions of (**32**) or with (**34a–c**) using $NaBH_4$ provide the α,β-unsaturated lactones or mixtures of these and the saturated analogs. Reduction with K-Selectride gives only the saturated lactones. Using α,β-unsaturated sulfonylimines (N-sulfonyl azadienes) instead of enals provides similar compounds (N-sulfonyl dihydropyrrolones), though in these cases the reaction is triggered by use of a Grignard reagent (*see Grignard Reagents*).[48]



Scheme 9

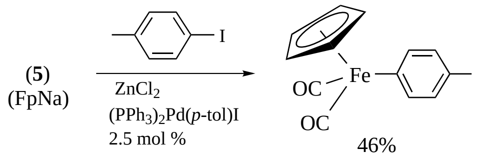


Scheme 10

3.4 σ-Aryl and σ-Heteroaryl Iron Complexes

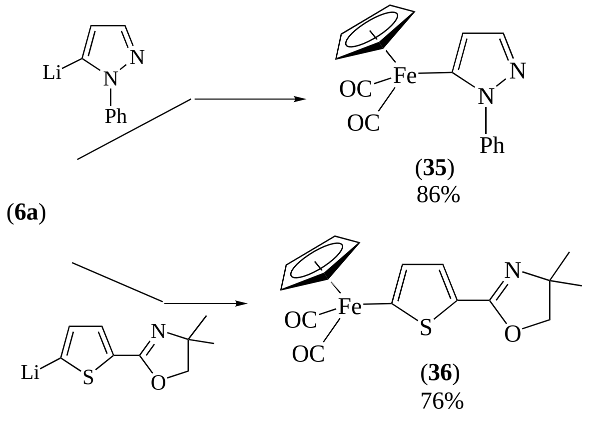
3.4.1 *Preparation*

Decarbonylation of σ-acyliron complexes by photolysis (Section 3.5) is the primary method for the preparation of σ-aryliron complexes.[2] Alternatively, σ-aryliron complexes can be prepared by the method of Beletskaya from FpNa (**5**).[49] For example, the p-tolyl analog has been recently prepared in order to study the C–H activation of benzene (equation 3).[50]



(3)

Aryl-Fp complexes can be prepared from FpNa (**5**) with aryl halides only in cases where the aryl halide is activated toward nucleophilic attack; polyflourinated benzenes and halo-substituted pyridines are examples.[51,52] Heteroaryliron



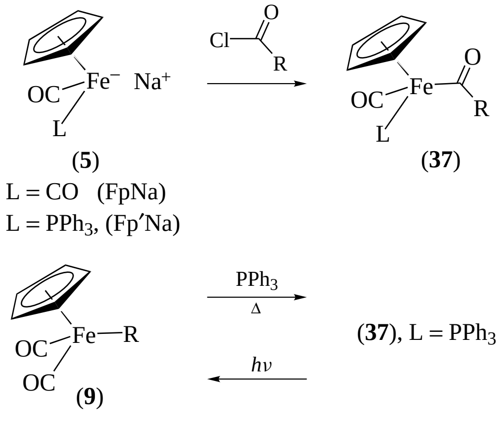
Scheme 11

complexes (**35, 36**) were obtained by Raubenheimer by treatment of $CpFe(CO)_2Cl$ (**6a**) with the appropriate heteroaryllithium species (Scheme 11).[53] Protonation of these complexes led to unusual iron carbene systems.

3.5 Iron Acyls

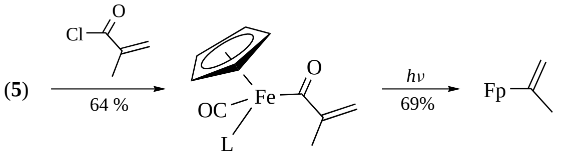
Iron acyl complexes are among the most widely studied of the organometallic iron species, especially as applied to organic synthesis. As previously mentioned they are prepared to provide access to iron alkyls (via decarbonylation), and because iron acyls can be deprotonated to form enolates much like any carbonyl they have been utilized as chiral auxiliaries in asymmetric synthesis. Also, iron acyls are an important entry point for the preparation of iron carbenes.

There are two primary methods used to prepare ‘simple’ iron acyls (Scheme 12). In analogy to the nucleophilic reaction of FpNa (**5**) and alkyl halides (Scheme 6), FpNa and its analog $[Cp(CO)(PPh_3)Fe]Na$ (occasionally abbreviated Fp′Na) readily react with acyl chlorides to afford the acyl complexes (**37**).[54,55] On the other hand, iron σ-alkyl complexes



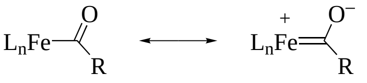
Scheme 12

(**9**) undergo carbonyl insertion in the presence of an external ligand to also produce the acyl complexes (**37**).[56] This may be promoted by the presence of Lewis acids or protic acids, even at 1% of the stoichiometric amount; however, alkoxyalkyl substituents are resistant to carbonylation. Vinyl iron complexes have been converted into the corresponding α,β-unsaturated acyl-iron complexes by $AgBF_4$-promoted CO insertion.[57] For acyl complexes in general, the reverse process – a decarbonylation – occurs upon photolysis; this is the best way to prepare vinyl iron complexes. An example is shown (equation 4).[55]



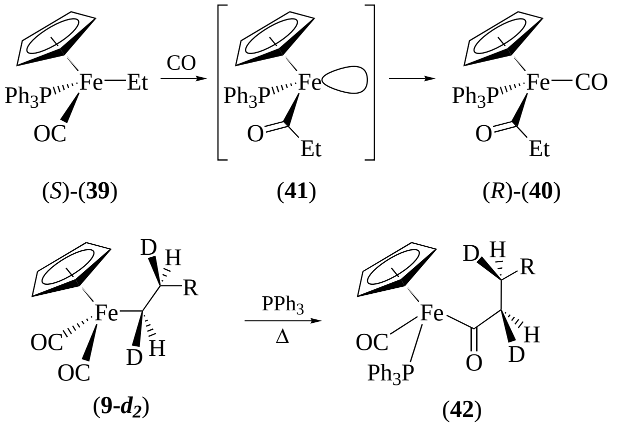
(4)

The acyl carbonyl stretching frequency appears in the range 1580–1700 cm^{-1},[58] and the acyl carbonyl ^{13}C resonance appears at ca. 255–275 ppm.[32] These physical data highlight the highly polar (*see Polar Bonds*) nature of the acyl bond. The positive charge at the carbon is delocalized (*see Delocalized Bonding*) by metal-to-ligand back bonding (*see Back Bonding*) donation into the acyl π^* antibonding (*see Antibonding*) orbital (cf. **38**). This property enables the formation of carbenes (Section 3.5) since these complexes react by alkylation on oxygen.[56] In general, this requires the use of highly reactive alkylation agents.

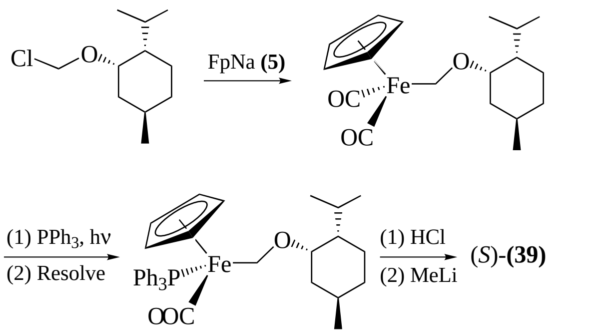


(**38**)

Because the presence of four different ligands about the metal in (**37**) makes complexes of this type chiral at the metal center,[59] the stereochemistry of the CO insertion/decarbonylation process is noteworthy. Thus the chiral complex (*S*)-(**39**)[60] undergoes carbonylation in nitroethane in the presence of carbon monoxide to give the corresponding acyl product (*R*)-(**40**) with greater than 90% enantiomeric excess (*see Enantioselectivity*) (Scheme 13). The stereochemistry of the product is consistent with an ‘alkyl migration’ (*see Alkyl Migration*) to generate the coordinatively unsaturated species (**41**), which is rapidly captured by an external ligand.[60] Photochemical (*see Photochemistry*) decarbonylation of (*R*)-(**40**) has likewise been shown to proceed via an alkyl migration mechanism to afford (*S*)-(**39**).[61] These alkyl migrations proceed with retention of configuration at the carbon atom which migrates. Thus carbonylation of the deuterium-labeled (*see Deuterium*) alkyl (**9**) affords the labeled acyl complex (**42**).[60] Decarbonylation proceeds with retention of configuration at carbon.



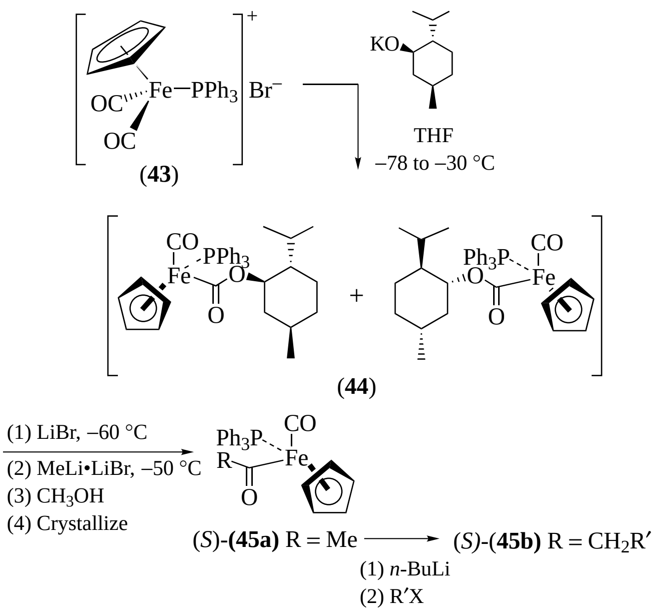
Scheme 13



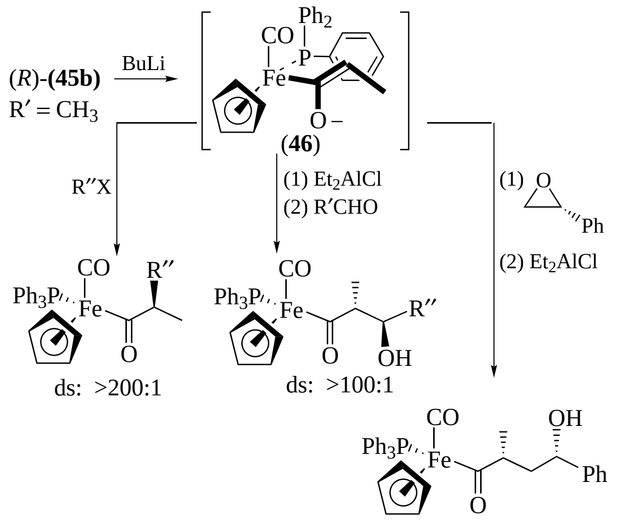
Scheme 14

To prepare the enantiomerically pure iron acyl complex (R)-(**39**), a precursor diastereomeric menthoxyalkyl complex was resolved and then manipulated (Scheme 14). More recently resolution of the chiral-at-metal acyl complexes themselves was achieved, and this has become the basis for a commercial preparation of the iron acyl developed for use as a chiral auxiliary (see below). Cationic iron complex (**43**) was treated with potassium L-mentholate to produce diastereomeric esters (**44**) that were not isolated but were reacted with LiBr/MeLi (Scheme 15).[62] After chromatography and recrystallization the enantiomerically pure ironacyl complex (S)-(**39a**) was obtained. It was suggested that only one diastereomeric ester can react (with inversion of configuration at iron, as shown) with the methyl nucleophile; the unreactive diastereomer suffers from severe steric congestion about the electrophilic CO ligand.

The α-protons of iron acyl complexes are acidic and these can be deprotonated with Lithium diisopropylamide (LDA) or with n-butyllithium. Thus the corresponding enolates are readily functionalized and undergo reaction with alkyl halides, aldehydes, disulfides, trimethylsilyl chloride, and epoxides to afford the corresponding α-derivatized products.[63–65] Early work on racemic complexes revealed that these transformations occur in a highly diastereoselective fashion,



Scheme 15



Scheme 16

with respect to the chiral metal center. The later work using enantiomerically pure complexes (described above) will be described here; examples of diastereoselective transformations are shown (Scheme 16). The diastereoselectivity has been rationalized on the basis that the preferred conformer for the enolate (**46**) has the enolate oxygen aligned *anti* to the carbonyl ligand, and that approach of the electrophile is directed toward the face of the enolate which is not blocked by the triphenylphosphine ligand. Since the acyl–iron bond can be cleaved by treatment with one-electron oxidants such as bromine to afford carboxylic acids or esters, the overall transformation has been used for the synthesis of optically pure

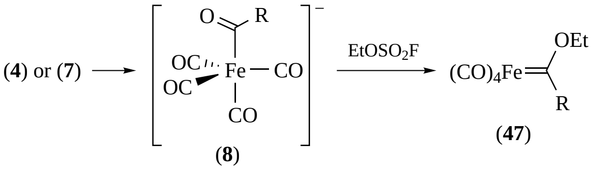
organic compounds. α,β-Unsaturated iron acyl complexes have also been prepared, and Michael-type nucleophilic additions, cyclopropanations, and Diels–Alder cycloadditions occur with high diastereoselectivity.[63–65] A review article by Davies that appeared in 1990 described the use of iron acyls as chiral auxiliaries in synthetic organic chemistry and should be consulted for further details; this area was also thoroughly covered in Fatiadi's 1991 review.[3,63] However, with the more recent advent of other nonmetal-containing chiral auxiliaries, this strategy for asymmetric synthesis is currently not in frequent use and only scattered applications have been reported.

3.6 Iron Carbenes

A substantial body of work has been published describing the preparation, properties, and synthetic applications of iron carbenes. These tend to be of the 'Fischer-type' (*see Fischer-type Carbene Complexes*) of carbene species: electrophilic and heteroatom-stabilized. However, electrophilic yet unstabilized iron carbenes can be readily prepared and utilized *in situ*.

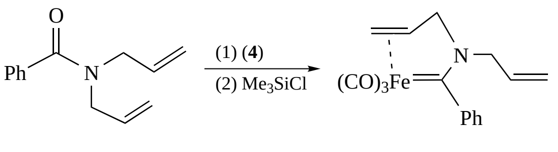
3.6.1 Preparation of Neutral Iron Carbene Complexes

While reaction of acyl anion [(**8**), from (**4**) or (**7**) in Scheme 3] with alkyl halides affords the corresponding organic ketone, alkylation of (**8**) with the highly activated ethyl fluorosulfonate generates the Fischer-type carbene complex (**47**) (equation 5).[66] Attempted alkylation of these iron acylates with trimethyloxonium salts, in the general fashion for the preparation of chromium Fischer-type carbene complexes (*see* ***Chromium: Organometallic Chemistry***) is unsuccessful.[67,68] Alternatively, addition of an alkyllithium or Grignard reagent to $Fe(CO)_5$ (**1**) also affords (**8**) by the classic method of Fischer.[68,69]



(5)

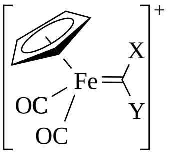
Exchange of the alkoxy substituent with an amino group can occur by treating (**47**) with an amine. Aminocarbenes can also be prepared by chemistry related to Fischer's method; in this case an alkoxide intermediate is trapped by TMSCl and directly expelled to produce the carbene (equation 6).[70]



(6)

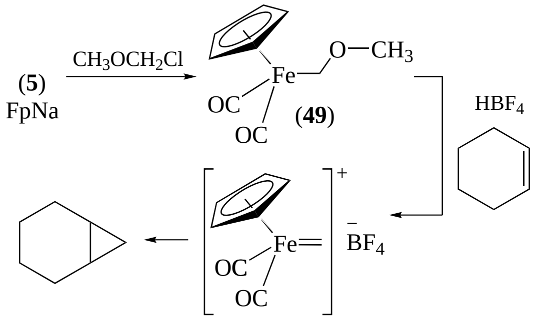
3.6.2 Preparation of Cationic Iron Carbene Complexes

In comparison to the neutral analogs, there are many cationic iron carbene complexes (**48**) that have been isolated or prepared *in situ*. In general, only those complexes in which one of the carbene substituents is a good electron-donor group (i.e. X or Y = OR, SR, or NHR) are stable enough to be isolated. There are a number of approaches these carbene complexes, and many of the earliest methods – still in current use – are summarized in a 1987 review by Brookhart.[71] (Readers should also consult the 1991 review by Fatiadi).[3]



(**48**)

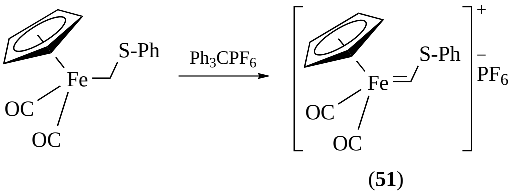
Pettit first described the preparation of these complexes; protonation of the methoxymethyl iron alkyl species (**49**) made by treatment of NaFp (**5**) with CH_3OCH_2Cl (as in Scheme 6) was carried out in the presence of alkenes (Scheme 17). The cyclopropanes that were produced suggested the intermediacy of a carbene complex (**48a**); more highly substituted carbene analogs were isolated and characterized.[72] Trimethylsilyl triflate can also be used to initiate carbene formation; ethylidene, benzylidene, and cyclopropylidene complexes have been generated in this fashion.[71] A milder method has since been developed by utilizing CH_3SCH_2Cl instead of CH_3OCH_2Cl; loss of the heteroatom to provide the carbene was performed by methylation (to give the stable, isolable sulfonium salt (**40**)) followed by thermolysis (100 °C) in the presence of an alkene (Scheme 18).[73] A more functionalized carbene complex (**51**) that has been used in organic syntheses has been prepared via hydride abstraction (equation 7).[74] Finally, the alkoxy carbene precursors can be obtained from the reaction of FpNa (**5**) and acetals in the presence of $BF_3 \cdot Et_2O$.[75] Alternatively, reaction of (**5**) with an aldehyde affords an



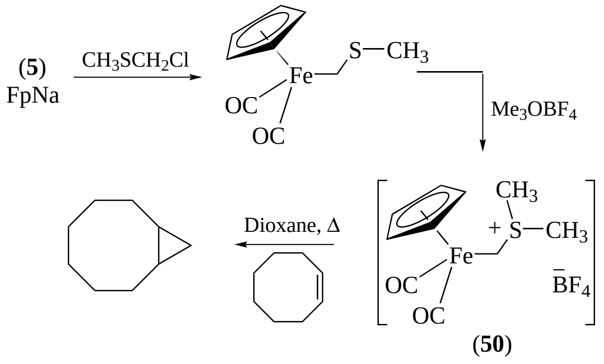
(**48a**)

Scheme 17

alkoxy intermediate that is trapped by trimethylsilylchloride.[76] This silyloxy carbene precursor may also be treated by TMSOTf to generate the iron carbene (Scheme 19).

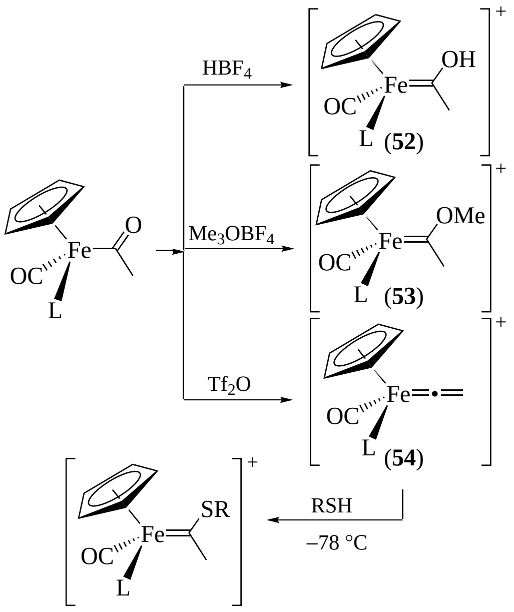


(7)



Scheme 18

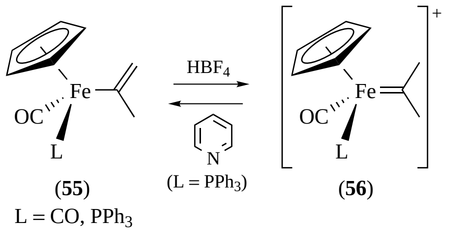
Alkylation of iron acyl complexes also provides access to iron carbenes. Thus, the neutral iron acyl complex will react with acid, with alkylating agents, or with trifluoromethanesulfonic anhydride to afford cationic hydroxy- or alkoxycarbene complexes (**52**) and (**53**) or the cationic vinylidene complex (**54**, L = CO) (Scheme 20).[77] The vinylidene complex can be used to prepare a more substituted analog of (**51**) by treatment with a thiol. The enantiomerically pure iron acyl complex (*R*)-(**45a**) can be converted to the corresponding enantiopure methoxycarbene complex with Me_3OBF_4 as well.[78] Finally,



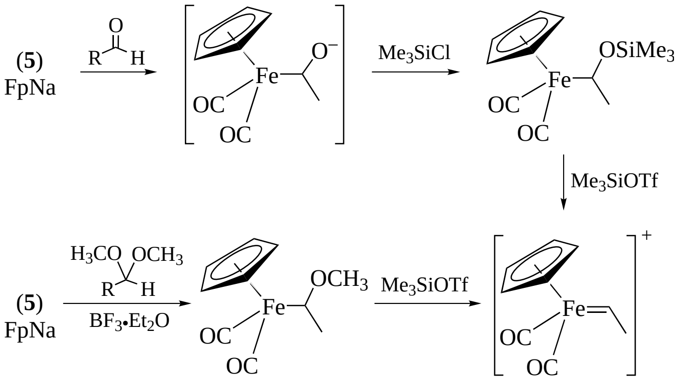
Scheme 20

the alkoxycarbene substituent can be exchanged with a primary amine to produce aminocarbenes complexes.[78,79]

Another tactic that has been used to prepare iron carbene complexes is the protonation of vinyl iron complexes. For example, vinyl iron (**55**) is readily converted to the carbene (equation 8). The acidity of the iron carbene has been demonstrated as well, as treatment of (**56**; L = PPh_3) with pyridine affords (**55**).[55]

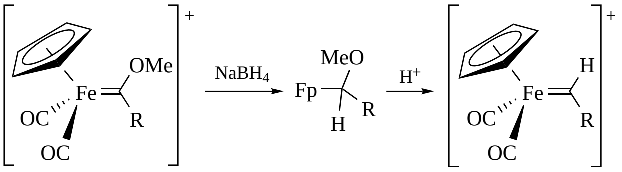


(8)



Scheme 19

Finally, a heteroatom-substituted carbene can be converted in a two-step process to an analog lacking the electron-donating substituent by hydride addition and subsequent protonation (equation 9).[80–83]

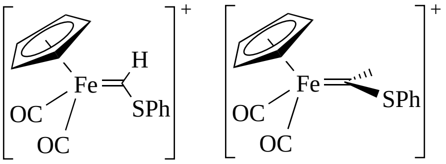


(9)

3.6.3 Structural Characterization

In NMR spectroscopy the carbene proton signals appear at ca. 12–15 ppm, and the carbene carbon resonances appear at ca. 320–420 ppm in NMR spectroscopy.

Thiocarbene complexes have been characterized by X-ray diffraction (*see X-ray Diffraction*) and this data has been tabulated by Kerber.[2,74,84] These structural studies indicate a Fe–C bond length (*see Bond Length*) (ca. 1.90 Å) which is shorter than the typical Fe–C bond length (ca. 2.0–2.2 Å); however, the conformations of the carbene ligand with respect to the remaining ligands are markedly different. In (**51**) the carbene adopts an 'upright' conformation, while in (**57**) the carbene adopts a 'crosswise' conformation. Extended Hückel Molecular Orbital Theory (*see Extended Hückel Molecular Orbital Theory*) calculations predict that the 'upright' conformation is lower in energy by 26 kJ mol^{-1} for methylene analog (**48**, X = Y = H).[85] This conformational preference has been identified for a methoxymethylenecarbene complex by NMR spectroscopy.[86] The solid-state structure of (**57**) has been rationalized on the basis of the steric effects (*see Steric Effect*) of the more substituted carbene ligand. For cationic carbene complexes that lack good electron-donor substituents such as (**48**, X = Y = H), stabilization has been achieved by the presence of the electron-donating bisphosphine ligand Diphenylphosphinoethane (dppe) or the presence of both a Me_5Cp and a PPh_3 ligand.[87,88] In the ^{1}H NMR spectrum of the former complex the methylene protons appear as two distinct signals, at low temperature, that coalesce at higher temperatures (ca. −45 °C). This is consistent with a low-energy 'upright' conformation with the two protons equilibrating by rotation about the Fe–C bond. The activation energy of this bond rotation was determined to be 43.5 kJ mol^{-1}.



(**51**) (**57**)

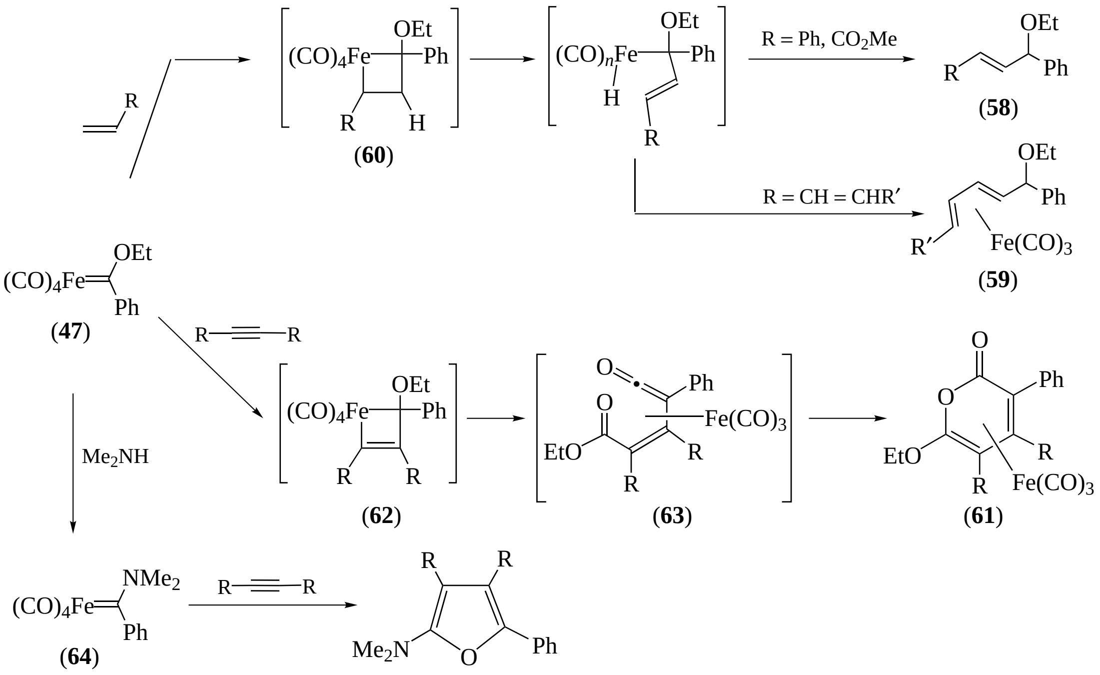
3.6.4 Reactions of Neutral Iron Carbenes

Whereas Fischer-type chromium carbenes react with alkenes, dienes, and alkynes to afford cyclopropanes, vinylcyclopropanes, and aromatic compounds, the iron Fischer-type carbene (**47**, e.g. R = Ph) reacts with alkenes and dienes to afford primarily coupled products (**58**) and (**59**) (Scheme 21).[89] The mechanism proposed involves a [2 + 2] cycloaddition of the alkene the carbene to form a metallacyclobutane (*see Metallacycle*) (**60**). This intermediate undergoes β-hydride elimination followed by reductive elimination to generate the coupled products. Carbenes (**47**) also react with alkynes under CO pressure (ca. 3.7 atm) to afford 6-ethoxy-α-pyrone complexes (**61**).[89] The unstable metallacyclobutene (**62**) is produced by the reaction of (**47**) with 2-butyne in the absence of CO. Complex (**62**) decomposes to the pyrone complex (**61**). It has been suggested that the intermediate (**62**) is transformed into the vinylketene complex (**63**) which undergoes cyclization to form (**61**). On the other hand, the reaction of an aminocarbene complex such as (**64**) with an alkyne gives predominantly the aminofuran as the product.

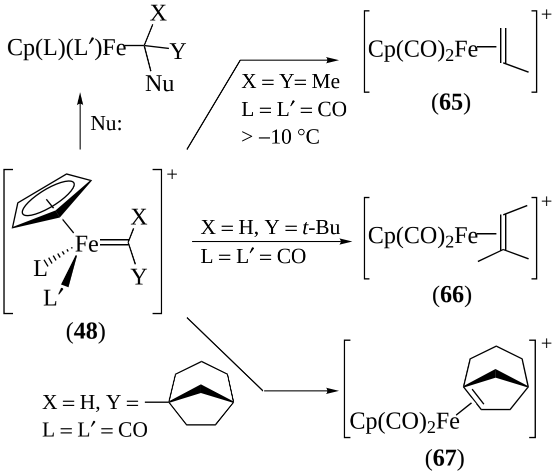
3.6.5 Reactions of Cationic Iron Carbenes

Owing to their electrophilic character, those cationic iron carbene complexes (**48**) which are isolable undergo reactions with nucleophiles to afford σ-alkyl complexes (Scheme 22).[74,84] The range of nucleophiles which are viable includes borohydrides (equation 9), Grignard reagents, alkyllithiums, organocuprates, enolates, amines, phosphines, and methoxide.[56] For example, the addition of enolates derived from β-alkylcyclohexanone to carbene (**45**) (equation 7) in order to prepare highly functionalized iron alkyl complexes for use in total synthesis has been performed (see below). Where the ligand array about iron is chiral (eg. L = CO, L′ = PPh_3), this nucleophilic addition occurs with excellent diastereoselectivity.[90] As noted previously, cationic carbene complexes which lack electron-donor substituents are unstable. The isopropylidene iron complex (**48**; X = Y = Me) may be generated in solution and spectroscopically characterized at low temperature (−40 °C); however, upon warming (>−10 °C) this complex undergoes rearrangement, via a β-hydride migration, to form the η^2-propene complex (**65**).[43,55,91] In carbene complexes which lack β-hydrogens, for example (**48**; X = H, Y = t-Bu), alkyl migration can occur to afford trisubstituted alkene complexes (**66**). When this involves a polycyclic hydrocarbon, the result is a strained bridgehead alkene complex (**67**).[92]

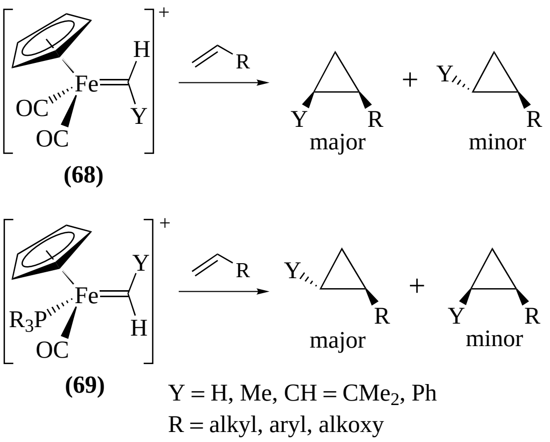
In contrast to the neutral iron carbene complexes (**47**), cationic methylidene, ethylidene, dimethylallylidene, and benzylidene complexes (**68**) and (**69**) (Y = H, Me, CH=CMe_2, Ph) react with alkenes to afford cyclopropanes in good yields (Scheme 23).[71,74,84,93] For the ethylidene and benzylidene complexes of $Fe(CO)_2Cp$ (**68**), *cis* stereoselectivity (*see*



Scheme 21



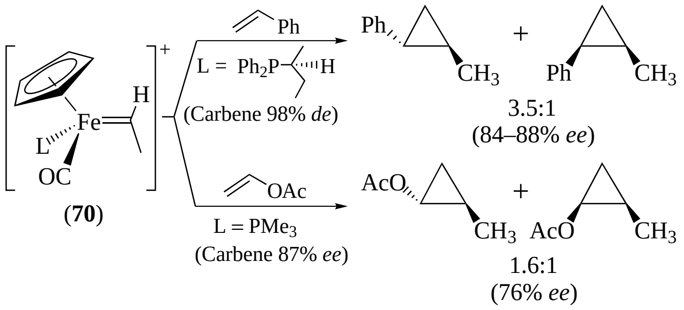
Scheme 22



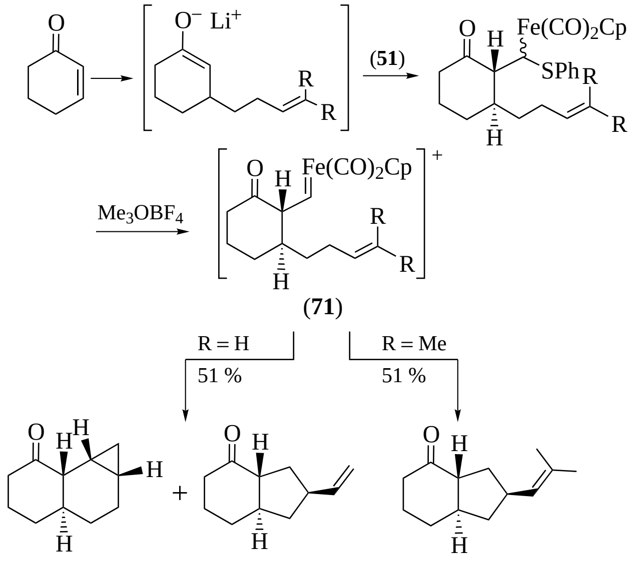
Scheme 23

Stereoselectivity) is observed; however, for ethylidene complexes of Fe(CO)(PR_3)Cp (**69**) the products reflect *trans* selectivity. This difference in stereoselectivity has been suggested to be dependent upon which conformer is more reactive. The reaction of a chiral-at-iron cationic carbene complex (**70**) with styrene or vinyl acetate affords optically active cyclopropane products with high enantioselectivity (Scheme 24).[71,93] Intramolecular cyclopropanation, as in the case of (**71**), proceeds moderately well for the formation of norcarane-type ring systems; however, intramolecular C–H insertion is a competing pathway when the alkene is highly substituted (Scheme 25).[94] In fact, this C–H insertion has also been studied in detail and it has been applied to total synthesis (Scheme 26).[95] Deuterium-labeling experiments have led to a proposal that the process occurs in a one-step, concerted manner.[96] While there have been a number of mechanisms proposed for the cyclopropanation reaction, a complete understanding of this reaction is not yet available.

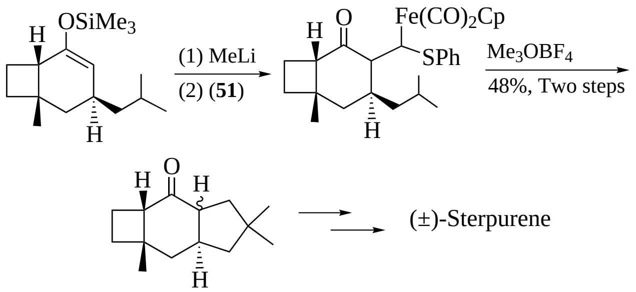
An intriguing approach to an enantioselective cyclopropanation has recently been reported (Scheme 27).[97] Enantiomerically pure planar chiral η^6-chromium benzaldehydes (**71**) were prepared in the manner described earlier (Scheme 19) and treated with alkenes at low temperature. For some cases



Scheme 24

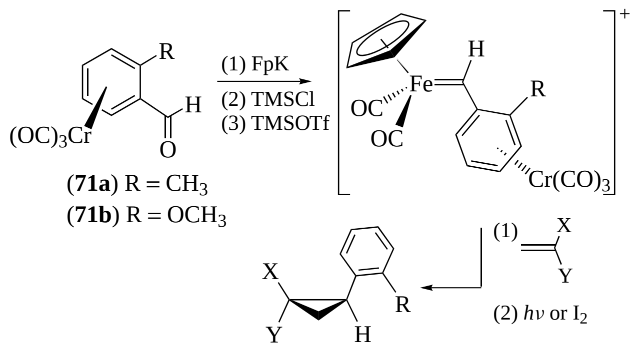


Scheme 25



Scheme 26

(especially with (**71a**) and X = Ar, Y = H), *cis*/*trans* selectivity was high and enantiomeric excesses were excellent (>95%). NMR studies revealed that enantioselectivity was dependent on the *syn*/*anti* ratio of the carbene (this refers to rotation of the iron–carbon double bond with respect to the aromatic substituent). The *anti* isomer (*see Isomer, Types of*) that is depicted is the only rotamer present between −90



Scheme 27

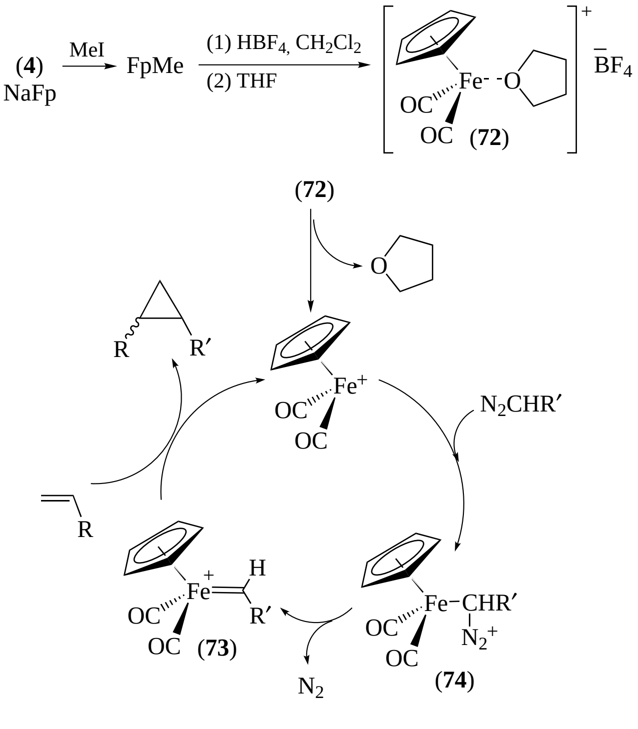
to +10 °C for R = CH_3 and thus a highly enantioselective cyclopropanation is possible.

Finally, a racemic cyclopropanation process has also been developed that utilizes an iron Lewis acid catalyst (**72**) that presumably proceeds through an iron carbene intermediate (**73**) (Scheme 28). The catalyst is activated by reaction with diazo compounds to produce an intermediate (**74**) that loses dinitrogen (*see Dinitrogen & Dinitrogen Complexes*) to afford the cyclopropane. This chemistry has been extended to the production of epoxides and aziridines and has recently been reviewed.[98]

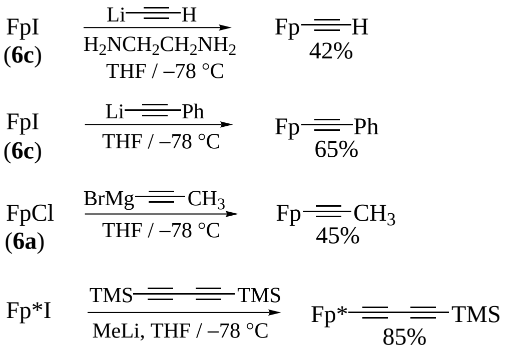
3.7 *σ*-Alkynyl Iron Complexes

In the fields of ‘organometallic polymer (*see Polymer*) chemistry’, in which complexes may have particularly interesting physical properties (liquid crystallinity, optical nonlinearity (*see Nonlinear Optical Materials*), etc.), or of ‘molecular electronics’, metal alkynyl complexes play a significant role. These areas have been the subject of recent reviews,[99,100] thus only a brief overview of methods to prepare iron alkynes will be given here. Liu has also recently reviewed the cyclization chemistry of alkynyl organometallics, including those of iron.[101]

Transmetallation of iron halides with lithium acetylides or alkynyl Grignards affords *σ*-alkynyl complexes in moderate

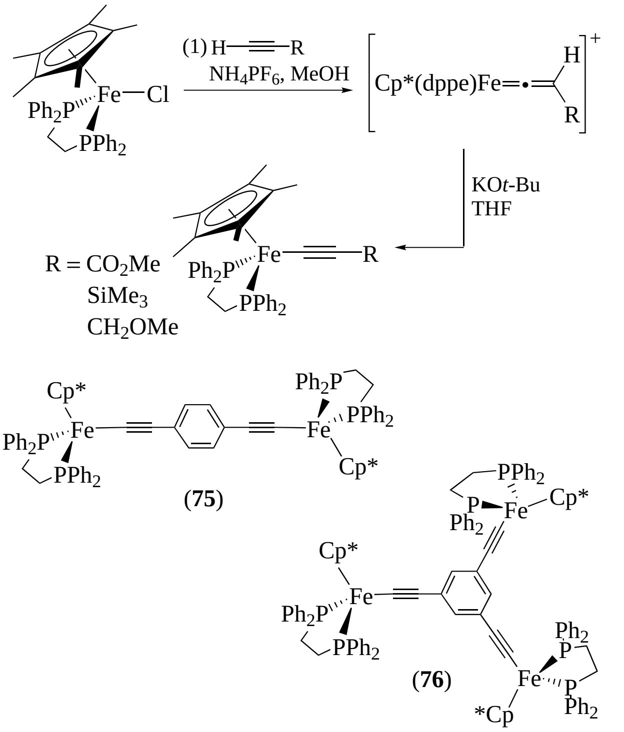


Scheme 28

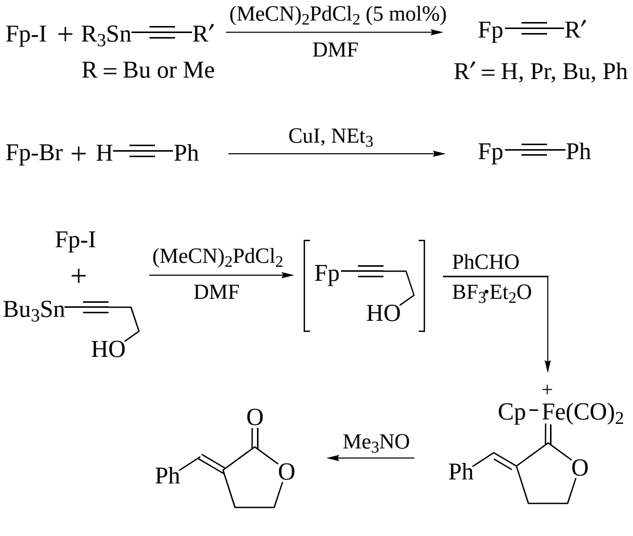


Scheme 29

to good yields. Representative examples are depicted (Scheme 29). Indirect conversion of alkynes into alkynylirons is also possible when a halide-ion abstractor is employed; treatment of the resulting isolable vinylidene complex (Section 3.7) with base then affords the alkyne complex (Scheme 30). Complexes (**75**) and (**76**) are examples that bear multiple organometallic units that have been made using this chemistry. Palladium-catalyzed ‘metalla-Stille’ couplings can also be utilized to produce alkynyliron complexes from iron halides,[102] as can copper-promoted transformations (Scheme 31). The former method was also used to generate an alkynyl iron complex *in situ*; treatment with an electrophile (aldehydes or trimethylorthoformate) in the presence of



Scheme 30

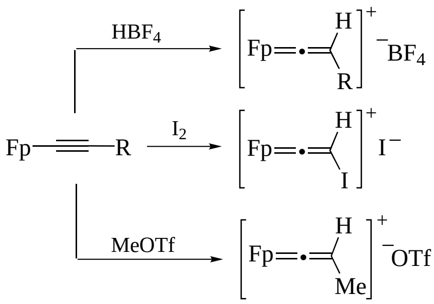


Scheme 31

$BF_3{\cdot}Et_2O$ led to a cyclic iron-oxacarbenium salt. Demetalation led to the α-alkylidene lactones.[101]

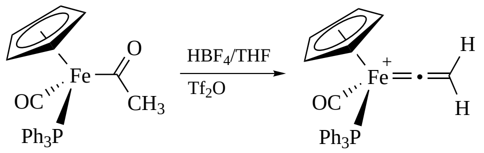
3.8 Iron Vinylidene Complexes

As detailed above, alkyne complexes can be prepared from vinylidene complexes by deprotonation. The reverse



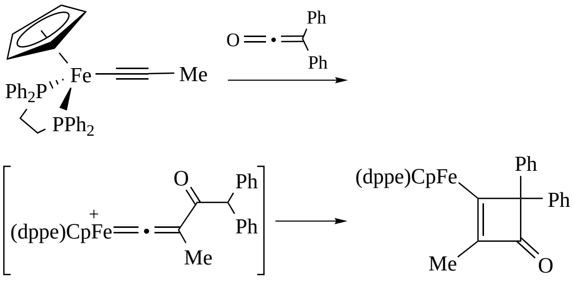
Scheme 32

process is also possible: iron alkynes are readily converted into vinylidenes by treatment with acid or an electrophile (Scheme 32). Vinylidene complexes can also be made by a formal dehydration of iron acyl complexes (equation 10). Furthermore, also as described above, they are available from the reaction of iron halides and alkynes in the presence of a halide-abstractor (Scheme 30).

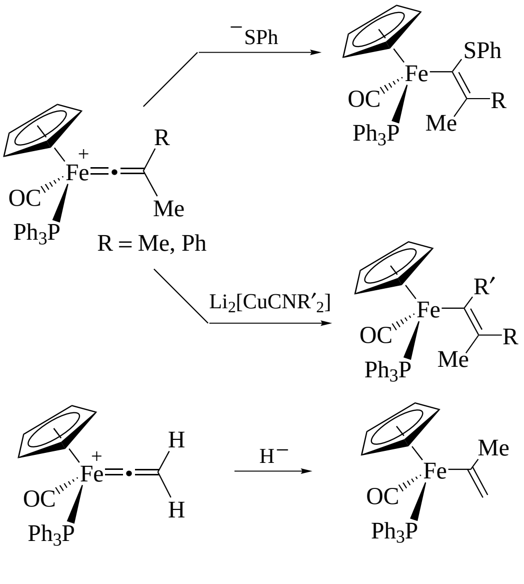


(10)

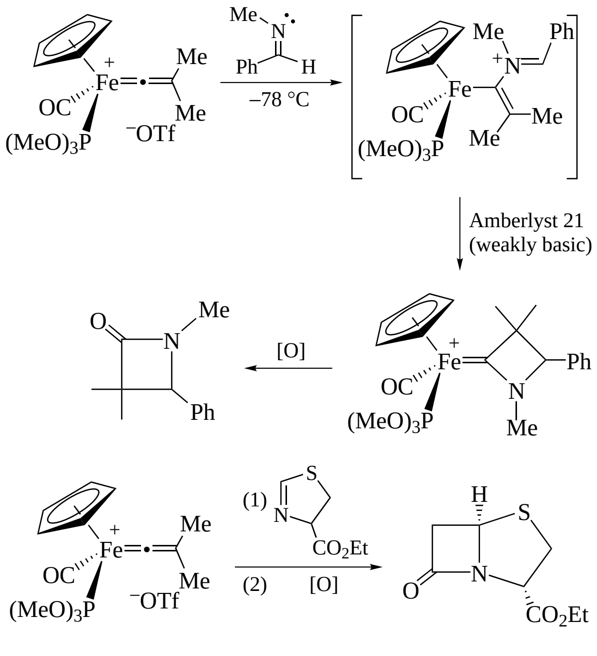
The chemistry of iron vinylidene complexes is dominated by the electrophilicity of the carbon atom adjacent to the iron organometallic unit. While addition of water leads to an acyl complex (i.e., the reverse of the dehydration shown in equation 10), addition of an alcohol leads to a vinyl ether complex. Similarly, other iron vinyl complexes can be prepared by the addition of thiolate, hydride, or an organocuprate (Scheme 33).[74] The nucleophilic addition of imines gave enaminoiron intermediates that could be further elaborated into cyclic aminocarbenes. This methodology has been used to provide access to β-lactams and ultimately penicillin analogs, and good diastereoselectivities were observed (6:1–15:1) (Scheme 34).[103,104] Also, vinylidene complexes are intermediates in cyclizations of alkynyl irons with substituted ketenes, acid chlorides, and related electrophiles; an example is shown (equation 11).[105] These cyclizations led to the formation of a series of isolable and characterizable cyclic vinyl iron complexes.



(11)



Scheme 33



Scheme 34

4 η^2-LIGAND COMPLEXES[106,107]

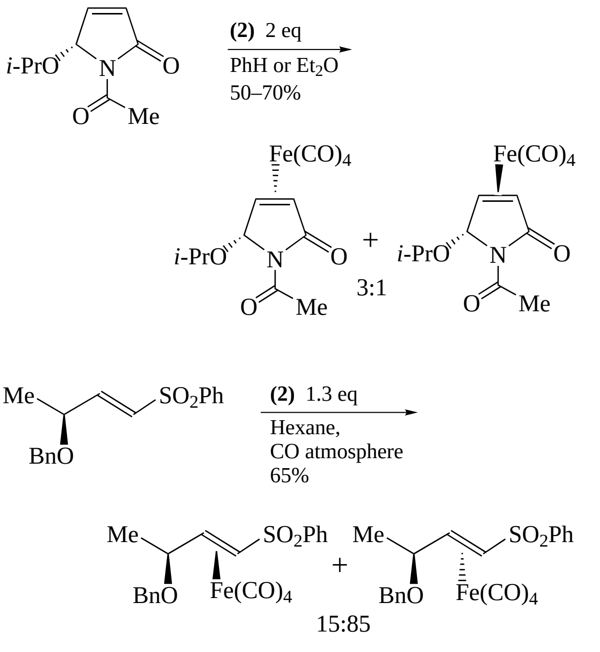
4.1 Preparation of Alkene Complexes

4.1.1 Neutral Alkene Complexes

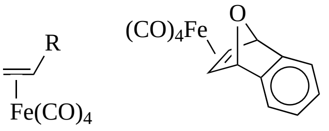
The reaction of (**2**) or (**3**) with alkenes in ether or benzene at or slightly above room temperature affords [Fe(CO)$_4$(η^2-alkene)] complexes (**77**) in good yield.[108] Alternatively, (**1**)

and Ultraviolet (UV) radiation at or below room temperature is also capable of effecting the same transformation.[109] The stability of the complexes varies with the alkene substrate. In general, alkenes bearing electron-withdrawing groups give more stable complexes than electron-rich (*see Electron Rich Compound*) alkenes; this may be attributed to the slightly electron-releasing nature of the $Fe(CO)_4$ unit.[107] It has, in general, proven possible to complex only one double bond of a conjugated or nonconjugated diene,[110] or solely the C=C double bond of a enone or enal.[111] In the dienes, *trans* double bonds are complexed in preference to *cis* double bonds. Allylic and homoallylic heteroatom substituents direct the complexation to the proximal face of the alkene, often exclusively (e.g. (**78**)), and in some cases may displace CO as a ligand.[112] This 'heteroatom delivery' of the metal fragment is typically a kinetic process. Enantiomerically pure $[Fe(CO)_4(\eta^2\text{-alkene})]$ complexes have been prepared by diastereoselective complexation (Scheme 35). The cyclic example shown relies on heteroatom delivery for selectivity, while for acyclic cases the metal fragment seems likely to complex to the less hindered alkene face.[113–115] The latter complexes have been used to provide access to enantiopure η^3-allyl iron complexes, while nucleophilic replacement of the isopropoxy group in the former examples presumably proceeded via the intermediacy of similar η^3-allyl iron complexes (Section 5.1.1).

Complexation reactions which give alkene complexes with greater than one iron carbonyl unit, or with more than one alkene unit per ion center, have been reported. Use of excess diene relative to the iron carbonyl source allows formation of $(diene)[Fe(CO)_4]_2$ complexes.[7,116] Low-temperature



Scheme 35



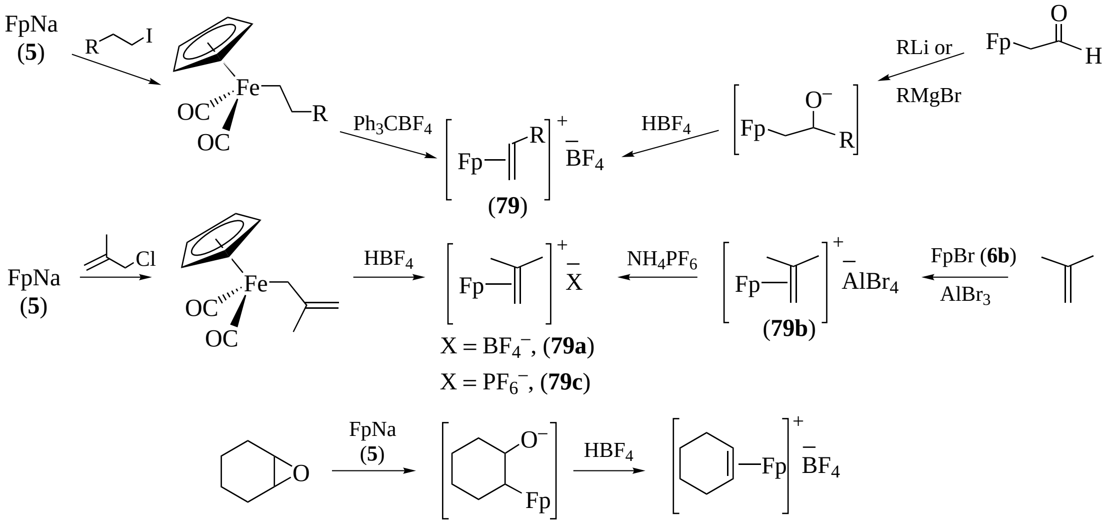
(**77**) (**78**)

photolysis of alkene and $Fe(CO)_5$ can afford high yields of $(alkene)_2Fe(CO)_3$, and even $(alkene)(alkene)Fe(CO)_3$ or $(alkene)_3Fe(CO)_2$ complexes.[117,118]

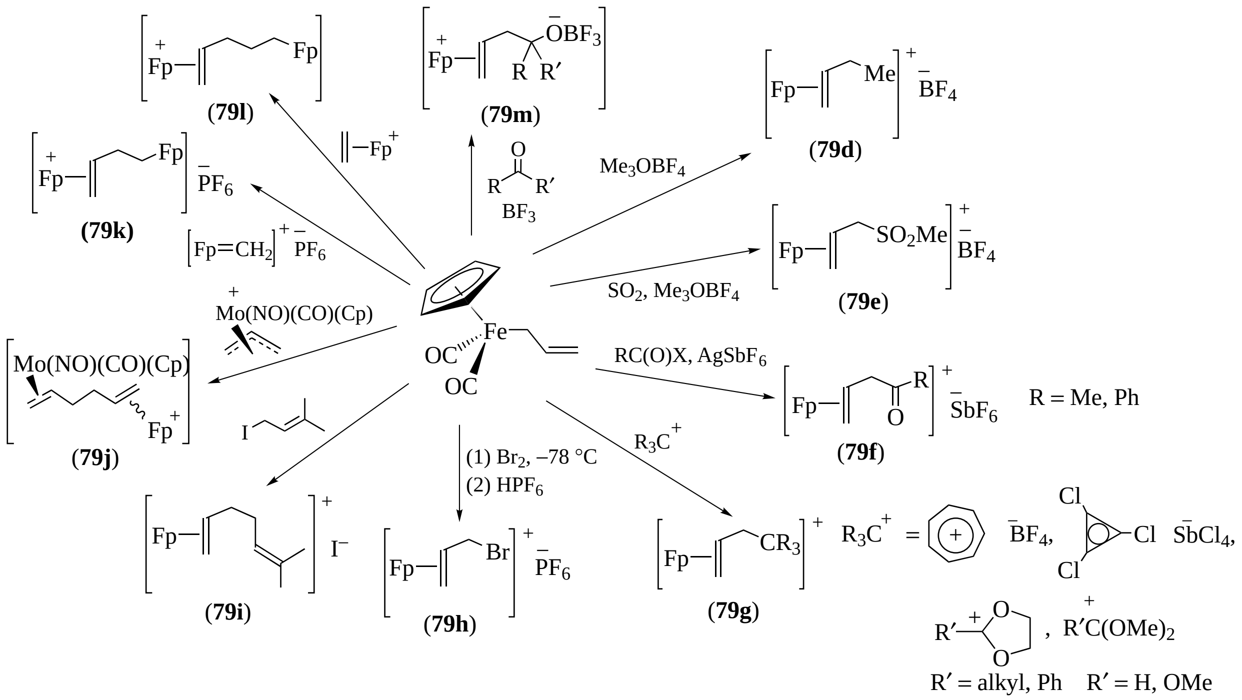
Other synthetic routes to $(\eta^2\text{-alkene})Fe(CO)_4$ complexes are much rarer. Nucleophilic attack upon $[(\eta^3\text{-allyl})Fe(CO)_4]^+$ cations results in $(alkene)Fe(CO)_4$ complexes, although they are rarely isolated; this is discussed more fully in Section 5.3.1. There have also been studies on the preparation of simple $(\eta^2\text{-alkene})FeL_4$ complexes with ligands other than CO. η^2-Alkene complexes of iron phosphines have been made in several cases by the reduction of Fe^{II} or Fe^{III} salts in the presence of alkene and phosphine.[119] Complexes with mixed CO and phosphine (or phosphite) ligands have been prepared by the treatment of *vic*-ditriflates with $[(R_3P)Fe(CO)_4]^{2-}$.[120] Complexes with mixed CO and NO ligands, with mixed CO and diazadiene ligands, or with mixed diphosphine and CO ligands may be prepared by photolysis of $Fe(CO)_2(NO)_2$, $(dad)Fe(CO)_3$, or $(diphosphine)Fe(CO)_3$, respectively.[121] In all cases the incoming alkene replaces the CO ligand.

4.1.2 Cationic (See Cation) Complexes

Owing to their relative stability in normal cases, cationic $[Fe(Cp)(CO)_2(\eta^2\text{-alkene})]^+$ complexes (**79** = $(\eta^2$-alkene)Fp^+) are the most widely investigated η^2-alkene complexes of iron (Scheme 36). These complexes may be obtained by hydride abstraction from an iron alkyl complex, by protonation of an allyl iron complex (typically using HBF_4), by treatment of an alkene with a Lewis acid and FpNa (**5**), or by epoxide ring-opening with (**5**) followed by protonation of the alkoxide and subsequent elimination of water. The complex of 2-methylpropene (**79a**, **79b**, or **79c**) has proven particularly effective for alkene exchange reactions with other monosubstituted and *cis*-disubstituted alkenes, and has been used as a double bond protecting group (less hindered alkenes are complexed over more hindered ones, and alkenes are preferred over alkynes). The rate of epoxide opening is greatly enhanced by using FpLi in place of FpNa (**5**); however, other rearrangements are also enhanced in some cases on use of the Li^+ cations.[122] The epoxide ring-opening strategy is particularly effective for preparing the $[Fp\text{–}alkene]^+$ complexes bearing electron-withdrawing groups. The intermediate alkoxides, and hence the $(alkene)Fp^+$ complexes, may also be formed by aryl/alkyllithium or Grignard attack at the aldehyde function of (β-oxoalkyl)Fp complexes.[123] Finally, hydrogen or alkyl group migration in iron carbene complexes (**48**) gives $(\eta^2\text{-alkene})Fp^+$ complexes (**65,66**), and is particularly good for preparing complexes



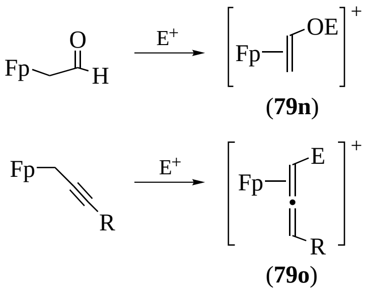
Scheme 36



Scheme 37

of bridgehead alkenes (**67**); this has been discussed in Section 3.5.5 (Scheme 22).[87–89]

As a mildly nucleophilic species, (η^1-Allyl)Fp compounds have been shown to react with a fairly wide range of electrophilic species to give substituted (η^2-alkene)Fp^+ cations (**79d–79m**) (Scheme 37).[18,19,124] In general, HBF_4 (as seen in Scheme 36), carbocations, bromine or its equivalents, and sulfur dioxide (provided the zwitterionic intermediate is trapped by $Me_3O^+BF_4^-$) react successfully.[124] More unusual electrophiles include (η^2-alkene)Fp^+ cations themselves, the cationic iron carbene $Fp{=}CH_2^+PF_6^-$, and cationic allylmolybdenum complexes.[125,126] Allyl iodides react very sluggishly, over a period of days; other alkyl halides are not normally reactive enough.[18–20] Although most aldehydes and ketones themselves will not react with (η^1-allyl)Fp complexes, BF_3 etherate induces reaction in



Scheme 38

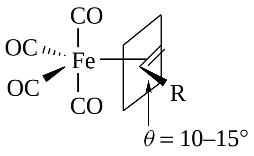
good yield; this chemistry has been developed further and will be discussed later (Section 4.4).[127] The elaboration of more complex (η^1-allyl)Fp compounds by this reaction in conjunction with subsequent Fp(η^2-alkene) deprotonation will also be described, as will intramolecular attack of (η^1-allyl)Fp complexes with (η^2-alkene)Fp^+ cations (Section 4.3.2).

The analogous reactions on (η^1-propargyl)Fp and (β-oxoalkyl)Fp complexes afford related complexes (**79n**) and (**79o**), respectively (Scheme 38). Cationic allenyl iron complexes related to (**79o**) can also be obtained by protonation of the propargylic species with HBF_4 or by transfer of the Fp cation via reagents (**79a–c**).[18,19]

4.2 Properties of Alkene Complexes

4.2.1 Neutral Alkene Complexes

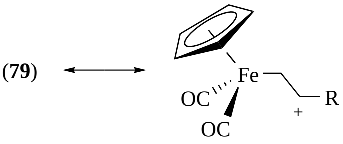
(η^2-Alkene)$Fe(CO)_4$ complexes are trigonal bipyramidal (*see Trigonal Bipyramidal*), with the alkene ligand occupying an equatorial position and aligned in the equatorial plane (**80**).[128] Fe–C(alkene) bond lengths range between 2.02 and 2.16 Å, with the apparent anomaly of the tetrafluoroethylene complex (1.989 Å) (*see* ***Diffraction Methods in Inorganic Chemistry***). Alkene C–C bond lengths are usually in the 1.39–1.42 Å range. Replacement of a CO ligand by a phosphine results in axial phosphine incorporation, whereas a second alkene ligand is incorporated at another equatorial position. The substituents on alkene carbons are bent back from idealized sp^2 geometry; angles of 10–15° are common. Small rotations of the alkene from the equatorial plane are also often found in crystal structures (*see Crystal Structures*). Temperature-induced changes of the CD spectra of optically active complexes are evidence that this rotation is an intrinsic property.[112] Alkene rotation barriers are in the 45–60 kJ mol^{-1} range; this rotation is coupled with Berry pseudorotation (*see Berry Pseudorotation*). For the (diazadiene)$Fe(CO)_2$ complexes the barrier ranges between 40 and 70 kJ mol^{-1}.[129] Typical ^{1}H NMR chemical shifts for the coordinated alkene vary significantly. Typical chemical shifts are 2.2–3.0 ppm for unsubstituted alkenes and 3.0–3.5 ppm for monosubstituted alkenes. For alkenes bearing electron-withdrawing groups, the α-protons are significantly downfield (3.7–5.5 ppm), whereas the β-protons are largely unperturbed. Substitution of a phosphine or phosphite for one carbonyl ligand results in shielding of the alkene protons.[130] Typical $^3J(trans)$, $^3J(cis)$, and $^2J(gem)$ are 9–12.5, 6.5–8, and 1–2.5 Hz, respectively. The ^{13}C NMR spectral resonances usually fall in the ranges of 23–35 ppm (unsubstituted) and 44–65 ppm (monosubstituted).[32] ^1J(C–H) coupling constants are approximately the same as the parent alkenes, and limited data give an average value for ^1J(C–C) of 46 Hz.[131]



(**80**)

4.2.2 Cationic Alkene Complexes

The average Fe–C bond distance has been determined from crystal structures of (**79**) is considered to be ≈2.20 Å (range of 2.09–2.82 Å), but the alkene carbon atoms are often highly unsymmetrically bonded to the Fe center, with the carbons substituted by electron-donating groups being much further away.[132] This is evidence for contribution of resonance form (**81**) to the bonding description (equation 12), which has been predicted in general terms by Extended Hückel molecular orbital (EHMO) calculations (*see* ***Molecular Orbital Theory***).[133] In the minimum energy conformation the alkene residue is roughly parallel to the plane of the Cp ring, with substituents oriented away from the Cp ring, if possible. Alkene rotation barriers have been shown to vary from ≈33 to >75 kJ mol^{-1}.[134] Typical ^{1}H NMR chemical shifts for (η^2-alkene)Fp^+ complexes are 3.5–4.1 ppm (unsubstituted) and 4.7–5.6 ppm (monosubstituted). Electron-donating substituents move the α-proton chemical shifts downfield, and the β-protons upfield, whereas electron-withdrawing groups give the opposite trend.[135,136] The ^{13}C NMR spectral resonances fall in the ranges of 48–61 ppm (unsubstituted) and 80–90 ppm (monosubstituted); the disubstituted alkene carbon of the isobutene complex is even further downfield (118.8 ppm).[17]

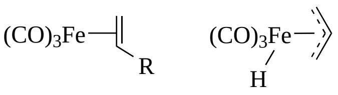


(**81**) (12)

4.3 Reactions of Alkene Complexes

4.3.1 Neutral Complexes

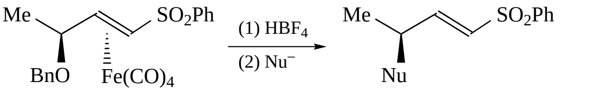
Alkene–tetracarbonyliron complexes are very susceptible to displacement of the alkene moiety. Reaction of these complexes with reasonably good nucleophiles, such as PPh_3, pyridine, or others, results in formation of free alkene and $LFe(CO)_4$ or $L_2Fe(CO)_3$.[106,107] Photolysis of these complexes in both the gas phase and in low-temperature alkane or Ar matrices results in CO displacement to afford coordinatively unsaturated (η^2-alkene)$Fe(CO)_3$ complexes (**82**). In the presence of H_2 and excess alkene, hydrogenation (*see Hydrogenation*) with high turnover ensues.[137] If the alkene possesses an allylic hydrogen, intramolecular C–H bond insertion occurs to give (**83**), which in turn induces isomerization of 1-pentene.[138] Infrared (IR) (*see Infrared Spectroscopy*) spectroscopic data suggests evidence of two isomers of (**83**).[139]



(**82**) (**83**)

Little synthetic work has been reported on (η^2-alkene)$_2Fe(CO)_3$ complexes, with the exception of $Fe(CO)_3$ (η^2-cyclooctene)$_2$. Grevels has shown this compound to be a versatile source of $Fe(CO)_3$ in solution, and it has been used for that purpose.[117] However, its use is far less common than other mild $Fe(CO)_3$ transfer reagents such as (bda)$Fe(CO)_3$ (Section 6.3.1).

α,β-Unsaturated carbonyl–$Fe(CO)_4$ complexes (**84**) are more stable than most [(η^2-alkene)$Fe(CO)_4$] complexes, and have produced more tractable reactions. Lewis acids react at the carbonyl oxygen to afford intermediate (**85**), which undergoes subsequent reactions with amines at the carbonyl carbon to give (**86**) initially, and often further products.[140] Wittig (*see Wittig Reagent*) and 'phospha-Wittig' reagents react at the aldehyde function of enal complexes; the alkenation is often followed by migration of the iron group.[141,142] Hard nucleophiles, such as organolithiums and Grignard reagents (RLi, RMgBr), give initial metal-bound CO attack, followed by acyl transfer to the β-carbon of the alkene, resulting in 1,4-dicarbonyls (**87**).[143] In some cases, carbonyl carbon attack has been observed. A CO ligand of η^2-enone complexes may be removed selectively using amine N-oxides. In the presence of phosphine or phosphite ligands, the result is ligand substitution (*see Ligand Substitution*) (**88**); in the absence of external ligands, an η^4-enone complex is formed. Since these complexes are chiral, the possibility exists that the enantiomers can be obtained with enantiomerically pure amine N-oxides. In fact, the use of brucine N-oxide has given significant kinetic resolution of both the alkene and enone complexes.[144] An enantiomerically pure vinyl sulfone complex was elaborated to the η^3-allyl complex with loss of the γ-benzyloxy group; this intermediate underwent nucleophilic addition with overall retention of configuration at the γ-position (equation 13).



(13)

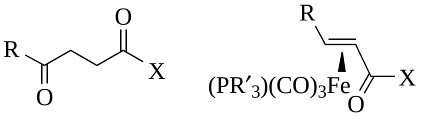
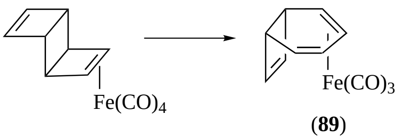
E^+ = Lewis acid



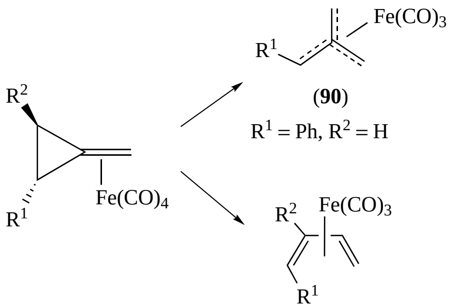
(**87**) (**88**) X = Ar, Me, H

η^2-Iron carbonyl complexes participate in ring-opening reactions of strained alkenes.[107,145] (Cyclobutene)$Fe(CO)_4$ complexes undergo concerted disrotary ring opening to give (η^4-cyclohexadiene)$Fe(CO)_3$ complexes (**89**) (equation 14). (Methylenecyclopropane)$Fe(CO)_4$ complexes undergo conrotary ring opening to (η^4-trimethylenemethane)$Fe(CO)_3$ complexes (**90**) or, in the case of Feist's ester, to give (η^4-butadiene)$Fe(CO)_3$ complexes (**91**) via C–H insertion and subsequent disrotary concerted ring opening (equation 15). All three rearrangements are preceded by CO loss from iron; detailed studies on the mechanistic aspects of these transformations have been reported.[145]



(**89**)

(14)



(**90**)

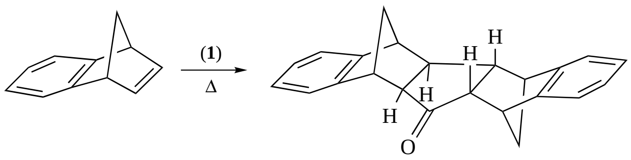
R^1 = Ph, R^2 = H

(**91**)

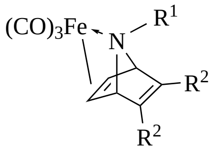
$R^1 = R^2 = CO_2Me$

(15)

Stable *N*-substituted (azabicyclo[2.2.1]heptadiene)Fe $(CO)_3$ complexes (**92**) undergo nitrene extrusion upon heating, to afford arenes; the analogous iron alkene complexes are almost undoubtedly intermediates in iron carbonyl-mediated deoxygenations of oxabicyclo[2.2.1]heptadienes,that is, (**78**).[146,147] Bicyclo[2.2.1]heptenes lacking a skeletal heteroatom undergo a highly stereoselective cycloaddition, via the η^2-alkene complexes, to give cyclopentanones (equation 16). The stereo- and regiochemical (*see Regiochemistry*) aspects of this reaction have been discussed in detail.[148]



(16)

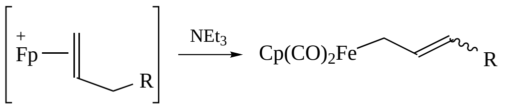


(**92**) $R^1 = CO_2Et$, SO_2Me, COMe; $R^2 = CO_2Me$

4.3.2 Cationic Alkene Complexes

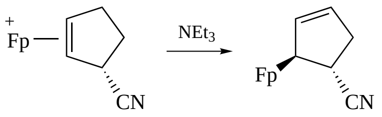
$Fp(\eta^2\text{-alkene})^+$ salts (**79**) are much more electrophilic than $(CO)_4Fe(\eta^2\text{-alkene})$ complexes. The former enter into reaction with a wide range of nucleophiles, and are also therefore susceptible to proton abstraction.

Trialkylamines are capable of deprotonating (**79**), the products being $(\eta^1\text{-allyl})FeCp(CO)_2$ complexes (equation 17). The abstracted proton must be oriented *anti* to the face of the alkene bearing the iron residue; $(\eta^2\text{-cyclopentene})Fp^+$ cations substituted with *trans* acidifying groups (**93**) deprotonate away from the electron-withdrawing group for this reason (equation 18).[136]



(17)

(**79**)

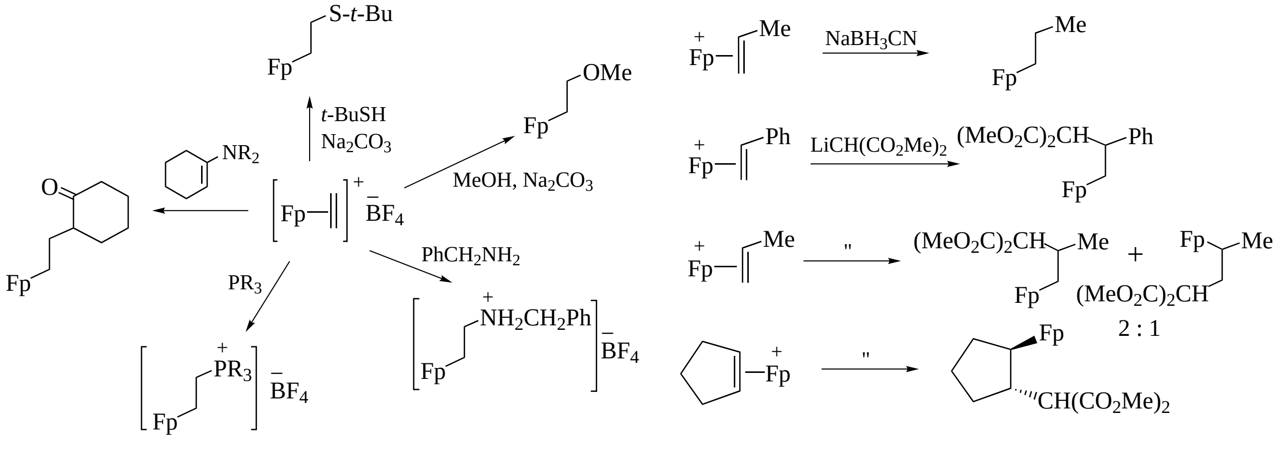


(18)

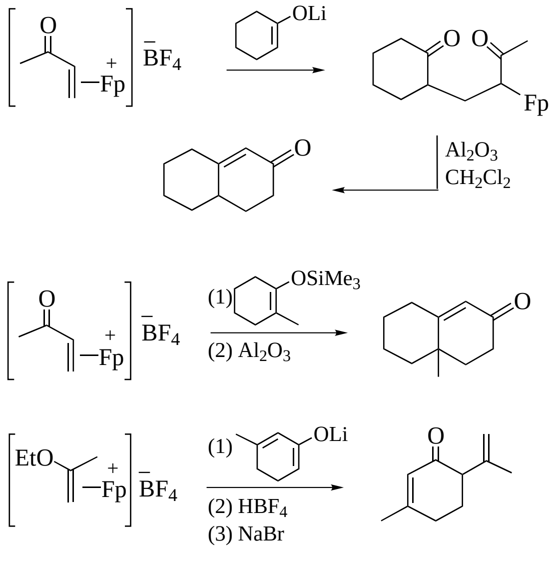
(**93**)

Nucleophilic attack on $(\eta^2\text{-alkene})Fp^+$ cations may be effected by heteroatom nucleophiles including amines, azide ion, cyanate ion (through N), alcohols, and thiols (Scheme 39). Carbon-based nucleophiles, such as the anions of active methylene compounds (malonic esters, β-keto esters, cyanoacetate), enamines, cyanide, cuprates, Grignard reagents, and $(\eta^1\text{-allyl})Fe(Cp)(CO)_2$ complexes react similarly. In addition, several hydride sources, most notably $NaBH_3CN$, deliver hydride ion to $Fp(\eta^2\text{-alkene})^+$ complexes. Subjecting complexes of type (**79**) to NaI or NaBr in acetone, however, does not give nucleophilic attack, but instead results reliably in the displacement of the alkene from the iron residue. Cyclohexanone enolates or silyl enol ethers also may be added, and the iron alkyl complexes thus produced can give Robinson annulation-type products (Scheme 40). Vinyl ether-cationic Fp complexes as the electrophiles are useful as vinyl cation equivalents.[4]

The stereochemistry of nucleophilic attack is consistently *trans* to the metal–alkene bond (Scheme 39, equation 19).[110,149] The regiochemistry of attack is normally at the alkene carbon bearing the most electron-donating (or least electron-withdrawing) group. For weakly electron-donating substituents, such as alkyl, the observed regioselection is modest for carbon-based nucleophiles. For amine and

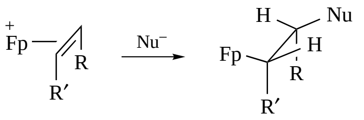


Scheme 39

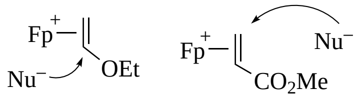


Scheme 40

oxygen-based nucleophiles, however, much better selectivity is realized, presumably due to the reversible nature of the addition of these heteroatom nucleophiles. With more highly electron-donating substituents, such as alkoxy (**94**), or electron-withdrawing ones, such as esters (**95**), the regioselection of attack is excellent.

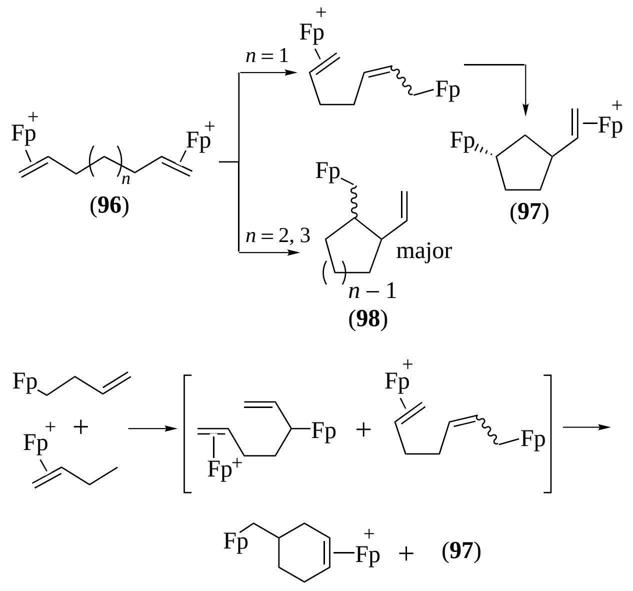


(19)



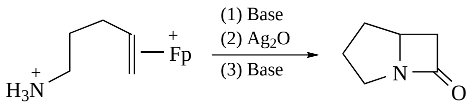
(**94**) (**95**)

Intramolecular nucleophilic attack has been demonstrated in several cases, particularly with amine and (η^1-allyl)Fp complexes; an example of the former is depicted (equation 20).[4] In such cases, the driving force for formation of five- or six-membered rings overrides the preference for attack at the more substituted alkene center. The ability of trialkylamines to convert (η^2-alkene)Fp^+ complexes into (η^1-allyl)Fp complexes via deprotonation allows conversion of alkadiene complexes (*see Diene Complexes*) (**96**) into carbocycles (**97,98**). The reasons for the stereochemical outcome of these cyclization reactions have not been fully delineated. Finally, (η^2-butadiene)Fp^+ cations react in two sequential (η^1-allyl)Fp–(η-alkene)Fp^+ pairs to give a mixture of cyclic

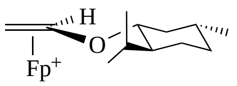


Scheme 41

products (Scheme 41).

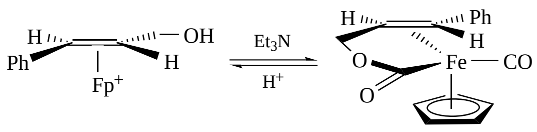


(20)



(**99**)

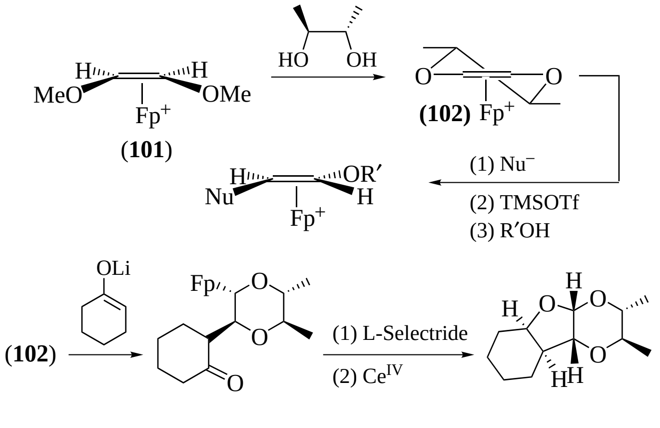
Work in this area has also focused on optically active complexes. Exchange of vinyl ether complex (**94**) with optically active alcohols gives unequal mixtures of diastereomeric vinyl ether complexes; in the best case, (−)-menthol gives a 4:1 mixture enriched in (**99**).[150] Optically active epoxides are capable of affording enantiomerically pure complexes; allylic alcohol substituents allow reversible conversion to the related lactone complexes (**100**) (equation 21).



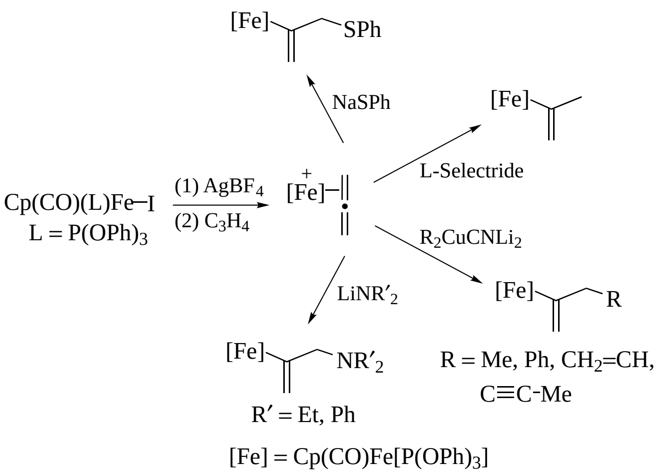
(**100**)

(21)

The reaction of the (*cis*-1,2-dimethoxyethylene)Fp^+ complex (**101**) (available from treatment of the alkene with (**79a**)) with (*R*,*R*)-2,3-butanediol gives the optically active Fp^+-dioxene complex (**102**). The reaction of (**102**) with nucleophiles proceeds *anti* to the metal fragment; treatment of



Scheme 42



Scheme 43

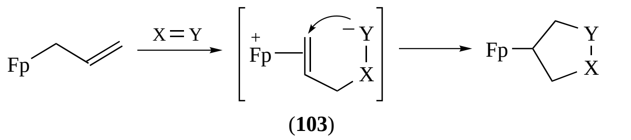
the iron alkyl thus obtained by with TMSOTf and subsequent exposure to alcohols, gives enantiomerically pure planar chiral vinyl ether complexes (Scheme 42).[4,132] Attack of (**102**) with a cyclohexene enolate, followed by ketone reduction and oxidative removal of the metal fragment gave a tricylic furan.[151]

Nucleophilic addition to the related cationic η^2-allenyl iron complexes is generally a high-yielding process that produces vinylic iron complexes (Scheme 43). Double bond isomerizations to give the internal alkene can be effected by column chromatography or catalytic amounts of acid.[152]

4.4 Alkene Complexes as Reaction Intermediates

Cationic iron alkene complexes are important intermediates in a well-studied series of [3 + 2] cycloaddition reactions between iron allyl complexes and alkenes and related electrophiles. This chemistry has been reviewed by Rosenblum, and was included in subsequent reviews by Welker and Liu.[18,19,101,153] Propargylic iron complexes react in a similar manner, and will be included in this section.

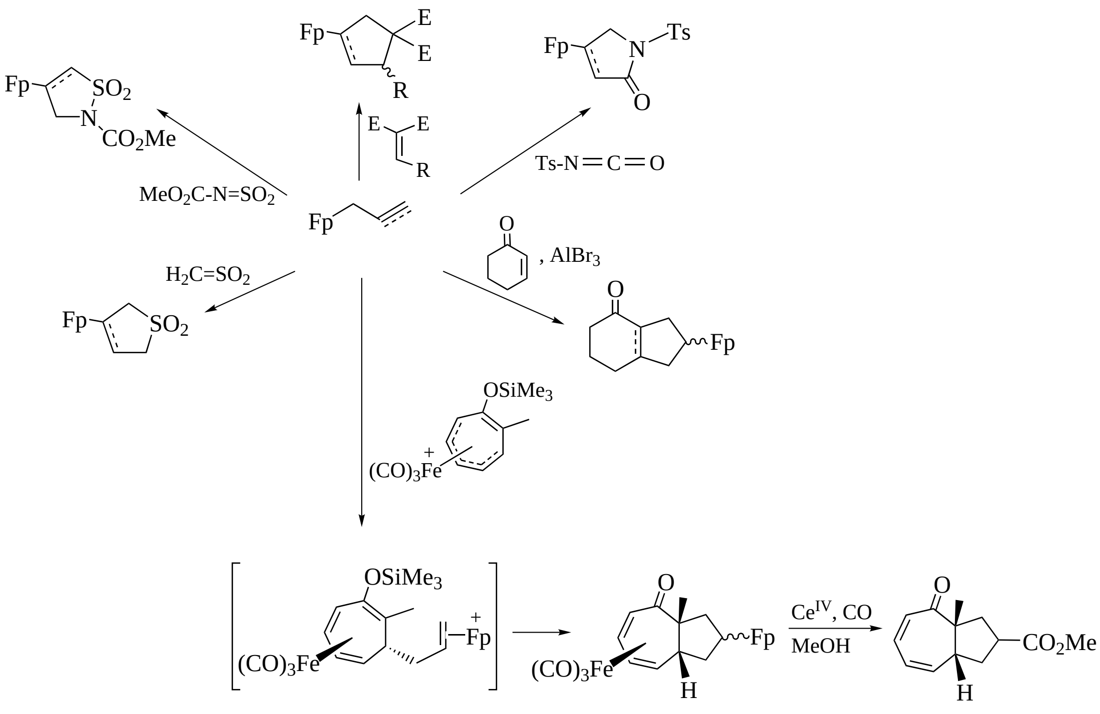
With reactive neutral electrophiles (E=Nu), (η^1-allyl)Fp complexes suffer nucleophilic attack to give zwitterionic intermediate (**103**), which undergoes subsequent intramolecular nucleophilic attack to give the overall product of [3 + 2] cycloaddition (equation 22). (η^1-Propargyl)Fp complexes react similarly. Among electrophilic species suitable in this reaction are α, β-unsaturated nitriles and esters (which must possess at least two geminal electron-withdrawing groups to be sufficiently reactive), isocyanates, hexafluoroacetone, and *N*-sulfonylurethane (Scheme 44). Enones may be induced to react only in the presence of Lewis acids, such as $AlBr_3$. Both allyl and propargyl complexes undergo [3 + 2] cycloaddition with the noncomplexed double bond of tropyliumiron tricarbonyl cationic salts to afford a 7,5-ring system; this chemistry has been used for the synthesis of functionalized hydroazulenes (**104**).[154] Oxidative demetalation of the iron fragment with ceric ammonium nitrate is a typical, though not the only, synthetic strategy employed in this chemistry. Other examples utilizing allyl iron complexes as well as those that employ the propargylic analogs (which presumably proceed via cationic η^2-iron allenyl complexes) are grouped separately (Schemes 45 and 46). It should be noted that the nucleophilicity of (η^1-allyl)Fp complexes may be enhanced by substituting one of the CO ligands with the more electron-donating phosphite ligand. The resulting complexes are $\approx 10^2 - 10^3$ times more reactive than the parent, and will react with alkenes to which the parent is inert.[23]



(22)

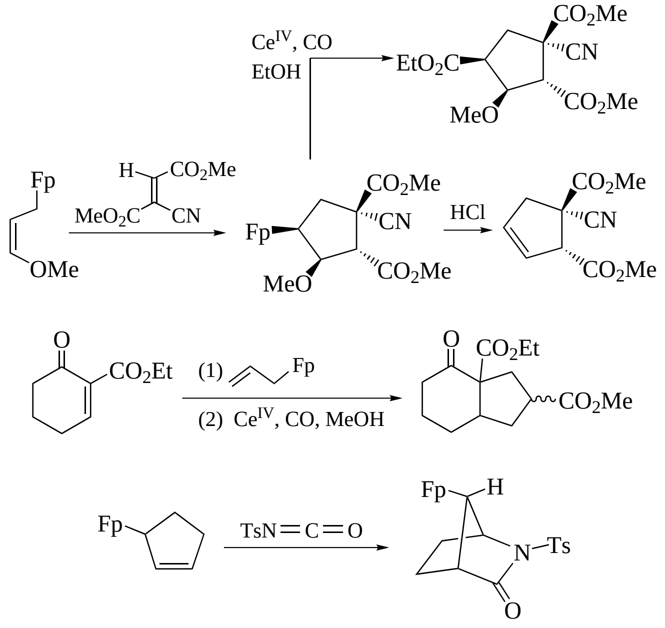
Other variations of the [3 + 2] cycloaddition chemistry involving either SO_2 or a S_2O equivalent have been explored (Scheme 47).[153,155,156] Iron allenyl complexes undergo reaction with SO_2 to give either vinyl iron (**105**) or (**106**), depending on the substitution pattern. A propargylic iron complex reacts in a similar manner to give (**107**), but reacts with a cyclic thiosulfinate ester to give (**108**).

As previously mentioned, the reaction of allyl iron complexes in the presence of carbonyls and BF_3 has investigated and reviewed (Scheme 37); isolable zwitterionic complexes of the type (**79m**) are obtained.[127,157] Synthetic sequences were developed to utilize these salts; unfortunately, there is only little or modest diastereoselectivity (Scheme 48).[158] Furan formation from the precursor of (**79m**), allylFp, can also be accomplished in a single operation using $ZnCl_2$. Crotyl iron complexes were shown to give the corresponding homoallyl alcohols with modest to good *syn*/*anti* selectivity (3:1 to 14:1).[159] The reaction has also been extended to include imines to provide the homoallyl amines; again, selectivities

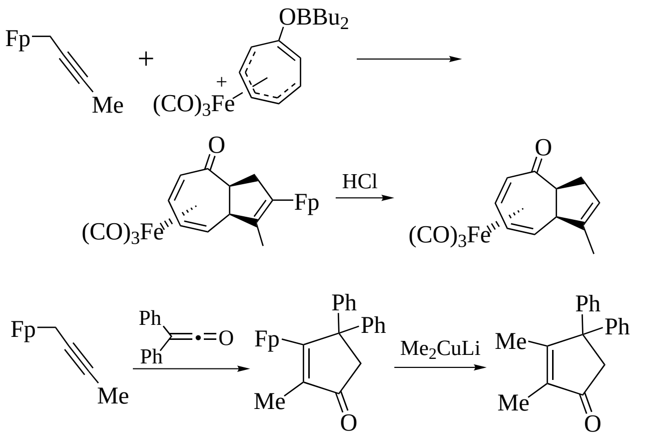


(**104**)

Scheme 44



Scheme 45



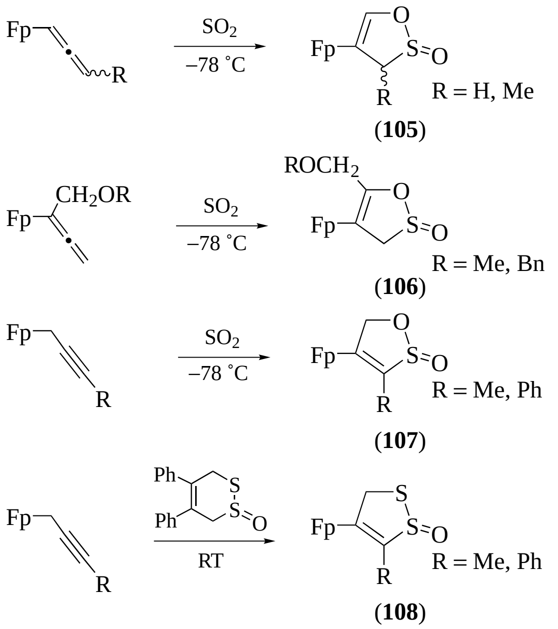
Scheme 46

were modest (ca. 2.5:1).[160] Pyrrolidines have been prepared as well. Finally, one intramolecular [3 + 2] cycloaddition was reported, yielding tricylic furan (**109**) in moderate yield and diastereoselectivity (Scheme 49).[158]

4.5 Alkyne Complexes

4.5.1 Neutral Complexes

It is typically difficult to isolate $[Fe(CO)_4(\eta^2\text{-R-CC-R}')]$ complexes (**110**) without bulky substituents,[161] as they undergo spontaneous alkyne–alkyne coupling reactions, (some of which have tangible synthetic promise).[162] In fact, prior to 1997, only the bistrimethylsilylacetylene complex (**110a**) had been fully characterized. However, a number



Scheme 47

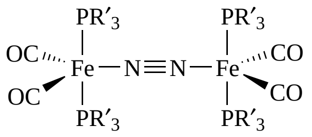
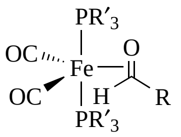
(**111**)

of other complexes (**110b–f**) – all thermally unstable – have now been successfully prepared in fair to good yields by careful photolysis at low temperature, though the reaction scale could not be increased.[163] Dissociation of one of the CO ligands from (**110b**) was reported to be 3×10^{13} faster than CO dissociation from $Fe(CO)_5$. Substitution of CO for more electron-rich ligands (such as phosphines or phosphites) leads to more stable alkyne complexes, and a number have been prepared and crystallized (**110g–l**). A remarkably stable iron tricarbonyl-alkyne complex has recently been reported (**111**); there is probably a significant amount of metallacyclic character to this species. Finally, photolysis of (**112**) in the presence of an alkyne also affords alkyne complexes (**110h, m**, and **n**).[164]



(**112**)

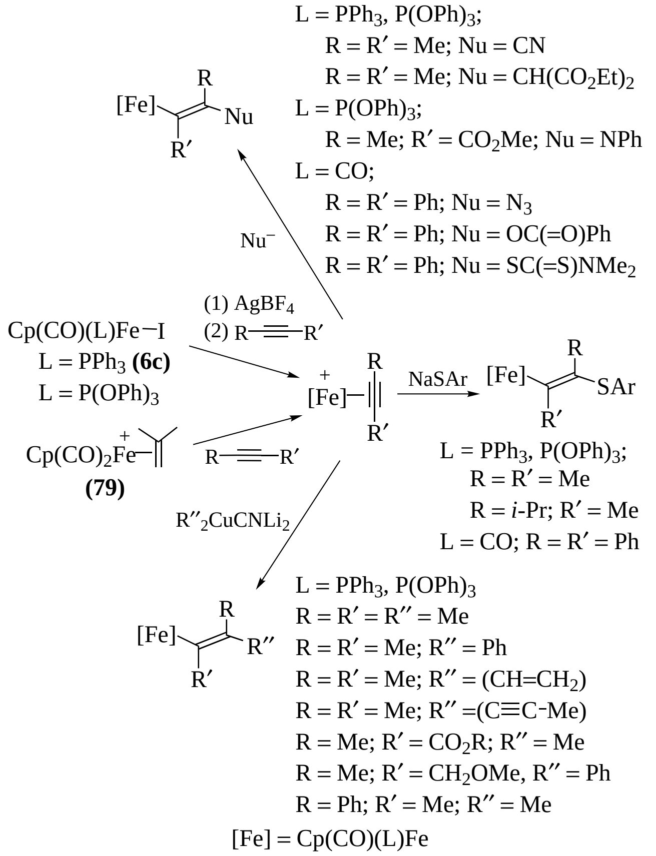


R′ = Et, OMe; R = H, Ph

(**113**)

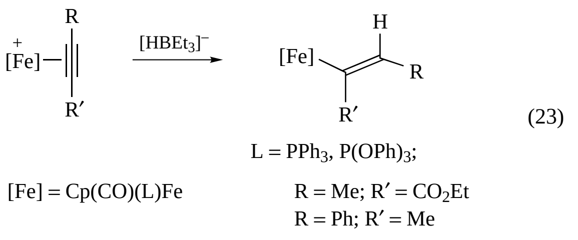
4.5.2 Cationic Complexes

Fp(η^2-alkyne)$^+$ complexes may been generated by Ag(I)-promoted halide ionization of (**6c**) in the presence of an alkyne or by transfer of the Fp^+ fragment from reagent



Scheme 50

(**79**); these are generally stable complexes except for terminal alkynes, which are in equilibrium with vinylidene complexes. The cationic alkyne complexes are very reactive electrophiles (Scheme 50).[18,19,152,165] Addition of nucleophiles in Scheme 48 proceed in a manner that is *anti* to the iron unit, to give the *trans* product. Other nucleophiles (such as hydride, equation 23) instead react to give the *cis* product, an outcome resulting from initial addition to the Cp ring followed by intramolecular transfer to the alkyne. While a silyl enol ether afforded the *trans* vinyl iron complex, allylation with allyl tributylstannane give a *cis*/*trans* mixture. A study of the addition of nucleophiles to Fp(η^2-alkyne)$^+$ complexes revealed that the product stereochemistry depended on the basicity of the nucleophile.[165]



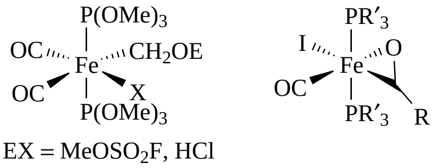
(23)

4.6 (η^2-C=X) Complexes

4.6.1 *Preparation and Reactivity*

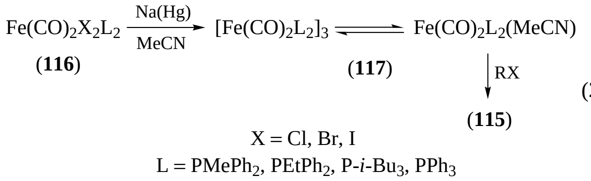
A number of $(CO)_2(L)_2Fe(\eta^2$-carbonyl) complexes have been isolated (**113**) (η^2-C=O). These have been prepared by replacement of N_2 from μ-dinitrogen complexes (**112**) by the aldehyde in question.[166] Two phosphine or phosphite ligands appear to be necessary for satisfactory stability of these complexes. This is in apparent agreement with the results of both ab initio (*see Ab Initio Calculations*) and EHMO calculations and emphasizes the importance of d−π* back-donation to the overall bonding in these complexes.[167] The EHMO calculations also emphasize the role of the repulsive four-electron ligand−ligand interactions in determining the likelihood of η^2 coordination.

Very limited reactivity studies have been reported for compounds of type (**113**). Complex (**113**; R = H, R′ = OMe) undergoes attack on electrophiles (E^+X^-) at oxygen to afford octahedral (*see Octahedral*) complexes (**114**), with the electrophile counterion occupying the final coordination site.[168]

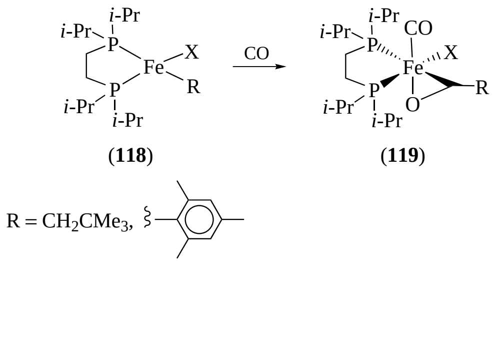


(114) **(115)**

Closely related are the η^2-acyl complexes of iron (**115**). These have been prepared by three methods. Loss of N_2 from (**112**) in the presence of an alkyl halide gives oxidative addition (*see Oxidative Addition*) to yield η^2-acyl complexes for some phosphine ligands.[169] Sodium amalgam reduction of Fe^{II} halide complexes (**116**), and exposure of the resulting (**117**) to an alkyl halide, gives similar complexes (equation 24).[170] Finally, placement of iron alkyl (aryl) complexes (**118**) under a CO atmosphere results in insertion to afford complexes (**119**) (equation 25).[171]

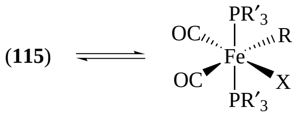


(24)



(25)

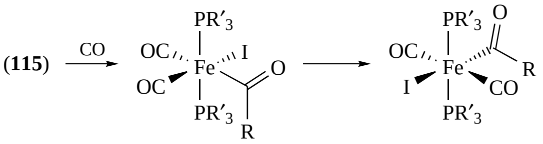
η^2-Acyl complexes of the type (**115**) are in a closely balanced equilibrium with their isomeric metal alkyl complexes (**120**) (equation 26). The equilibrium between (**115**; R = Me, R'_3 = Ph_2Me) and its corresponding (**120**), for example, has a ΔH of 5.4 kJ mol^{-1} (favoring **115**), with activation parameters of $\Delta H\ddagger = 41.9$ kJ mol^{-1} and $\Delta S\ddagger = -28$ J mol^{-1} K^{-1}.[172] In fact, η^2-acyl complexes are isolated only with phosphine ligands which have a cone angle (*see Cone Angle*) >135°; less bulky phosphines usually give the alkyl complexes (**120**). The basicity of the phosphine appears to be much less important in the position of this equilibrium.



(26)

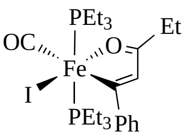
(**120**)

Reactivity studies of η^2-acyl complexes are limited. Compounds (**115**) react with CO to afford octahedral *cis,trans*-η^1-acyl complexes (**121**), probably via prior conversion to a coordinatively unsaturated monodentate (*see Monodentate Ligand*) acyl (equation 27). The *cis,trans*-(**121**) then isomerizes to *trans,trans*-(**121**). Phenylacetylene reacts with (**115**; R = R′ = Et) to give a mixture of acyl–alkyne coupling products,that is (**122**). Reaction with the R = *i*-Pr compound proceeds in a different way, by equilibration to the η^1-alkyl, followed by alkyl–alkyne coupling, and finally CO insertion to give η^2-acyl complex (**123**).[173]

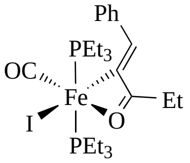


(27)

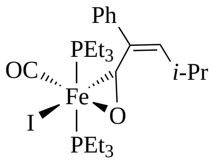
cis, trans (**121**) *trans, trans*



(**122a**)

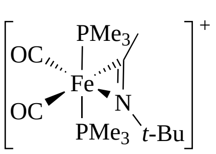


(**122b**)

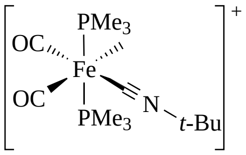


(**123**)

The related η^2-iminoacyl complexes (**124**) are known (η^2-C=N). These may be prepared by reaction of $[Fe(CO)_2(PMe_3)_2(Me)I]$ with *t*-butyl isocyanide, through an equilibrium with η^1-iminoacyl complex (**125**). The equilibration is catalyzed by halide ion, NO_3^-, and ClO_4^-, but not by BF_4^-, PF_6^-, or BPh_4^-; consequently, the pure compounds are isolated by precipitating the BPh_4^- salt from the mixture. The mechanistic details of the equilibrium have been investigated in detail.[174]

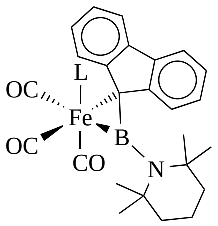


(**124**)



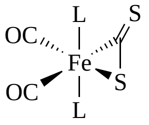
(**125**)

Examples of iron η^2-B=C complexes of a boraalkene are known as well. The $Fe(CO)_4$ complex of 9-fluorenylidene(tetramethylpiperidino)borane (**126**) has recently been prepared by the thermal reaction of the borane and (**2**) or by the photolytic reaction of (**1**) and the borane. The monophosphine/phosphite complexes are prepared from the tetracarbonyl by photolytic CO dissociation, followed by PR_3 addition.[175]



L = CO, PR_3

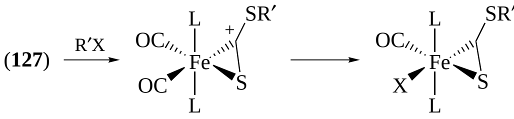
(**126**)



(**127**)

Thiocarbonyl (*see Thiocarbonyl*) compounds react rapidly with iron carbonyls, but only in a few cases are mononuclear η^2-C=S complexes realized. Most of the work in this area has resulted from the discovery that carbon disulfide reacts with iron carbonyl transfer agents, in the presence of phosphines or phosphites, to give complexes (**127**).[176] In several of these cases, it is possible to exchange one or both of the phosphine/phosphite ligands in high yield.

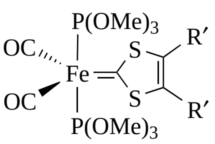
These compounds are nucleophilic at the noncoordinated sulfur, and undergo alkylation there with iodomethane or benzyl bromide to give initially (**128**) (which may be isolated as the PF_6^- salt) and ultimately (**129**) (equation 28). They also react with electron-deficient alkynes, possibly by a dipolar mechanism, to afford cyclized iron carbene complex (**130**).[177] Finally, compounds (**129**) are subject to attack by some nucleophiles; hydride attack occurs initially at the metal, but ultimately gives η^2-dithioester complexes, such as (**131**).[178]



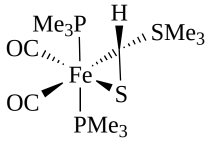
(28)

(**128**) (**129**)

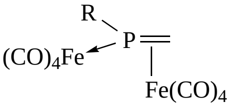
η^2-Complexes of C=P bonds have been reported occasionally. In the majority of cases, the phosphorus atom is coordinated to another transition metal fragment, as the



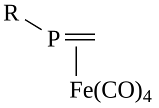
(**130**)



(**131**)

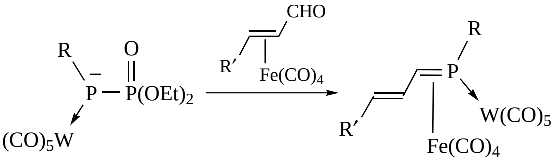


(**132**)



(**133**)

unpaired electrons on phosphorus make it the most Lewis basic site. Reaction of a bulky *P*-arylphosphaalkene with excess (**2**) gives complex (**132**). If only one equivalent of (**2**) is added, only traces of η^2-complex (**133**) can be detected.[179] Phospha-Wittig reagents react with (η^2-alkenal)$Fe(CO)_4$ complexes, with migration of the iron carbonyl residue, to give complex (**134**) (equation 29).[142] These complexes lose CO to give the η^4-complex upon heating.



(**134**) (29)

4.6.2 *Structure*

X-ray crystallographic (*see X-ray Crystallography*) studies on (η^2-C=X)FeL_4 complexes show a distinct structural similarity regardless of the nature of the heteroatom. Almost invariably, these complexes display a trigonal bipyramidal structure, with axial phosphine/phosphite ligands if present and the η^2-C=X ligand in the equatorial plane. For (η^2-carbonyl) complexes (**113**), bond lengths of 1.29 and 1.32 Å for C=O have been observed.[168] Limited spectral data have revealed a weak $\nu_{C=O}$ of 1215 cm^{-1} in the IR spectrum in one case. The formaldehyde complexes have also given ^{1}H NMR chemical shifts of 3.99 and 4.75 ppm for the $H_2C=O$ resonance, and a ^{13}C NMR chemical shift of 73.7 ppm (for the aldehyde carbon) in one case.

Crystallographic studies on (**113**) show the common trigonal bipyramidal structure, with axial phosphine ligands and equatorial η^2-carbonyl ligands; (η^2-acyl) complexes (**115**) show the same properties, with the additional feature that the O-atom of the acyl ligand lies *cis* to the halogen. Complexes (**119**) are somewhat exceptional in that one end of the bidentate (*see Bidentate Ligand*) phosphine is equatorial; the other axial site is occupied by halogen. Acyl C–O bond lengths of 1.23–1.28 Å have been reported for compounds of type (**115/119**). Bonding of iron to the CO unit is not symmetrical: Fe–C and Fe–O bond lengths of 1.8–1.83 and 2.19–2.25 Å, respectively, are typical. IR spectra give a typical $\nu_{C=O}$ of 1586–1605 cm^{-1}. The acyl carbon resonance appears at 280 ppm in the ^{13}C NMR spectra but is not always observable at room temperature. Structurally, η^2-iminoacyl complexes (**124**) are strictly analogous to η^2-acyl complexes (**115**), with a C–N bond length intermediate between double and triple bond length (1.21–1.30 Å).

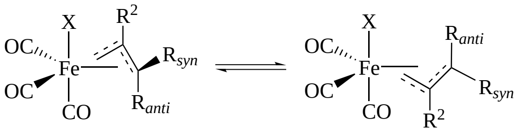
The boraalkene complex (**126**) shows many structural properties that parallel the η^2-carbonyl complexes, although the trigonal bipyramid is severely distorted. In the PMe_3 complex it is most reasonable to assign both the PMe_3 and B=C ligands as axial. Another distinctive feature in (**126**) is that the B atom on the η^2-B=C unit is closer to iron (2.125 Å) than the C atom (2.190 Å); this is indicative of the importance of back bonding from the Fe-centered 2a′ orbital to the boron-centered π^*_{BC} orbital.[175] The η^2-C=S complexes are similar, with the C=S bond length intermediate between single and double bond lengths (1.676 Å).[176]

5 η^3-ALLYL COMPLEXES[106,107]

5.1 Preparation

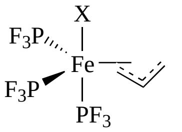
5.1.1 *(η^3-Allyl)FeL_4 Complexes*

The reaction of allyl halides with (**1**) or (**2**) under photolytic or thermal (40 °C) conditions results in oxidative addition of the C–X bond to afford (η^3-allyl)$Fe(CO)_3X$ complexes (**135**) (equation 30). This is successful for a wide range of allyl complexes, including η^3-pentadienyl complexes.[180] In some cases, such as the 2-methoxy case, the η^3-allyl complex (for X = Cl, and partially for X = Br) undergoes subsequent HX loss to give a vinylketene complex.[181] Recently, the preparation of (**135**) via $Me_2SiFe_2(CO)_8$ and allyl halides has been reported.[182] (η^4-Diene)$Fe(CO)_3$ complexes undergo electrophilic attack by HCl (or DCl) to give *anti*-substituted complexes (**135**).[183] Finally, transfer of the allyl unit from other π-allyl transition metal complexes can give complexes of the type (**135**). Specifically, both the reaction of $[PdX(\eta^3\text{-allyl})]_2$ with (**2**) or the combination of either $[Pd(\eta^3\text{-allyl})_2]$ or the corresponding Ni or Pt bis(allyl) complexes with (**2**), followed by X_2, have given (**135**) successfully.[107]

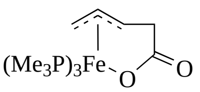


exo (**135**) *endo* (30)

Reports of complexes of this class bearing phosphorus ligands also exist. The oxidative addition of allyl bromides and iodides to $Fe(PF_3)_5$ gives the analogous η^3-allyl complexes (**136**).[184] The reaction of (η^4-diene)$Fe(PMe_3)_3$ with CO_2 under pressure gives chelated π-allyl complex (**137**).[185]

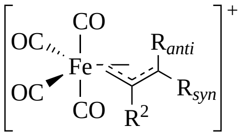


(136)

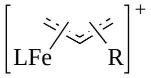


(137)

Closely related to (**135**) are the $[(\eta^3\text{-allyl})Fe(CO)_4]^+$ complexes (**138**). The predominant methods for the preparation of (**138**) include formation of η^2-tetracarbonyliron alkene complexes of allylic alcohols or ethers, followed by ionization of the ether or alcohol function by strong acid (HBF_4, HPF_6) or Lewis acid.[186] In fact, the simultaneous addition of allylic alcohol, (**2**), and HBF_4 together results in the formation of (**138**) in variable yields.[187] The second common method for the preparation of (**138**) employs previously formed (η^3-allyl)$FeX(CO)_3$ complexes (**135**), silver salts ($AgBF_4$, $AgClO_4$), and a CO atmosphere. Finally, the addition of strong acids (HBF_4, $HClO_4$, $HSbCl_6$) to (η^4-diene)$Fe(CO)_3$ complexes, in the absence or presence (for better yields) of CO, gives (**138**) in excellent yields.[188] The carbon atom protonated in this process invariably ends up as an *anti*-oriented substituent in the product allyliron. Performing a similar sequence on the analogous (diene)$Fe(CO)_3(PPh_3)$ complexes gives the allyliron monophosphine complex (**139a**).[189] The corresponding (η^2-diene)$Fe(CO)_4$ complex also affords (**138**) upon protonation by HBF_4; in this case the protonated carbon atom ends up predominantly as a *syn* substituent. It has also proved possible to perform a 'one-pot' reaction of this type, with diene, (**2**), and HBF_4 added all at once.[187] Numerous papers on the preparation and chemistry of enantiopure cationic (η^3-allyl)$Fe(CO)_4$ complexes have appeared; this work has been reviewed, and is exemplified by complexes (**140**).[114,115]

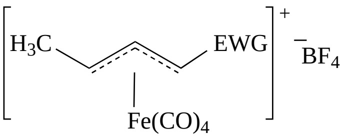


(138)



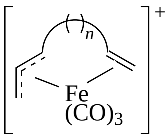
(**139a**) L = $(CO)_3(PPh_3)$
(**139b**) L = $\{P(OMe)_3\}_4$
(**139c**) L = $(CO)_2(PR_3)_2$

Chelated complexes related to (**138**) may be made by closely analogous methods. If the allylic alcohol in question contains a remote, coordinated alkene, protonation can result in (η^3-allyl)$Fe(CO)_3(\text{alkene})^+$ cations (**141**).[107] Electrophilic attack on (η^4-cyclooctatetraene)Fe$(CO)_3$ gives reorganization of the carbon framework, to afford

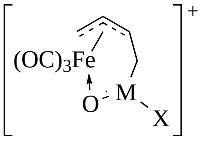


(**140**)
EWG = CO_2Me, SO_2Ph

a similar type of complex.[107,190] In the absence of added CO, addition of electrophiles to acyclic (η^4-diene)$Fe(CO)_3$ may also give chelated complexes. If the electrophile bears an appropriately located oxygen atom, the oxygen atom may occupy the final coordination site of the 18-electron (*see Eighteen Electron Compounds*) complex, to give cations of the type (**142**). Electrophiles that give these types of complexes are acetyl chloride/$AlCl_3$ and SO_2/BF_3 combinations.[107]



(**141**)



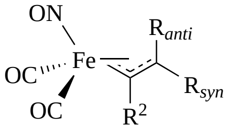
(**142**)
M = S, X = OBF_3^-, $OSbCl_3^-$
M = C, X = Me

Cationic phosphine/phosphite η^3-allyliron complexes are more rare. Aside from the previously mentioned report of the preparation of (**139a**), complex (**139b**) has been made from the reaction of allyl halides and $Fe[P(OMe)_3]_5$.[191] Additionally, complexes with mixed CO/phosphine ligands (**139c**) have been prepared by the reaction of either (**135**; X = Br) or $[(\eta^3\text{-allyl})Fe(CO)_3]_2$ with two equivalents of phosphine, followed by $NaBPh_4$ addition.[192]

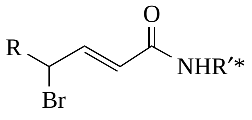
5.1.2 *(η^3-Allyl)FeL$_3$ Complexes*

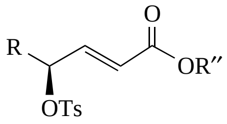
The most thoroughly investigated complexes of this general type are the neutral complexes with mixed nitrosyl and carbonyl ligands, (η^3-allyl)$Fe(CO)_2(NO)$ (**143**), and a review is available.[193] These are commonly prepared by the reaction of $Na[Fe(CO)_3(NO)]$ with allylic halides.[194–197] A variation employing the potassium salt and a mesylate leaving group (*see Leaving Group*) has been reported,[198] and addition of $Na[Fe(CO)_3(NO)]$ to the allyl transmetallation reagent $[(\eta^3\text{-allyl})PdX)]_2$ has been successful as well.[197] Also, complexes (**143**, R^2 = C(O)R) may be formed by treatment of allenes and alkyl halides with $Bu_4N[Fe(CO)_3(NO)]$ (TBAFe), or from alkenyl epoxides in the presence of acetyl chloride and pyridine (**143**, R_{anti} = $CH_2OC(O)Me$ or CHPhOC(O)Me).[199,200] A number of enantiomerically pure complexes have been made using TBAFe and either enantiopure allyl tosylates or allyl bromides bearing an amide-based chiral auxiliary.[195]

Diastereoselective complexation of the latter cases (**144a**) proceeded with only modest selectivity; for the former cases (**144b**) selectivity varied with solvent and temperature. The best case (dr, 97:3) utilized a 'matched' enantiopure allyl tosylate with a menthyl ester auxiliary. Finally, in a few cases the addition of $HFe(CO)_3(NO)$ across diene has also proved successful in the synthesis of (**143**).[106]



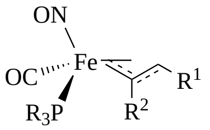
(**143**)

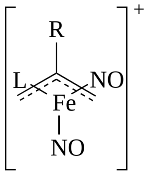




(**144a**) R = H or Me, R′ = chiral aux. (**144b**) R = Me, R″ = Et or (−)–Menthyl

Substitution of the CO ligand for others in (**143**) has proved to be fairly facile. The mixing of equimolar amounts of (**143**) and a number of phosphines or phosphites results in the formation of complexes (**145**),[28,201] through the intermediacy of (η^1-allyl)$Fe(CO)_2(NO)(PR_3)$ complexes. Selected compounds of type (**145**) have also been prepared by the allyl halide attack method.[202] Even in compound (**145**; $L = P(OMe)_3$) the remaining CO ligand has been shown to be capable of replacement by an NO ligand from $NO^+PF_6^-$ to give cationic complexes (**146**).[203]

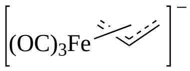


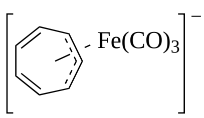


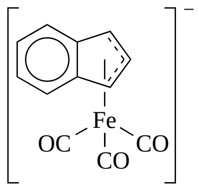
(**145**) (**146**)

Allyltricarbonyliron anions (**147**) have been prepared by the reduction of the corresponding halides with sodium amalgam.[204] Although little work has been done on substituted analogs of (**148**), two other related anionic species have received attention. Proton abstraction of (η^4-cycloheptatriene)$Fe(CO)_3$ results in an anionic species which was eventually determined to be the (η^3-cycloheptatrienyl)$Fe(CO)_3^-$ complex (**148**).[205] Additionally, subjecting the (η^5-indenyl)$Fe(CO)_2^-$ anion to an atmosphere of CO results in formation of η^3-indenyl complex (**149**).[206]

Although protonation of diene complexes with strong acids is one the most common methods for preparation of (η^3-allyl)FeL_4^+ complexes, it is now clear that the initially

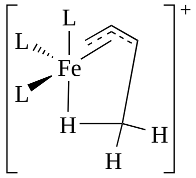






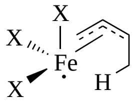
(**147**) (**148**) (**149**)

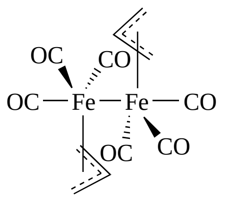
formed species are the formally 16-electron (η^3-allyl)FeL_3^+ complexes (**150**; L = CO, $P(OMe)_3$). These complexes may be observed spectroscopically at low temperatures for the L = CO complexes (Section 5.2.2), but upon warming they convert to (**138**).[207] The L = $P(OMe)_3$ complexes are stable enough to allow isolation at ambient temperatures.[208]



(**150**)

The 17-electron (*see Seventeen Electron Configuration*) (η^3-allyl)FeL_3 radical species (**151**) are also known.[209] These are prepared by the one-electron reduction of allyltricarbonyl halides (**135**; X = CO) or of the (η^3-allyl)$Fe[P(OMe)_3]_3^+$ cations (X = $P(OMe)_3$). For the X = CO complexes, the radical species is in equilibrium with dimeric allyl (**152**) (the dimer can be isolated as a solid, whereas (**151**) is increasingly prevalent at higher dilution). Increasing allyl substitution and increasing the number of phosphine substituents increases the relative concentration of (**151**), to the point where the X = $P(OMe)_3$ complexes are paramagnetic (*see Paramagnetism*) monomers even in the solid state.[209]

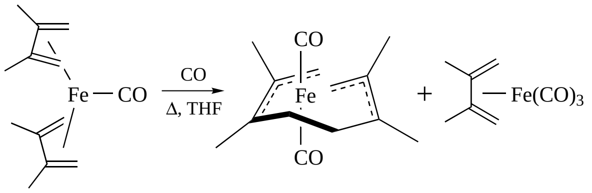




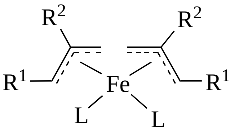
(**151**) (**152**)

Bis(allyl)iron complexes, (η^3-allyl)$_2FeL_2$ (**153**), are encountered only infrequently. The parent complex (**153a**) has been prepared by allylation of allyltricarbonyliron anion (**147**), but it is an unstable complex, the allyl units spontaneously dimerizing at room temperature. Increased stability in this class of compounds is realized if both allyls are part of a chelating ligand (*see Chelating Ligands*), or if the CO ligands are replaced by phosphine or phosphite ligands. The

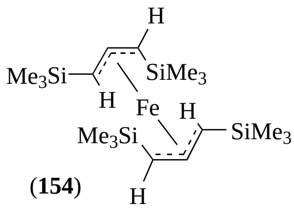
chelating bis(allyls) have been prepared either by coupling of (η^4-diene)$_2$Fe(CO) complexes (equation 31),[106,210] or in selected cases through nucleophilic attack of aryllithiums on (diene)Fe(CO)$_3$ complexes, which proceeds with ring opening and carbonylation.[211] The phosphine/phosphite complexes (**153a,b,c**) may be prepared in good yields for the allyl, 2-methylallyl, and η^3-pentadienyl complexes by the action of allylmetals (or pentadienylmetals) on Cl$_2$Fe(PR$_3$)$_2$.[212,213] Homoleptic (*see Homoleptic Compound*) bis(allyl)iron complex (**154**) has been recently prepared and characterized by X-ray crystallography; the SiMe$_3$ of each allyl are in a *syn, anti* arrangement in order to minimize their steric bulk.[214] This complex was stable under an inert atmosphere at room temperature, whereas the bis(allyl)Fe(PR$_3$)$_2$ complexes typically decompose above 0 °C. Bis(allyl) complexes can also be prepared from trimethylenemethane (TMM) complexes (Section 6.1).



(31)



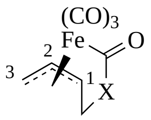
(**153a**) L = CO, R^1 = R^2 = H
(**153b**) L = PR$_3$, R^1 = R^2 = H
(**153c**) L = PR$_3$, R^1 = H, R^2 = Me
(**153d**) L = PMe$_3$, R^1 = vinyl, R^2 = H



(**154**)

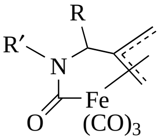
5.1.3 (η^3-Allyl)FeL$_3$R Complexes

The chemistry of this class of complexes is dominated by the π-allyliron tricarbonyl lactone complexes (**155**), which have been studied extensively and reviewed.[215–217] Compounds (**155**) are normally prepared by reaction of vinyl epoxides with a source of 'Fe(CO)$_4$', such as (**1**) and photolysis, (**2**) and heat, or (**2**) in Tetrahydrofuran (THF) or with ultrasonication (*see Sonication*); the latter two methods are considered to be superior. It has been reported that butene-1,4-diols, particularly the *cis* isomers, (with or without Lewis acids), 3-butene-1,2-diol sulfites, 3,6-dihydrooxazines, or related compounds also give (**155**) with (**2**).[218] The complexes are isolated as *anti* isomers at C-1. Substituents at C-3 are oriented *syn* when not constrained in a ring, whereas additional substitution at the oxygen-bearing C atom results in a diastereomeric mixture of products (see below).



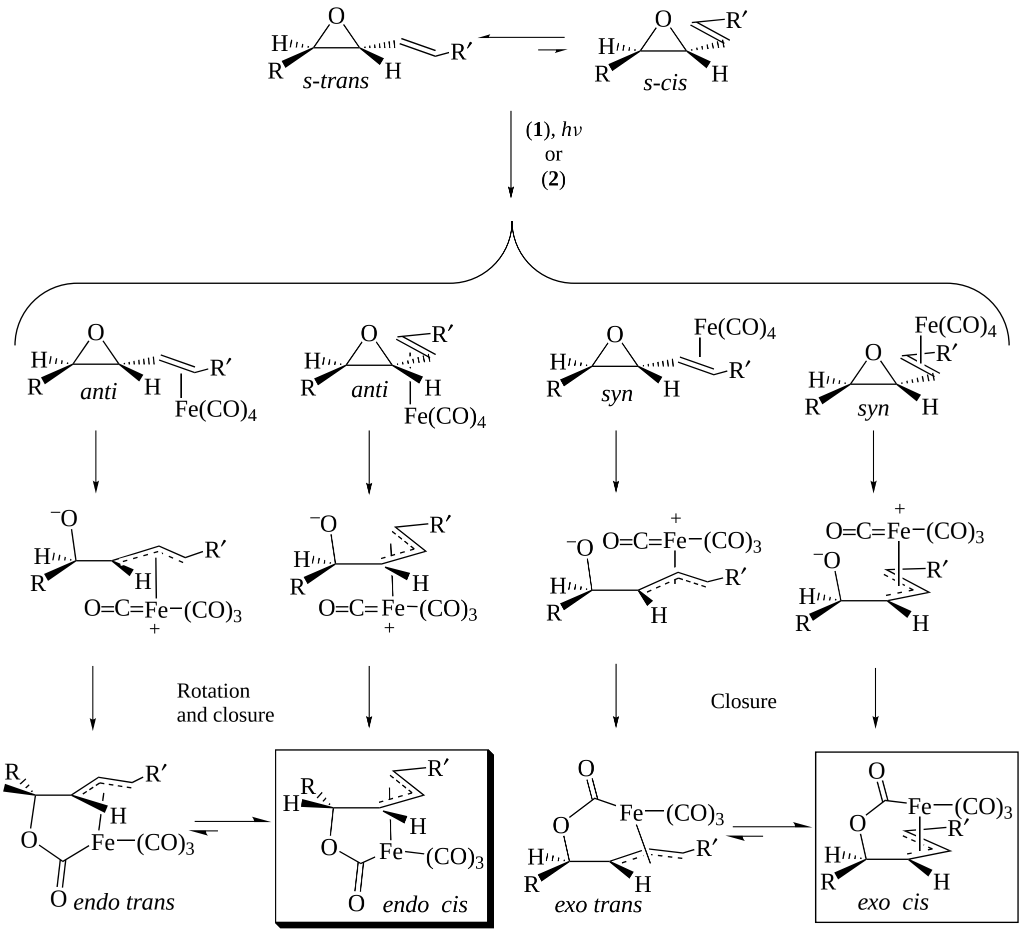
(**155**) X = O
(**156**) X = NR′

A number of enantiomerically pure complexes have been made, and this chemistry has been used in several natural product syntheses.[219] Enantiopure complexes are readily available from the corresponding vinylic epoxides, and in cases where diastereoselective complexation is possible, diastereoselectivities tend to be moderate (typically 3:1–4:1). The rationale for the origin of this diastereoselectivity has been proposed to derive from a preferential complexation of a Fe(CO)$_4$ fragment to the alkene *anti* to the epoxide.[217] Since the initial vinyl epoxide is conformationally flexible, four diastereomeric π-complexes would be produced as a consequence of *anti* or *syn* complexation to the *s-trans* or *s-cis* conformers. Isomerization of these initial π-complexes to alkoxy-π-allyl species would then enable interception of an iron-bound carbonyl ligand by the alkoxide to afford diastereomeric lactone complexes. Fortunately, equilibria between the two possible *trans* π-allyl complexes and their more stable *cis* π-allyl analogs simplifies the outcome significantly. Thus, for *trans* vinyl epoxides, the major diastereomer typically is the one designated as *endo cis* (the C-1 substituent points toward the iron atom); the minor diastereomer corresponds to the *exo cis* isomer (the C-1 substituent points away from the iron atom) (Scheme 51). For *cis* vinyl epoxides, this outcome is reversed – the *exo cis* isomer is the major product.



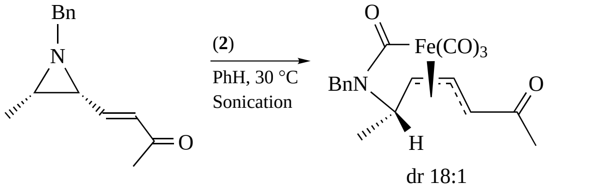
(**157**)

The corresponding ferrilactams (**156**), which have also been the subject of much attention, are available by the nucleophilic substitution of (**155**) by amines in the presence of a Lewis acid, usually ZnCl$_2$. The substitution occurs with allylic transposition,that is, attack at C-3 of (**155**). In selected cases, compounds of the type (**156**) have been prepared by oxidative addition of vinylaziridines or *cis*-4-amino-l-butenols with (**2**). A bridged ferrilactam bonded through C-2 of the allyl (**157**) unit has been reported recently and was prepared by way of oxidative addition of a cyclic allylic



Scheme 51

carbamate; corresponding bridged lactone complexes are also known.[220] Finally, an enantiopure *exo*-π-allyltricarbonyliron lactam has recently been prepared from the corresponding *cis* vinyl aziridine; the complex diastereomer ratio was 18:1 (equation 32).[221]



(32)

Other reports of (η^3-allyl)Fe(CO)$_3$R complexes are much more scattered and much less systematic. At least three general types of reactions have been observed in more than one case. First, the reaction of (diene)Fe(CO)$_3$ complexes with electrophilic alkenes gives allyliron complexes in two different ways. If the diene in question is acylic, electrophilic attack at C-1 of the diene gives compounds of type (**158**) (equation 33). In the case of substituted η^4-cycloheptatriene–or azepine–Fe(CO)$_3$ complexes, reaction with TCNE (or less often 4-phenyltriazoline-3,5-dione) gives kinetic [3 + 2] cycloaddition reactions, affording complexes of the type (**159**) (equation 34). These complexes interconvert with other, isomeric σ,π-adducts of this type, as well as (η^4-diene)Fe(CO)$_3$ complexes, by what Goldschmidt has coined [2,2]-, [3,3]-, or [4,4]-sigmahaptotropic rearrangements.[222] Both the cycloaddition and the rearrangements are considered to be concerted, nonsynchronous reactions. In a related transformation, η^4-vinylketene iron tricarbonyl complexes react with alkynes to afford (**160**), a vinylic analog of (**158**) (equation 35). Enantiomerically pure vinylketene complexes undergo this reaction without loss of planar chirality.[223] Second, vinylcyclopropanes undergo, in some cases, oxidative addition with ring opening with iron carbonyls to give (η^3-allyl)(η^1-alkyl)Fe(CO)$_3$ complexes.[107] Although only a minor product in the case of vinylcyclopropane itself, other cases, such as in semibullvalenes, give this reaction in consequential yields of (**161**) (equation 36). (η^3-Allyl)(η^1-alkyl)Fe(CO)$_3$ complexes and/or the corresponding (η^1-Allyl)(η^1-alkyl)Fe(CO)$_3$ complexes are likely intermediates in the thermal conversion of vinylcyclopropanes to η^4-diene Fe(CO)$_3$ complexes using (**1**), or of enantiomerically pure

vinylcyclopropanes into alkyl-substituted cyclohexenones of high optical purity.[224,225] Finally, attack of soft nucleophiles (Nu^-) on (η^5-pentadienyl)$Fe(CO)_3^+$ cations can occur at C-2 of the pentadienyl unit to afford (**162**) (equation 37) (Section 7.1.2).[226]

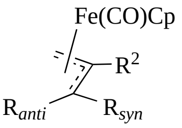
(**162**)

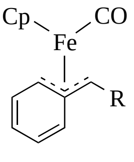
5.1.4 (η^3-Allyl)FeCp(CO) Complexes

Each of (η^1-allyl)Fp, (η^1-pentadienyl)Fp, and (η^1-cyclopentadienyl)Fp complexes undergo photolytic loss of CO to afford their respective Cp(CO)Fe(η^3) complexes.[26,27,227] In both the cases of allyl and acyclic pentadienyl complexes, the η^3-complexes are stable compounds, isolated as a mixture of *exo* and *endo* complexes, with the *exo* complex being more thermodynamically stable. In the pentadienyl case a significant amount of the (η^5-pentadienyl)FeCp complex is also isolated. In the case of (η^1-cyclopentadienyl)Fp complexes the η^3-complexes are observable (again as an *exo*/*endo* mixture) only at 77 K, by IR spectroscopy. At room temperature, only the (η^5-cyclopentadienyl)FeCp is realized.[228]

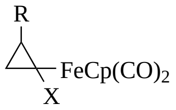
Although less common than the related (η^1-allyl)Fp complexes (Section 3.2), (η^3-allyl)FeCp(CO) complexes (**163**) are often encountered. The most common method for preparation of (**163**) involves photolytic ejection of a CO ligand from (**9**). On occasion, CO loss also occurs thermally. This transformation is stereospecific: *trans* (**14**) and *cis* (**14**) afford *syn* and *anti* (**163**), respectively. This approach is successful for a wide range of cases, including alkylidenyl, vinyl, and carboxyl substituents.[26,227,229,230] In the case of (η^1-benzyl)Fp complexes, low-temperature photolysis gives the η^3-benzyl complexes (**164**), which decompose at 25 °C over a period of 1–2 h.[231]



(**163**)



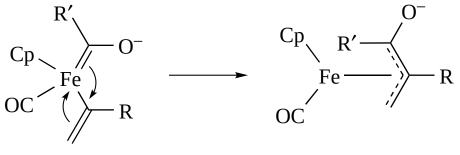
(**164**)



(**165**)
X = OMe, OEt, SPh, Ph
R = H, Me, F

Other syntheses of compounds of the type (**163**) are more specialized. Photolysis of (cyclopropane)Fp complexes (**165**) in several cases ultimately gives cyclopropane ring opening to yield stereoisomeric mixtures of (**163**; R^2 = X) when (**165**) possesses β-substituents (the ring opening is not regioselective for R = H in **165**).[232] Nucleophilic attack of alkoxide ion ($R'O^-$) upon (η^2-allene)Fp^+ cations occurs often[27] but not always with CO insertion to give C-2 substituted complexes (**163**; R = CO_2R', OR′).[233]

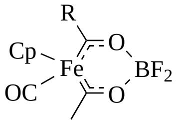
Finally, the coupling reaction of vinyl and alkylidene (*see Alkylidene*) ligands in complexes of the type (**166**) results in the formation of (η^3-allyl)FeCp(CO) complexes (equation 38). The vinyl substituent in these reactions is most often an enolate, whereas the alkylidene unit is formally of the Fischer carbene type.[234] The ultimate product depends upon the starting material and additional reagents. In the case of (ferra-β-diketonato)difluoroboron complexes (**167**), the resulting anion is isolated as tetramethylammonium salt (**168**). In the case of Fp(acyl) complexes as starting materials, benzoylation of the resultant anions gives complexes (**163**; R_{syn} = OBz, R^2 = OBz, OMe, Me).



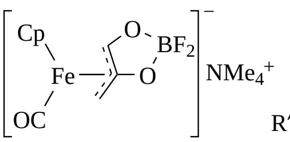
(38)

(**166**) R = O−, Me, OMe

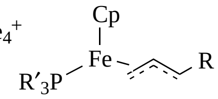
The corresponding phosphine/phosphite complexes (**169**) may be made, in at least selected cases, from (**163**) by photolysis in the presence of the phosphine or phosphite in



(**167**)



(**168**)



(**169**)

question (R_{syn} = CO_2Me).[230] In the case of cyclopropane ring-opening reactions of (**165**), the L = PPh_3 complexes undergo an analogous reaction under thermal conditions to afford (**169**).

5.2 Properties

5.2.1 *(η^3-Allyl)FeL$_4$ Complexes*

In (η^3-allyl)Fe(CO)$_3$X complexes (**135**), the molecules are oriented in what is normally considered an octahedral assembly of ligands around iron (allyl being bidentate) with a *fac* arrangement of the carbonyls. The allyl unit may be oriented in an *endo* or *exo* manner. Spectroscopic studies show that the two isomers are in equilibrium, although the coalescence temperature was above the decomposition temperature of the sample. Furthermore, the *endo* isomer predominates, although the *endo*/*exo* isomer ratios may vary from very large (minor isomer not observable) to 1.3:1.[235]

In the crystallographic structure of compounds of type (**135**), the *endo* isomer is the one observed. In the allyl unit the central carbon is normally found to be closer to Fe than the terminal carbon atoms; for example, the Fe–C bond distances are 2.058 and 2.126 Å, respectively, in (η^3-allyl)Fe(CO)$_3$Br.[236] This trend may be overridden by other effects.[237]

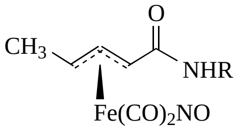
In the case of [(η^3-allyl)Fe(CO)$_4$]$^+$ cations (**138**), there is no possibility for *endo*/*exo* isomerism. Crystal structures of this type of complex have been reported, and are similar to those of (**135**). Noteworthy in the character of these complexes is their geometric stability: the *syn* and *anti* isomers do not interconvert unless heated to 60–70 °C for extended periods of time.[186]

The NMR spectroscopy of (η^3-allyl)iron complexes reveals a consistency across the various types of complexes. The relative shielding of the protons on the allyl unit is invariably $H_{anti} > H_{syn} > H_2$ (see Table 1). The coupling constants are also fairly consistent and extremely useful in isomer determination. The ^{13}C NMR spectra display a similar trend, with resonances of $C_{1,3}$ further upfield than that of C_2. Substitution on any of the atoms of the allyl unit shift both the ^{13}C resonances of the substituted atoms and the resonances for any remaining protons on that atom significantly downfield; the changes in the other ^{13}C and ^{1}H resonances are far less significant. For complexes of the type (**135**), the ^{1}H NMR spectroscopy is complicated in some cases by the presence of both *endo* and *exo* isomers, although in a large number of cases the *exo* isomer is so minor as to be barely observable. For those complexes with significant percentages of *exo*, apparent, H_{anti} and H_{syn} protons resonate upfield and H_2 protons resonate downfield relative to the *endo* isomer.[235]

The most noticeable difference between NMR spectra of (**135**) and (**138**) is revealed in the ^{57}Fe NMR.[238] In these spectra the iron allyl cations (**138**) resonate at much higher field (800–1000 ppm) than the halides (**135**) (1235–1700 ppm).

5.2.2 *(η^3-Allyl)FeL$_3$ Complexes*

A report of the X-ray crystallographic studies of enantiopure (η^3-allyl)Fe(CO)$_2$(NO) complex (**170**) has appeared, though little detail was provided.[196] The same report described the CD spectrum of this complex in more detail; the negative band at *ca.* 350 nm and the positive band at *ca.* 450 nm can be used to assign the configuration of the complex. Diastereomeric complexes exhibit the opposite Cotton effect. The crystal structures of corresponding monophosphine complexes (**145**) have been determined.[198,239] It is possible to consider these complexes as either trigonal bipyramidal (bidentate allyl) or tetrahedral (*see Tetrahedral*) (monodentate allyl), with the central carbon of the allyl closer to the iron atom (2.084 Å) than the terminal carbon atoms (2.117 and 2.142 Å). These complexes are chiral at the iron atom, and it has proved possible to separate the diastereomeric complexes formed by enantiomerically pure aminophosphines.



R = (*S*)-CH(CH$_3$)Ph

(**137**)	2.12	2.96	5.70	~12	~6	–	–	–
(**155**) *exo*	0.47	2.72	4.33	11	7	2.5	–	–
(η^3-allyl)Fe(CO)$_3$Me	2.18	3.04	3.92	12.2	7.5	2	–	–

It is possible to prepare the *anti* and *syn* isomers of (**143**) stereospecifically from the (Z)- and (E)-mesylates, respectively, and under room temperature conditions they do not interconvert. Replacement of the CO ligand with phosphine (PPh_3, 50 °C) gives only *syn*-(**145**) from either isomer of (**143**); this constitutes evidence for the possible intermediacy of an η^1-allyl in the substitution.[198]

The formally 16-electron (η^3-allyl)$FeL_3{}^+$ complexes (**150**) have been studied crystallographically for the (η^3-cyclooctenyl)$Fe(P(OMe)_3)_3{}^+$ complex and by low-temperature spectroscopy for the L = $P(OMe)_3$ and L = CO complexes.[207,208] Prominent among the structural features of these compounds is an agostic C–H interaction with iron (a 3-center, 2-electron bond). The crystal structure possesses a long C–H bond (1.164 Å) and a Fe–H contact of 1.874 Å. Spectroscopically, both the ^{13}C and ^{1}H NMR spectra are fairly unexceptional for the allyl portion, whereas the agostic H resonance (−14.59 ppm when frozen out at −86 °C in the parent complex) and C–H coupling constant (J_{CH} = 106 Hz for the cyclohexenyl complex) provide strong evidence for this type of bonding. Structures of this type have also been studied calculationally by both EHMO and Intermediate neglect of differential overlap (INDO) methods.[240]

In contrast to the tricarbonyl halide complexes, it is the *exo* conformation of (η^3-allyl)FeCp(CO) complexes (**163**) which is preferred, and at equilibrium only traces of the *endo* isomer can be observed. Existing crystal structures of members of this class are of the *exo* conformation.[26,27,227,229,230] Reasonable percentages of the *endo* conformer are realized upon low-temperature photolyses of their (η^1-allyl)Fp precursors, however, and the activation barrier to *endo*/*exo* conversion has been determined to be $\Delta G\ddagger = 100.8\,\mathrm{kJ\,mol^{-1}}$ for the 2-methallyl complex.[227] In addition, the *anti* isomers, which can be prepared stereospecifically from the (η^1-allyl)Fp complexes, isomerize to the *syn* isomers with brief heating. The ^{57}Fe NMR spectra are known for several of the complexes where CO has been replaced by a phosphine or phosphite (**145**); the chemical shift is highly dependent on the nature of the phosphorus ligand.[241]

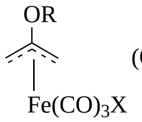
In contrast to almost all other iron allyls, the ferrilactone (**155**) and ferrilactam (**156**) allyliron complexes are more stable in their *anti* configuration. Their structures can be considered to be a distorted octahedron with *fac* arrangement of CO ligands. In other respects, the structure is typical of other η^3-allyls, and the NMR spectroscopy is characteristic of an *anti* monosubstituted iron allyl in terms of both chemical shifts and coupling constants.[218,242]

5.3 Reactions

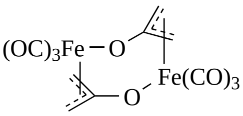
5.3.1 (η^3-Allyl)FeL_4 Complexes

Reactions of (η^3-allyl)$Fe(CO)_3X$ complexes (**135**) have been restricted to silver salt-induced halide replacement, CO replacement by phosphines, or conversion to allyl cations (**138**) (Section 5.1.1). There exists a report of conversion of (**135**; X = Cl) to η^1-allyliron complexes by reaction with thioamide ion; the transformation includes CO insertion into the Fe–N bond.[243]

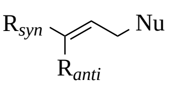
A noteworthy work on complexes of this type has been on the oxyallyl complexes (**171**) and their related dimers (**172**).[237,244] Despite the fact that only electrophilic substitution is observed in the reactions of these complexes and their derived (oxyallyl)$Fe(CO)_4$ cations, these compounds, or structurally very similar ones, have been proposed as intermediates in iron carbonyl mediated [4 + 3] cycloaddition reactions of α,α'-dibromoketones and dienes.[245]



(**171**)
R = H, SiMe3
X = Br, Cl

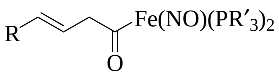


(**172**)

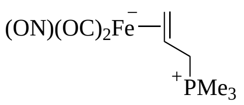


(**173**)

(η^3-Allyl)$Fe(CO)_4{}^+$ cations (**138**) are considerably more electrophilic than (**135**), and are more useful for C–C bond-forming reactions with nucleophiles as a result. Compounds of type (**138**) have been shown to react at the terminal carbon atoms with amines, phosphines, highly stabilized carbanions, electron-rich arenes, allylmetal reagents (silanes, stannanes, (**12**)) and silyl enol ethers, silyl ketene acetals, and ester dienolates. The product iron alkene complexes are often quite unstable, and are not isolated; decomplexation to the alkenes (**173**) is either spontaneous or induced by oxidation. The reactions of (**138**) with organometallics has only seen sporadic attention; organocadmium reagents give fair yields of alkylation, whereas organocopper compounds, RCu(CN)ZnI, give mixtures of alkylation and acylation. Allylic deprotonation to give (η^4-diene)$Fe(CO)_3$ complexes is sometimes a competing reaction. Regiochemistry of attack is predominantly at the least-substituted side of the allyl, and remote to electron-withdrawing or trialkylsilyl groups, whereas stereospecific *anti*-(**138**) to *cis*-alkene and *syn*-(**138**) to *trans*-alkene transformations are observed.[186,246] More recently it has been reported that this nucleophilic attack proceeds with high selectivity for the face *anti* to iron, thus allowing the preparation of highly enantiomerically enriched products from enantiomerically pure allyliron complexes.[113] This reactivity has been utilized with enantiopure complexes of type (**140**), where a number of soft nucleophiles add stereoselectively *anti* to the iron fragment and exclusively γ to the electron-withdrawing group to produce η^2-iron complexes that were subsequently demetalated with ceric ammonium nitrate. This methodology was featured in a number of natural product syntheses.[114]



(**174**)

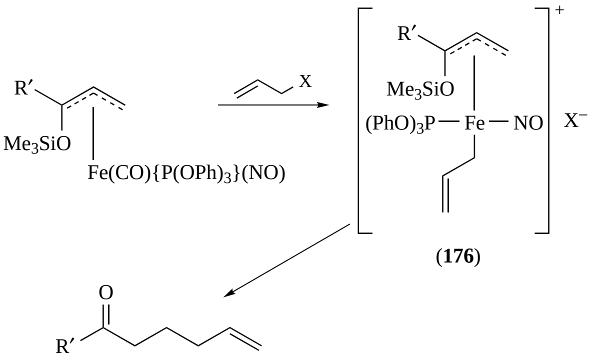


(**175**)

$(PR'_3)_2 = [P(OMe)_3]_2$, $[P(OEt)_3]_2$, dppe

5.3.2 (η^3-Allyl)FeL_3 Complexes

Complexes of type (**143**) behave much like (η^3-allyl)$Fe(CO)_4^+$ cations of type (**140**) with respect to the addition of soft nucleophiles (amines, malonate anions,and so on), though regioselectivity appears to be more substrate-dependent.[247] Although the conversion of (η^3-allyl)$Fe(CO)_2(NO)$ complexes (**143**) to their monocarbonyl/monosphosphite analogs (**145**) has been described, there is in some cases a side product, acyl-iron complexes (**174**), which arise from CO insertion into the least-substituted terminus of the allyl ligand. This is also the dominant mode of reaction with dppe as added ligand.[175] If more basic trialkylphosphines are reacted with (**143**), nucleophilic attack at the allyl ligand occurs to afford (**175**).[248] Terminal allyl carbon attack has also been observed with highly stabilized carbanions, such as malonate, or with enamines to ultimately give substitution products of the type (**173**).[194,249] Like cations (**138**), stereospecific production of alkene products is possible, and the attack is predominantly at the less-substituted allyl terminus on the allyl face opposite that of the iron residue. Curiously, selected substituted compounds of type (**143**) also undergo reaction with allylic halide electrophiles, the yields of which are enhanced by added $P(OPh)_3$. This transformation is thought to occur by oxidative addition of the allyl halide to the generated (**145**), affording intermediate (**176**), which undergoes subsequent reductive elimination to give (**177**) (equation 39).



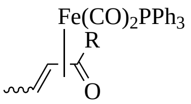
(**176**)

(**177**)

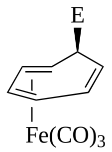
(39)

The cationic dinitrosyl complexes (**146**) are apparently much more electrophilic than (**143**). Studies of the reactivity of (**146**) have been focused on attack of coordinated organic ligands of other transition metal complexes, such as the cyclooctatetraene ligand in L_3M(cot) complexes (M = Fe, Ru) and Cp′Co(cot) complexes (Cp′ = Cp, Cp*), the cyclopentadienyl ligand of CpRh(cot) complexes, and the cyanide ligand of $(dppm)_2Mn(CO)(CN)$ complexes.[250] Subsequent ligand rearrangements are often observed in these transformations.

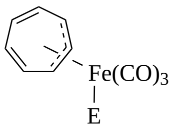
As expected, allyltricarbonyliron anions (**147**) possess nucleophilic reactivity. Reaction of these species with alkyl halides (RX) gives initial attack at iron, which is followed by CO insertion and acyl–allyl coupling. Subsequent reorganization of the ligand following PPh_3 addition gives an (enone)$Fe(CO)_2(PPh_3)$ complex (**178**). The use of different trapping ligands (PPh_3 or CH_3CN) gives different regioselectivities and stereoselectivities.[204,251] Phosphorus-based electrophiles appear to react at iron, without subsequent rearrangement.[252] Work on the (η^3-heptatrienyl)$Fe(CO)_3^-$ anions (**148**) reveals the following reaction dichotomy: C-, Si-, and Ge-based electrophiles give ultimate reaction at allyl carbon (**179**), whereas Sn- and Pb-based electrophiles and transition metal carbonyl halides give ultimate reaction at Fe to give cyclic bimetallic species (**180**).[253]



(**178**)

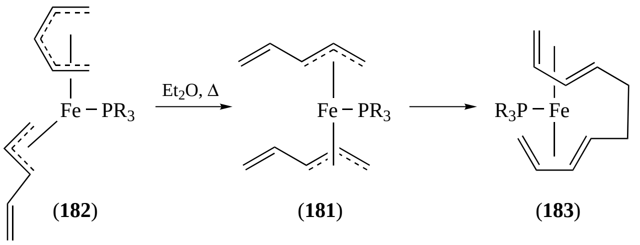


(**179**)



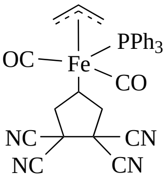
(**180**)

The facile allyl–allyl coupling of parent bis(allyl) complexes (**153a**) has already been mentioned. Related reactions have been observed in the (η^3-pentadienyl)$_2Fe(PR_3)$ complexes (**181**). Heating (η^5-pentadienyl)(η^3-pentadienyl)$Fe(PR_3)$ complexes (**182**) in the presence of additional phosphine results in transient formation of (**181**), which undergoes interligand coupling to give bis(η^4-diene) complex (**183**) (equation 40).[210] In these type of complexes, removal of the allyl ligand by oxidation or protonation is facile. In one case, cycloaddition of (**153a**) with TCNE has been reported to give, after PPh_3 addition, (**184**).[254]



(**182**) (**181**) (**183**)

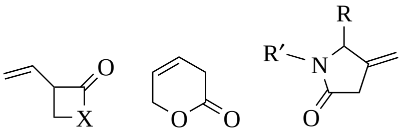
(40)



(**184**)

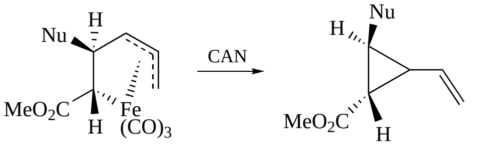
5.3.3 *(η^3-Allyl)FeL$_3$R Complexes*

As π-allyliron tricarbonyl lactone complexes (**155**) have been the subject of extensive study by Ley, their modes of reactivity are well-established.[215–217] The reaction with nucleophiles, such as amines, to give the corresponding ferrilactams (**156**) has previously been discussed (Section 5.1.3). On the other hand, oxidation of (**155**), normally by Ceric ammonium nitrate (CAN), affords mixtures of α-vinyl-β-lactones (**185**, major) and β, γ-unsaturated-δ-lactones (**186**, minor). However, the δ-lactones are often obtained in much higher yield by subjecting complexes (**155**) to CO under pressure. CAN oxidation of the ferrilactams (**156**) and (**157**) give predominantly α-vinyl-β-lactams (**187**) and β-methylene-γ-lactams (**188**), respectively.[215–218] The oxygen- or nitrogen-bearing carbon atoms in (**155–157**) give (**185–187**) with retention of configuration at the N- or O-bearing carbon atom, so that enantiomerically pure or enriched complexes do not lose their optical activity upon reductive elimination. This methodology has been used extensively in the synthesis of many naturally occurring molecules of biological importance (*see* ***Organic Synthesis using Transition Metal Complexes Containing π-Bonded Ligands***). Another synthetically useful transformation of complexes of type (**155**) involves basic hydrolysis with Ba(OH)$_2$; η^4-iron diene complexes are formed with concomitant decarboxylation of the lactone complex. No loss of enantiomeric purity is observed when enantiopure lactone complexes are employed. Finally, lactone complexes (**155**) can be used as a stereodirecting group in a manner similar to that of η^4-iron diene complexes (Section 6.3). A ketone adjacent to the π-allyliron tricarbonyl lactone complex is subject to nucleophilic addition *anti* to the metal fragment; allyl stannanes (in the presence of BF$_3$Et$_2$O) and organoaluminum reagents have been used to prepare diastereomerically pure alcohols. Decomplexation and simultaneous reduction of the lactone moiety of the complex to afford an alcohol may be effected with sodium triacetoxyborohydride.[255]



(**185**) X = O (**186**) (**188**)
(**187**) X = NR

Complexes (**160**) (see equation 35) undergo conversion to phenols upon thermolysis.[223] Alternatively, treatment with AlCl$_3$ under a CO atmosphere gives an η^4-iron cyclohexadienone complex; thermolysis or treatment with CuCl$_2$ affords a phenol as well. Complexes (**162**), derived from nucleophilic addition to (η^5-pentadienyl)Fe(CO)$_3$$^+$ cations (see equation 37), can be converted to vinyl cyclopropanes by using CAN (equation 41).[256]



(**162**) (41)

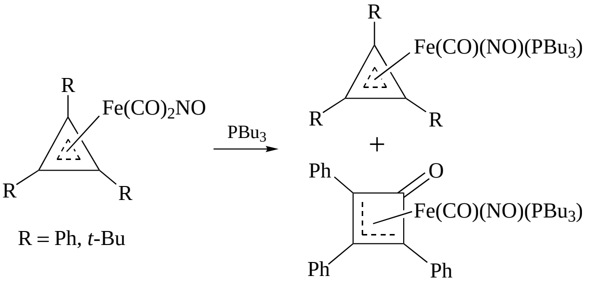
5.3.4 *(η^3-Allyl)FeCp(CO) Complexes*

Reactivity studies of compounds of this class have received little attention. Aryl-substituted complexes (**161**) (R_{syn} = Ar) are, under heat and photolysis, sources of radical coupling reactions with acrylonitrile to give predominantly (**189**). As the conditions for reaction are also sufficient for conversion of the corresponding (η^1-allyl)Fp complexes (**12**) to (**161**), compounds of type (**12**) may also be used as reagents.[257]

(**189**)

5.4 (η^3-Cyclopropenyl)FeL$_3$Complexes

η^3-Cyclopropenyl iron complexes have been prepared by treatment of cyclopropenyl salts [C$_3$R$_3$][BF$_4$] with [PPN][Fe(CO)$_3$NO], and properties such as the kinetics of their CO substitution reactions have been studied.[258] While treatment of the tri-*t*-butyl complex with phosphine ligand led to a single product, treatment of the triphenyl analog led to a mixture of the η^3-cyclopropenyl and ring-expanded η^3-cyclobutenone complexes. Evidence was presented for a mechanism involving ring-slippage (*see Slip Processes in Ligands*) to the η^1-cyclopropenyl species and subsequent CO insertion (equation 42).



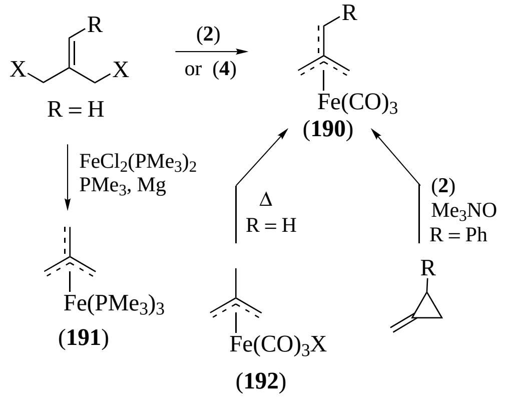
(42)

6 η^4-LIGAND COMPLEXES

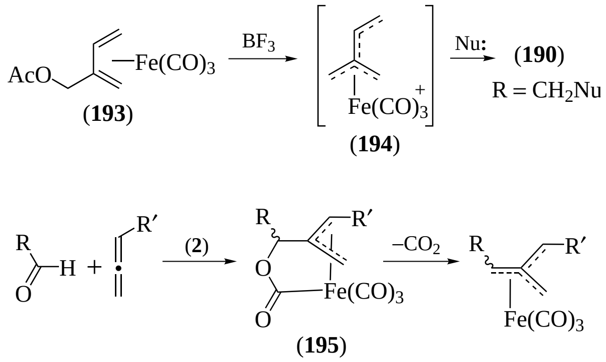
6.1 Trimethylenemethane Complexes

6.1.1 *Preparation and Structure*[259]

Trimethylenemethane (TMM) is a highly reactive species that has only been detected by Electron spin resonance (ESR)



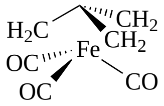
Scheme 52



Scheme 53

(*see Electron Paramagnetic Resonance*) spectroscopy at low temperature. It was suggested that this unstable organic species could be stabilized by complexation to a transition metal.[260] Indeed, stable tricarbonyliron complexes of TMM (**190**) have been prepared by the reaction of 2-chloromethyl-3-chloropropene with (**2**) or with (**4**) (Scheme 52).[261] Alkyl, aryl, and methoxycarbonyl substituted derivatives of (**190**) may be prepared in a similar fashion. Reaction of 2-chloromethyl-3-chloropropene and $FeCl_2(PR_3)_2$ with Mg in the presence of additional phosphine gives an electron-rich triphosphine–iron complex (**191**).[262] Thermal dehydrohalogenation of (η^3-2-methallyl)$Fe(CO)_3X$ (**192**; X = Cl, Br) generates the parent TMM complex (**190**), albeit in poor yield.[261] If 1-alkyl-substituted derivatives of (**192**) are used, mixtures of TMM and η^4-diene complexes are generated. The reaction of 2-phenyl-1-methylenecyclopropane with (**2**) affords (**90**) (equation 15).[145] The reaction of (2-acetoxymethyl-1,3-butadiene)$Fe(CO)_3$ (**193**) with weak nucleophiles in the presence of a Lewis acid has been reported to afford substituted TMM complexes (Scheme 53).[263] This reaction is believed to proceed via the intermediacy of a ‘cross-conjugated’ pentadienyl cation (**194**). The photochemical reaction of aldehydes with allenes in the presence of (**2**) gave π-allyl–σ-acyl complexes (**195**), which undergo decarboxylation to give the substituted TMM complexes, again in poor yield.[264]

The electron and X-ray diffraction structures of a number of TMM complexes have been determined.[259,265,266] The TMM ligand adopts an ‘umbrella-like’ shape with the central carbon of the TMM ligand displaced out of the plane created by the three terminal carbons (cf. **196**). Even with this ligand puckering, the central atom remains the closest to the metal ($Fe–C_{central}$ = 1.93 Å, $Fe–C_{terminal}$ = 2.12 Å). The three carbonyl ligands are staggered with respect to the TMM ligand. Substituents on the TMM ligand are tilted away from the metal. Because of its C_{3v} symmetry, the parent (TMM)$Fe(CO)_3$ complex (**190**; R = H) gives only one signal in the ^{1}H NMR spectrum (2.00 ppm, CS_2) and three signals in the ^{13}C NMR spectrum (211.9 ppm, CO; 106.1 ppm, $C_{central}$; 54.9 ppm, $C_{terminal}$; CS_2). For substituted (TMM)$Fe(CO)_3$ complexes the three carbonyl ligands give rise to three distinct signals by ^{13}C NMR spectroscopy, thus indicating restricted rotation about the Fe–TMM bond. The barrier for this rotation is 71–84 kJ mol^{-1}.[267] Extended Hückel calculations, using the solid-state geometry, predict a barrier of 98.6 kJ mol^{-1} for rotation in the parent TMM complex.[268] This barrier to rotation is due to a loss of overlap of the metal fragment orbitals with the ligand orbitals. The protons of a monosubstituted (TMM)$Fe(CO)_3$ complex appear as distinct signals by ^{1}H NMR spectroscopy. Geminal coupling is not observed; however, protons aligned with a ‘W’ relationship exhibit couplings on the order of 2–4 Hz.[261]

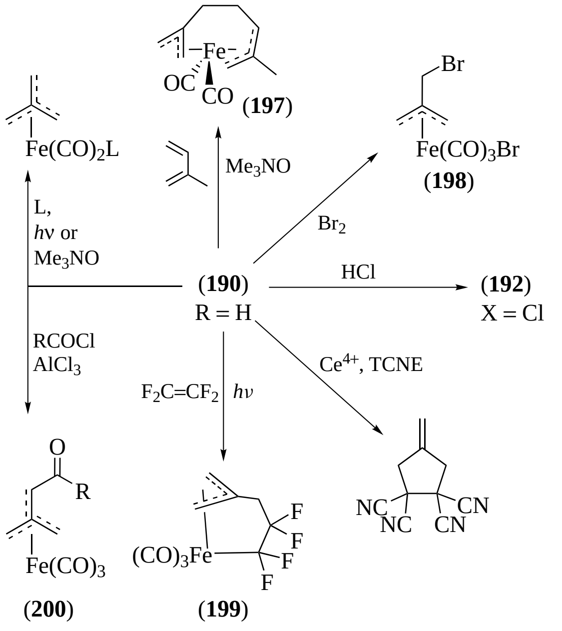


(**196**)

The electronic properties of aryl-substituted analogs of (**190**; R = Ph, *m*-FPh, *p*-FPh, *m*-COOHPh, *p*-COOHPh) have been studied, and Hammett substituent constants were obtained.[269] It was concluded that the TMMFe(CO)$_3$ group behaves much like a phenyl group – weakly electron-donating via resonance and weakly electron-withdrawing via induction.

6.1.2 *Reactions*

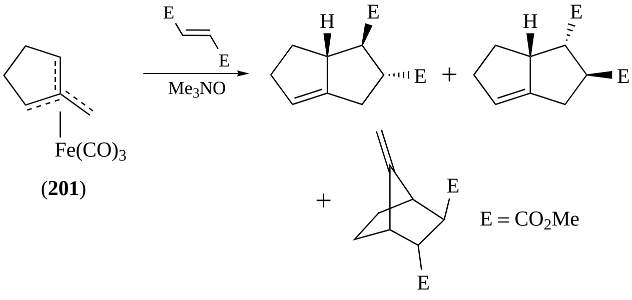
The parent TMM complex (**190**; R = H) undergoes photochemical ligand substitution with trifluorophosphine or trimethylamine *N*-oxide assisted substitution with tertiary phosphines or *t*-butyl isocyanide (Scheme 54).[266] Trimethylamine *N*-oxide assisted substitution using isoprene as the incoming ligand results in C–C bond formation to afford the bis-π-allyl complex (**197**).[270] An intramolecular version of this reaction is also known.[271] The parent complex (**190**; R = H) reacts with electrophiles. Addition of HCl or Br_2 gives the methallyl complexes (**192**) and (**198**), respectively.[261] Tetrafluoroethylene adds across the Fe–C bond to afford (**199**) under photochemical conditions.[272] Complex (**190**) undergoes Friedel–Crafts-type acylation with



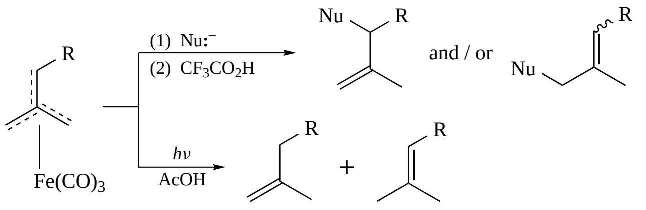
Scheme 54

acetyl or benzoyl chloride to give ketones (**200**) in poor yields (<25%).[261] (Methyltrimethylenemethane)$Fe(CO)_3$ (**190**; R = Me) isomerizes to (η^4-isoprene)$Fe(CO)_3$ in 85% H_2SO_4.[263,272]

Decomplexation of the TMM ligand has been examined. Oxidation of (**190**) in the presence of tetracyanoethylene (Scheme 54) or (**201**) in the presence of diethyl fumarate (equation 43) affords [3 + 2] cycloaddition products in very poor yields (4–19%).[273] This reaction is believed to involve the initial formation of an iron-bound intermediate, which can competitively react with an electron-deficient alkene, or undergo loss of the iron metal to give a triplet (*see Triplet State*) diradical. Photochemical reduction of substituted TMM complexes in acetic acid affords the corresponding alkenes in good yields, but with poor regioselectivity.[274] Reaction of the parent and substituted TMM complexes (**190**; R = H, Me, Ph) with nucleophiles followed by acidic workup affords the corresponding alkenes in which a new C–C bond has been formed (equation 44).[275] This reaction probably occurs via formation of a (π-allyl)$Fe(CO)_3^-$ anion. In the case of alkyl- or aryllithium nucleophiles, products incorporating carbon monoxide are observed.

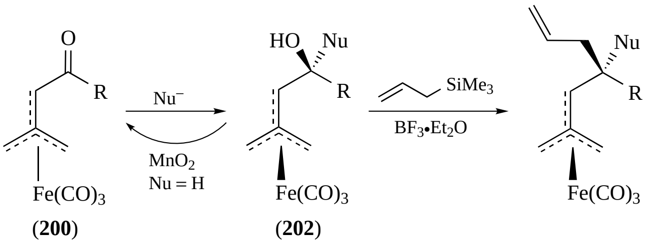


(43)

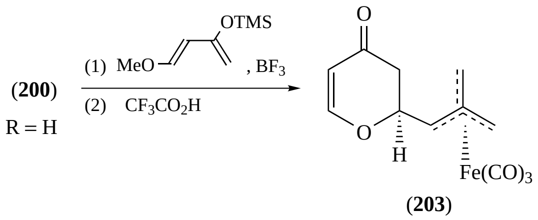


(44)

Reactions that modify the side chains of TMM complexes have been examined. Nucleophilic addition to a carbonyl adjacent to the TMM ligand occurs with high diastereoselectivity (equation 45).[261,274,276] Likewise, nucleophilic substitution of acetoxymethyl or hydroxymethyl TMM complexes (**202**) with weak carbon nucleophiles proceeds in a stereoselective fashion.[263,277] Similar to the reaction of (**193**), this substitution probably occurs via the intermediacy of a 'cross-conjugated' pentadienyl cation (**194**). Surprisingly, the terminal alkene of this product can be oxidatively cleaved to the aldehyde by ozonolysis without loss of the iron fragment.[271] A hydroxymethyl functionality adjacent to the TMM ligand may be oxidized to the aldehyde by use of MnO_2, without oxidation of the iron.[274] A formyl-TMM complex (**200**, R = H) undergoes hetero-Diels–Alder reaction with Danishefsky's diene to produce a dihydropyrone TMM complex (**203**) with a diastereoselectivity that is greater than the similar reaction with η^4-dienal iron complexes (>25:1 *vs.* <4:1).[278] Complex (**203**) was stable to a number of subsequent transformations (reduction, alkoxymercuration, dihydroxylation). The resolution of a chiral TMM ester complex (**200**, R = O-succinimide) using (*S*)-ethyl lactate or (*R*)-α-methylbenzylamine has also been reported.[279]



(45)

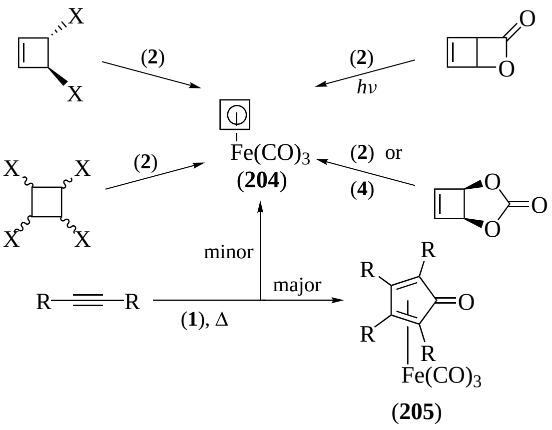


(46)

6.2 Cyclobutadiene Complexes

6.2.1 Preparation and Structure[280]

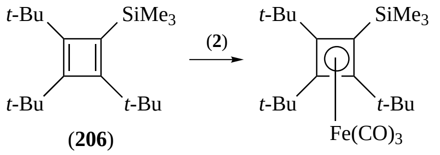
Cyclobutadiene, the simplest cyclic polyene, has long intrigued chemists; however, the π-electron molecule has



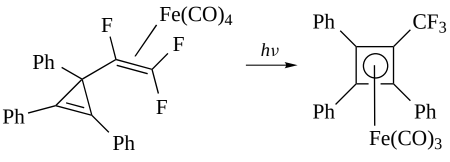
Scheme 55

only been isolated at low temperatures in noble gas matrices. Certain highly hindered derivatives of cyclobutadiene have been prepared and their crystal structures determined. Of these, tetra-*t*-butylcyclobutadiene is the only compound to exhibit a 'square', rather than rectangular, geometry.[281] Similar to trimethylenemethane, cyclobutadiene can be stabilized by complexation to a transition metal.[260]

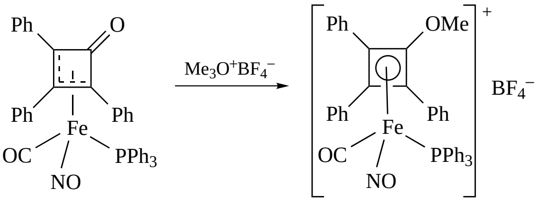
Tricarbonyl(cyclobutadiene)iron (**204**) and substituted derivatives may be prepared in good overall yields by the reaction of 3,4-dihalocyclobutenes or 1,2,3,4-tetrahalocyclobutanes with (**2**), or by the photolysis of photo-α-pyrone with (**1**) (Scheme 55).[282] The reaction of *cis*-3,4-carbonyldioxycyclobutenes with (**2**) or (**4**) generates (cyclobutadiene)Fe(CO)$_3$ complexes, and while this reaction is stereospecific it is not known if it occurs with inversion or retention of configuration.[283] Thermal reaction of alkynes with Fe(CO)$_5$ gives predominantly cyclopentadienone complexes (**205**), but small amounts of cyclobutadiene complexes can be isolated.[280] Thermal reaction of (**1**) with Ni, Pd, or Pt cyclobutadiene complexes results in π-ligand exchange to give the iron cyclobutadiene complexes in high yield.[61] In general, since cyclobutadiene is a highly reactive species, direct complexation of the ligand is not possible; however, a stable highly hindered cyclobutadiene (**206**) may be complexed to iron (equation 47).[284] The photochemical rearrangement of an (η^2-vinylcyclopropene)Fe(CO)$_4$ complex (**207**) has been reported to afford the novel trifluoromethyl substituted cyclobutadiene complex (**208**) (equation 48).[286] Methylation of the iron cyclobutenonyl complex (**209**) affords the cationic methoxycyclobutadiene complex (**210**) (equation 49).[287] Carbomethoxy-substituted complex (**211**) was prepared by pyrone photolysis (equation 50) and has served as the starting point for a number of synthetic applications (Section 6.2.2).



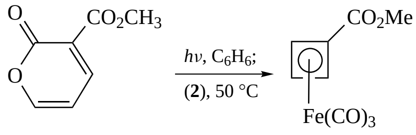
(**206**) (47)



(**207**) (**208**) (48)

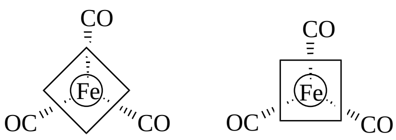


(**209**) (**210**) (49)



(**211**) (50)

The X-ray diffraction of several iron cyclobutadiene complexes have been determined.[288] In the majority of these structures, the cyclobutadiene ring is planar with the four C–C ring bonds of nearly equal length (ca. 1.45 Å) and the four carbons equidistant from the iron atom (ca. 2.05 Å). The orientation of the cyclobutadiene ring with respect to the three carbonyl ligands is variable. The parent (cyclobutadiene)Fe(CO)$_3$, at −45 °C, adopts conformation (**212**), whereas other substituted cyclobutadiene complexes adopt conformations between (**212**) and (**213**). On the basis of temperature-dependent proton spin−lattice relaxation times in the solid state, the barrier to rotation about the cyclobutadiene−Fe bond in (**204**) is 22.6 kJ mol^{-1}. Based on calculations, this barrier appears to depend primarily on intermolecular interactions in the crystal.[285] The protons of (**204**) appear as a singlet at 3.91 ppm (CDCl$_3$).[289] The presence of an electron-withdrawing substituent on the cyclobutadiene ligand causes a downfield shift, while the presence of an electron-donor substituent causes an upfield shift of both the α- and β-protons. The ring carbons of (**204**) appear at 63 ppm.[32]

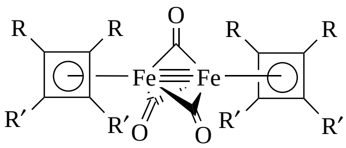


(**212**) (**213**)

(1,2-Disubstituted-cyclobutadiene)Fe(CO)$_3$ complexes with two different substituents are chiral, and the two enantiomers may be separated by standard resolution techniques.[290] The optically active cyclobutadiene complexes are stable to racemization at 120 °C for 48 h.

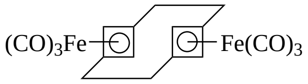
6.2.2 Reactions

Neutral (cyclobutadiene)iron complexes undergo thermal and photochemical ligand substitution with phosphines, with alkenes such as dimethyl fumarate and dimethyl maleate, and with the nitrosonium cation. Cationic nitrosyl complexes (e.g. **210**) undergo ligand substitution by treatment with phosphines. Photolysis of (tetraphenylcyclobutadiene)$Fe(CO)_3$ in THF at $-40\,°C$ is reported to give the novel bimetallic complex (**214**), which reacts with carbon monoxide (140 atm, 80 °C) to regenerate the starting material.[291] An X-ray diffraction analysis of (**214**; R = Ph, R′ = t-Bu) reveals a very short Fe–Fe distance of 2.117 Å.



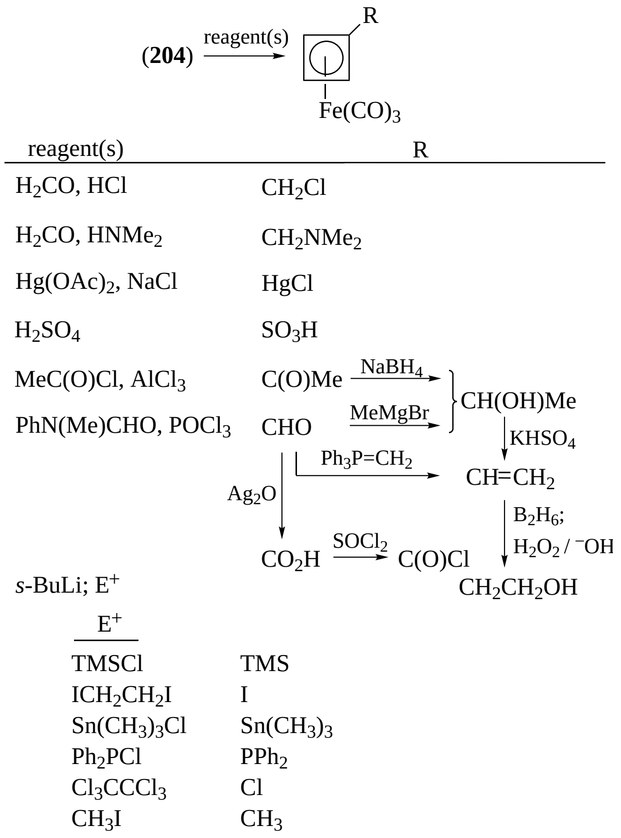
(**214**)

The organic chemistry of (cyclobutadiene)$Fe(CO)_3$ is much like that of ferrocene (Section 7.2). Protonation in HSO_3F/SO_2 generates a cationic species that exhibits a signal at -11.16 ppm, consistent with a hydride structure, but the proton is coupled to a ring carbon ($J = 91.2$ Hz). A bridging hydride (*see Bridging Ligand*) structure is favored. This protonation occurs on the *endo* face of the ligand.[292] Complex (**204**) behaves like an aromatic compound and will undergo electrophilic substitution with a wide variety of reagents; deprotonation and electrophilic trapping of the resulting anion is also possible (Scheme 56).[293,294] Notably (**204**), unlike ferrocene, will undergo sulfonation with H_2SO_4. It is not clear whether electrophilic attack occurs on the *exo* or *endo* face of the cyclobutadiene ligand. Acylation of monoalkyl-substituted (cyclobutadiene)$Fe(CO)_3$ complexes generates the 1,3-disubstituted (major) and 1,2-disubstituted (minor) derivatives. The side chains of substituted (cyclobutadiene)$Fe(CO)_3$ complexes may undergo a wide variety of organic transformations. Examples include the conversion of carboxylic acids to acyl halides and the hydroboration (*see Hydroboration*)/oxidation of alkenes. Chemistry of this type has been used to generate the novel cyclobutadiene-cyclophane (**215**).[295]



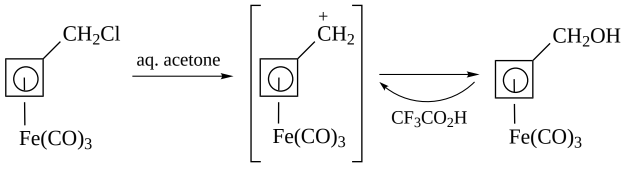
(**215**)

The solvolysis (*see Solvolysis*) of (chloromethylcyclobutadiene)$Fe(CO)_3$ (**216**) in 5% aqueous acetone proceeds at a rate 108 times faster than that of benzyl chloride.[296] The rapid rate of this S_N1 solvolysis is attributed to the



Scheme 56

stability of the α-carbocation (**217**), which can be generated and spectroscopically characterized by treatment of the alcohol (**218**) with CF_3CO_2H or HBF_4 (equation 51). A bis(cyclobutadienyliron tricarbonyl)phenylcarbonium ion has been crystallographically characterized; the data indicate that the cyclobutadiene ligand is planar and that iron is symmetrically bound to the ligand. The α-carbonium center is essentially planar with each cyclobutadiene ligand and is not bent out of the plane as is the case for the α-ferrocenyl carbocation (Section 7.2.3). The $pK_R{}^+$ value has been determined for (cyclobutadiene)$Fe(CO)_3\alpha$-carbocations; these cations are more stable than the corresponding benzyl carbocations, but less stable than the corresponding α-ferrocenyl carbocations.



(**216**) (**217**) (**218**)

(51)

The cyclobutadiene ligand may be liberated by oxidation of the complex with CAN, $Pb(OAc)_4$, or trimethylamine

N-oxide. In the absence of an alkene or acetylene, the cyclobutadiene ligand undergoes dimerization to afford a mixture of *syn*- and *anti*-tricyclo[4.2.0.0^{2,5}]-3,7-octadiene (**219**). In the presence of a dieneophile, cyclobutadiene undergoes Diels–Alder cycloaddition to afford the bicyclo[2.2.0]hexene product (equation 52). A variety of dieneophiles have been used in this reaction, and the products may be carried forward to a series of strained cage compounds.[280] Oxidation of optically active disubstituted (cyclobutadiene)Fe(CO)$_3$ complexes in the presence of a symmetrical alkene generates racemic products.[290] Thus, the chemical oxidation appears to generate ‘free’ cyclobutadiene. Additional evidence for the presence of the free ligand was provided by the ‘three-phase test’. Transfer of the ligand from a polymer-bound (cyclobutadiene)iron complex by oxidation in the presence of a separately polymer-bound dienophile can only be accounted for by the generation of the free ligand, since there is negligible contact between the functionalized sites of the two different polymeric supports.[297] Oxidation of the optically enriched complex (**220**) containing a pendant alkyne dieneophile produces the achiral phthalan (75%) and the optically enriched tricyclic ketone (**221**) (20%) (Scheme 57). The product (**221**) is probably formed via initial coordination of the dienophile to the oxidized complex, followed by alkene insertion, carbonyl insertion, and reductive elimination.[298]

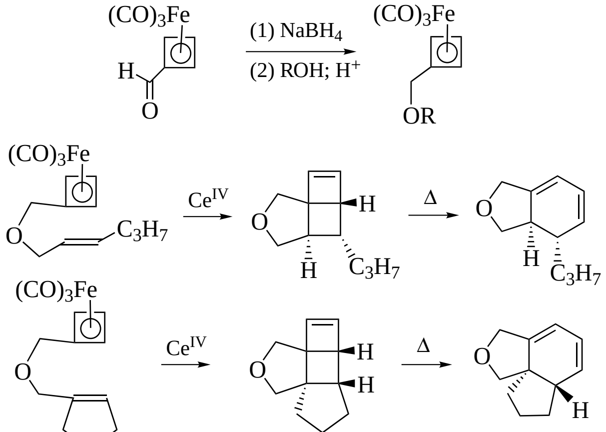
(**221**) 20%

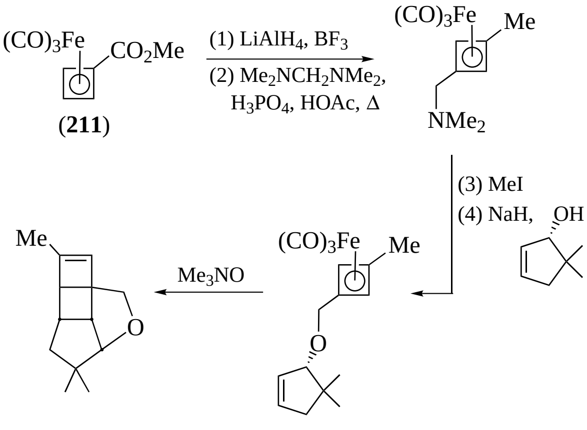
Scheme 57

Intramolecular cycloadditions using (cyclobutadiene)Fe(CO)$_3$ complexes with pendant alkenes have recently been exploited for use in synthetic methodology. The formyl-substituted (cyclobutadiene)Fe(CO)$_3$ complex can be reduced to the corresponding alcohol and then may be etherified by treatment with an allylic alcohol in the presence of an acid catalyst (Scheme 58).[299,300] The intramolecular cycloaddition strategy has been employed in the total synthesis of the natural product (+)-asteriscanolide beginning with carbomethoxy-substituted cyclobutadiene iron complex (**211**) (Scheme 59).[301] The use of a related example using a propargyl alcohol give a Dewar-benzene containing cycloadduct that isomerized to the aromatic benzene system.[298]

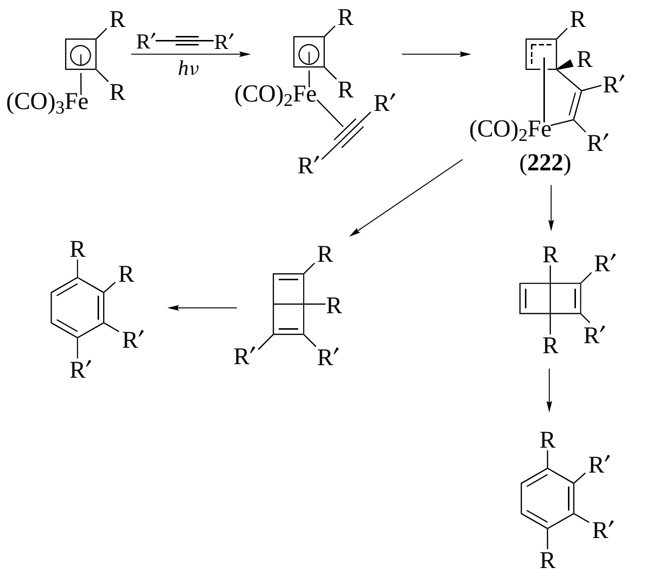
Photolysis of substituted (cyclobutadiene)Fe(CO)$_3$ complexes in the presence of alkynes affords substituted benzenes (Scheme 60). From the substituent patterns of the products, it is clear that this reaction cannot be accounted for by generation of the free ligand. The proposed mechanism involves initial loss of a carbon monoxide ligand and coordination of the alkyne. Insertion of the alkyne predominantly into the



Scheme 58



Scheme 59



Scheme 60

more substituted cyclobutadiene–iron bond will generate the bridged species (**222**), which undergoes reductive elimination to afford the Dewar-benzene intermediate. Secondary photolysis of this Dewar-benzene gives the observed aromatic product.[302]

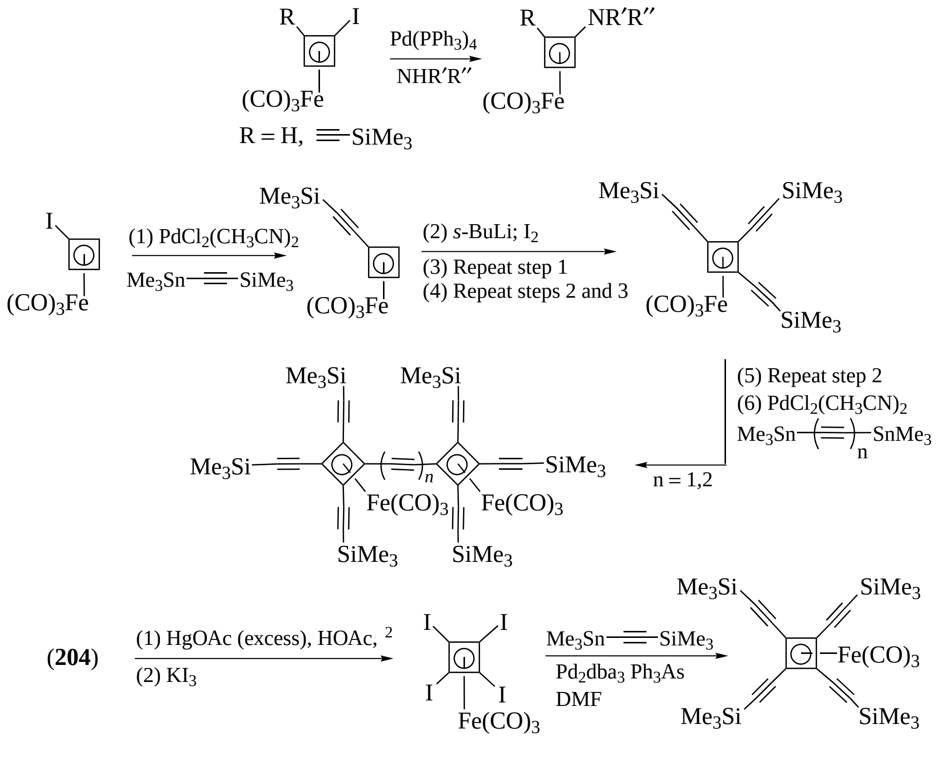
Finally, iodo-substituted (cyclobutadiene)$Fe(CO)_3$ complexes can undergo palladium-catalyzed animations as well as Stille reactions using alkynylstannanes (Scheme 61). An iterative process allowed the diiron 'dumbbell' complex to be prepared; alternatively, tetraethynyl complexes could be prepared directly from the tetraiodo(cyclobutadiene)$Fe(CO)_3$ complex.[303–305]

6.3 (Diene)Iron Complexes

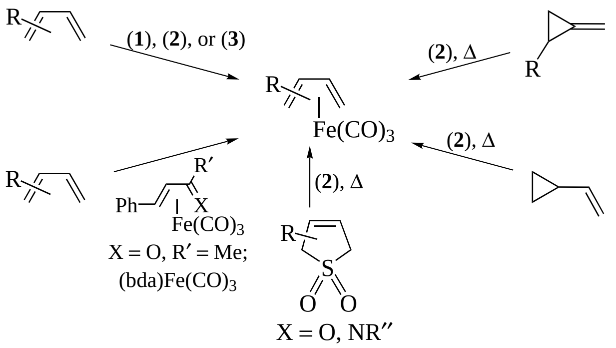
Investigations into the synthesis and reactivity of η^4-diene iron tricarbonyl complexes are among the most active areas of research in iron organometallic chemistry. A number of excellent reviews are available for the reader seeking greater detail than can be provided here.[306–313]

6.3.1 Acyclic (Diene)Iron Complexes

Acyclic tricarbonyl(diene)iron complexes may be prepared by reaction of a 1,3-diene with (**1**), (**2**), or (**3**) either thermally, photochemically, or under the influence of ultrasonic stirring (Scheme 62).[106] Ligand transfer species, such as (benzylideneacetone)$Fe(CO)_3$, (1-aza-1,3-diene)$Fe(CO)_3$, or bis(η^2-cyclooctene)$Fe(CO)_3$ are also useful for the complexation of dienes under mild reaction conditions.[117,219,314] The thermal reaction of unconjugated dienes with (**1**) generally results in double bond migration

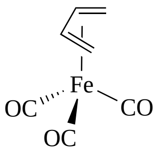


Scheme 61



Scheme 62

to afford the 1,3-diene complex, except in cases where this is geometrically impossible. Diene complexes can also be generated by the isomerization of strained organic rings, such as η^2-methylenecyclopropane and η^2-vinylcyclopropane complexes.[136,315] The preparation of 1,3-diene complexes by the thermal extrusion of SO_2 from 2,5-dihydrothiophene 1,1-dioxides or the reduction of 1,2-bis(bromomethyl)benzene with (**4**) is believed to proceed via the formation of the highly reactive free dienes.[316]

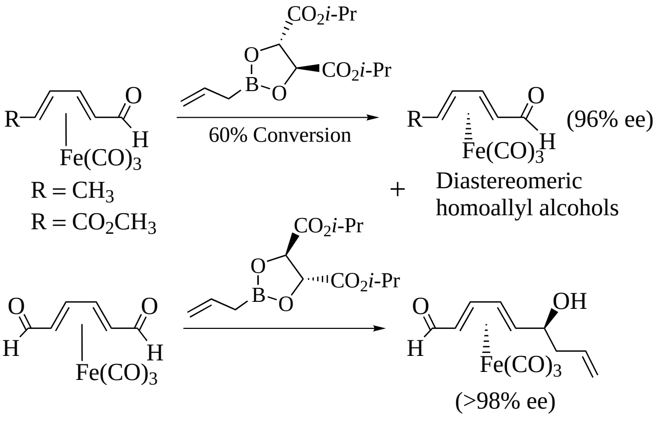


(**223**)

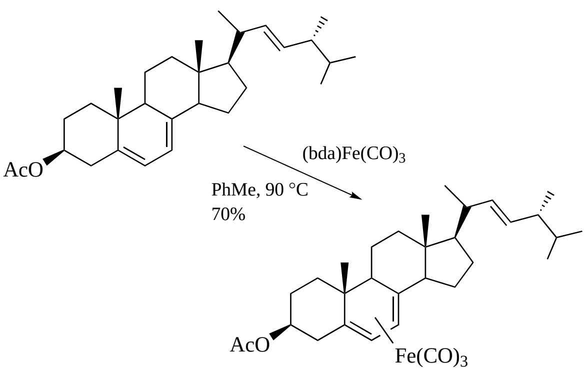
The structures of a wide variety of substituted (1,3-butadiene)$Fe(CO)_3$ complexes have been determined by single-crystal X-ray diffraction.[317] In the parent (1,3-butadiene)$Fe(CO)_3$ complex (**223**) the diene ligand is essentially planar, and all three C–C bond lengths are roughly the same (ca. 1.41 Å). The ligands about iron describe a square-pyramidal geometry, with one carbon monoxide ligand occupying the apical position and the remaining two carbonyls and the diene ligand in the basal plane. The outer diene carbons are slightly further from iron (Fe–C, 2.13 Å) than are the inner carbon atoms (Fe-C, 2.05 Å). The two basal carbonyls eclipse the 1,2- and 3,4-diene bonds, and the apical carbonyl points toward the 'open' end of the diene. Only one ^{13}C NMR signal is observed in the metal carbonyl region, thus indicating a rapid interchange between the two sites. Substituents at C-1 and C-4 are bent out of the plane of the diene ligand, with *exo* substituents displaced towards iron and *endo* substituents displaced away from iron. Complexation of the diene to iron causes distinct changes in the ^{1}H and ^{13}C NMR spectra of these complexes. Resonance signals for protons on the internal carbons (C-2 and C-3) appear in the region 5–6 ppm, while terminal protons in the *exo* and *endo* positions appear considerably further upfield (ca. 1.9 and 0.3 ppm, respectively). As a consequence of the twisting of the substituents out of the plane of the diene ligand, the *cis* and *trans* couplings are reduced in value to about 7 and 9 Hz, respectively.[318] The resonance signals for the diene carbons appear upfield, with C-2 and C-3 having resonances at 85 ppm and those for C-1 and C-4 at 42 ppm.[32] These spectral features are highly constructive for assigning the relative stereochemistry of substituents on the diene ligand.

The complexation of prochiral dienes to the $Fe(CO)_3$ fragment results in the formation of a racemic mixture of enantiomers. These racemic planar chiral complexes have been resolved and the enantiomerically pure (or enriched) complexes are configurationally stable at 23 °C; however, they undergo a thermal racemization at >100 °C with a $\Delta G‡ = 130\,\text{kJ mol}^{-1}$.[319] The resolution of the racemic mixtures has been accomplished by classical formation of diastereomeric derivatives, by chiral chromatography, and by kinetic resolution using optically active reagents or biotransformations.[306,307,320,321] Of particular note was the discovery that dienal complexes underwent kinetic resolution upon reaction with enantiopure allyl boronate, and an analogous transformation of a meso complex proceeded with excellent diastereoselectivity (Scheme 63).[322] This finding led directly to the development of additional diastereoselective transformations along the periphery of the diene unit, as well as to applications in natural product synthesis. The same meso complex has also undergone asymmetric alkylation with alkyl zinc reagents in the presence of chiral ligands.[323]

The complexation of chiral dienes leads to the formation of diastereomeric η^4-diene iron tricarbonyl complexes. An early example was actually carried out for the protection of the diene unit found in the steroid B-ring of ergosteryl acetate (equation 53); neither the stereochemical assignment nor the diastereomer ratio were established.[324,325] Similarly, the tricarbonyl iron complex of calciferol was also prepared.[326]

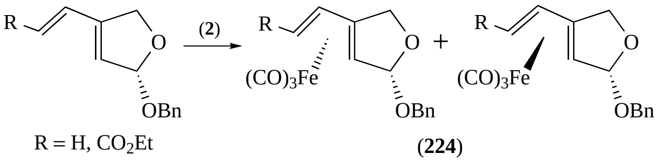


Scheme 63



(53)

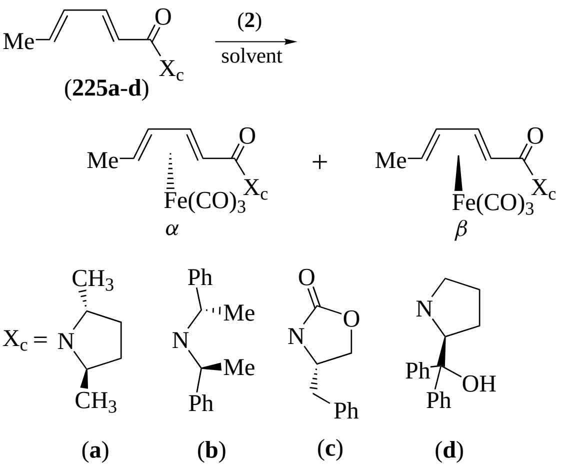
Complexation of an enantiopure diene derived from (+)-*L*-arabinose was a modestly diastereoselective process (equation 54).[327] The major η^4-iron diene complex formed (**224**) was likely the result of heteroatomic delivery and installation of the $Fe(CO)_3$ unit *syn* to the benzyloxy group. The diastereoselectivity of this transformation was solvent dependent; this may be result of conformational differences in different solvents. The diastereomeric iron diene complexes were separable by chromatography and each could be transformed into various derivatives under carefully controlled conditions without loss of optical integrity.[328]



(54)

Chiral auxiliaries may also be used to effect diastereoselective complexations of acyclic dienes. For chiral dienamides (**225a–d**), the best case employed the sterically demanding (*S*)-2-(diphenylhydroxymethyl)pyrrolidine auxiliary. Diene (**225d**) was complexed with excellent diastereoselectivity but in modest yield (Scheme 64).[329] For substrates (**217a–c**), diastereomer ratios of the corresponding complexes were poorer (1.5:1 to 4.6:1), likely a result of the increased distance between the auxiliary's chiral center and the diene.

Diastereoselective complexations of an iron tricarbonyl unit to a series of enantiopure sulfinyl dienes has also been reported.[330] (*Z*)-1-Sulfinyl dienes (**226**) (rather than the isomeric (*E*)-1-sulfinyl dienes or 2-sulfinyl dienes) afforded the greatest diastereoselectivities (10:1 to 16:1); 1,3-allylic strain has been cited as the origin of the selectivity, as the favored conformation would place the bulky aromatic group of the sulfoxide group in a position where it blocks one diene face (Scheme 65). While unsubstituted (*Z*)-1-sulfinyldienes (**226**, R, R′ = H) or their 4-substituted analogs (**226**, R = $CH(OEt)_2$, R′ = H) can be efficiently complexed using (**1**)/NMO, 3,4-disubstituted-(*Z*)-1-sulfinyldienes (**226**, R, R′ ≠ H) required the use of (bda)$Fe(CO)_3$ as the complexing reagent in order to obtain good (ca. 80%) chemical yields. In



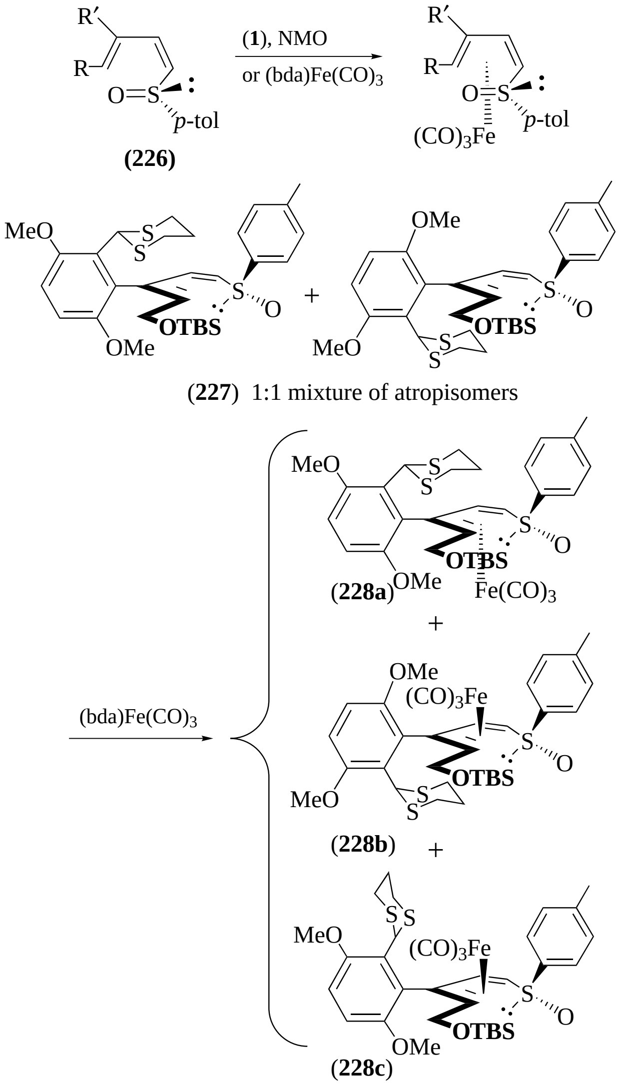
X_c	Solvent / temp	α / β ratio	% Yield
a	Et_2O / Δ	4.6:1	95
b	Et_2O / Δ	1.5:1	46
c	Et_2O / Δ	2:1	78
d	Et_2O-DCM / Δ	>99:1	40 (84, brsm)

Scheme 64

virtually all cases, it was demonstrated the complexations with (bda)$Fe(CO)_3$ were under kinetic control. Transformations along the diene periphery have been used to install new chiral centers in a diastereoselective manner. Also, 3-(*o*-dithianylaryl) analogs (**227**) are complexes prepared with simultaneous installation of planar and axial chirality. In the example shown, the iron diene complexes are formed in a ratio for (**228a:228b:228c**) of 34:2.6:1; the selectivity results from dynamic kinetic resolution (Scheme 65).[331] These complexes are part of a growing class of nonbiaryl atropisomeric complexes.[332]

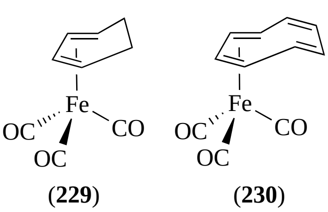
6.3.2 *Cyclic (Diene)Iron Complexes*

The reaction of 1,3- or 1,4-cyclohexadienes with (**1**), (**2**), or ligand transfer species generates the corresponding (1,3-cyclohexadiene)$Fe(CO)_3$ complexes (**229**).[333] In a similar fashion, reactions of dihydroanisoles, 1,2-dihydrobenzoic acid esters, 1,3-cycloheptadiene, cycloheptatriene, tropone, 1,3-cyclooctadiene, 1,3,5-cyclooctatriene, or cyclooctatetraene with (**1**), (**2**), or (**3**) give the corresponding cyclic (1,3-diene)iron complexes. Monophosphinedicarbonyl or monophosphitedicarbonyl complexes are also available in some cases by treatment of the tricarbonyliron complex with the appropriate phosphine or phosphite. The structures of the cyclic diene complexes are similar to those of the acyclic diene complexes. The cyclooctatetraene complex (**230**) exhibits a single signal in its ^1H NMR spectrum (5.39 ppm, $CDCl_3$) at 23 °C, indicating stereochemical nonrigidity. The ^{13}C NMR spectrum of (**230**) is temperature dependent, and

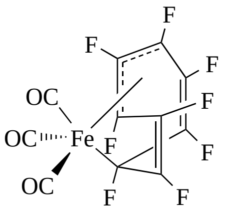


Scheme 65

the single cyclooctatetraene signal at −20 °C splits into four signals at −134 °C. Analysis of the different rates of peak broadening indicates that the fluxional behavior is a 1,2-shift of the $Fe(CO)_3$ (a 'ring-whizzing' process (*see Ring Whizzers*)) which has an activation energy of 33.9 kJ mol^{-1}.[334] Compound (**230**) is also fluxional in the solid state. The reaction of perfluorocyclooctatetraene with (**2**) gives the unusual 1,2,3,6 − η-bonded complex (**231**), which has been characterized by X-ray diffraction.[335]

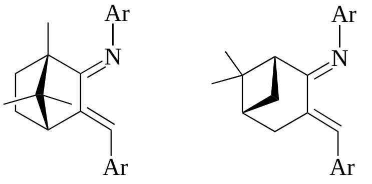


(**229**) (**230**)



(**231**)

As with acyclic dienes, methods have been developed for enantioselective and diastereoselective complexation of prochiral and chiral cyclic dienes. An approach has been developed for the asymmetric catalytic complexation of prochiral cyclohexa-1,3-dienes using (**1**) in the presence of catalytic amounts of 1-azabuta-1,3-dienes such as (**232**) or (**233**); an enantiomeric excess as high as 86% has been reported.[311–313] By contrast, attempts to effect diastereoselective complexations using cyclic diene systems equipped with chiral auxiliaries have met with limited success.[336–339] On the other hand, direct complexation of chiral cyclic dienes such as (**234**) and (**235**) proceed with a high degree of diastereoselectivity, where the iron tricarbonyl fragment is directed *syn* to alcohols or ethers by transient coordination ('heteroatom delivery') (Scheme 66).[340,341]



(**232**) (**233**)

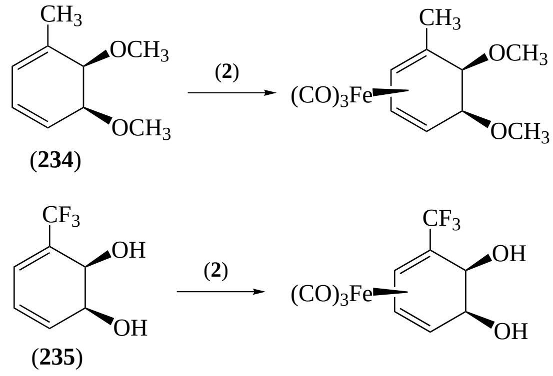
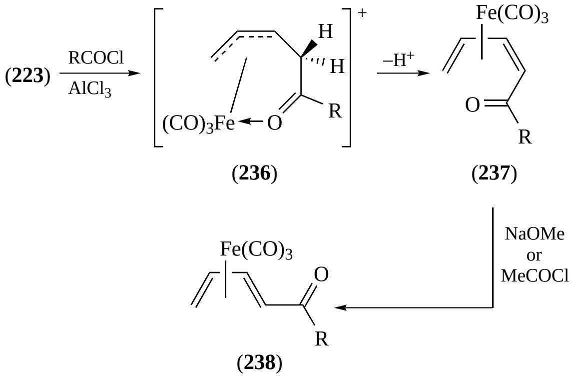


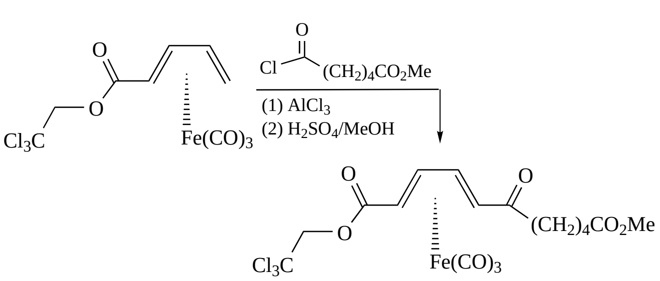
Scheme 66

6.3.3 *Reaction at the η^4-Diene*

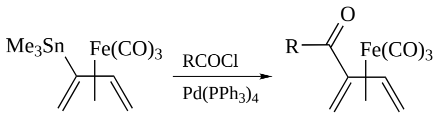
In general, the complexed dienes are not reactive under the same conditions as the free ligand; the (tricarbonyl)iron fragment thus serves as a protecting group for the diene functionality. (Diene)$Fe(CO)_3$ complexes will undergo reaction with electrophiles. Protonation of these complexes generates a cationic η^3-allyl complex (Section 5.1.1). Electrophilic acylation of (butadiene)$Fe(CO)_3$ complexes generates the corresponding dienone complexes. The rate of acylation of (**223**) is 3850 times faster than that of benzene. Acylation occurs on the *endo* face of the diene ligand via initial formation of a cationic η^3-allyl complex (**236**) (equation 55). Deprotonation affords the *cis*-dienone complex (**237**). Complexes (**237**) isomerize to the thermodynamically more stable *trans*-dienone complexes (**238**) in the presence of sodium methoxide or acid.[342] An example of this methodology, used in the synthesis of an enantiomerically pure arachadonic acid metabolite (LTA_4) is shown (equation 56).[343] In general, the electrophilic acylation proceeds at the unsubstituted terminus of 1-substituted diene complexes, and for 2-substituted complexes it occurs with low regioselectivity. The acylation of 1,4-disubstituted diene complexes and diene complexes containing an electron-withdrawing substituent will occur under forcing conditions.[342] Substitution of an acyl group at the internal position of a diene iron complex may be accomplished by palladium-catalyzed coupling of an acyl halide with the 2-stannylated butadiene complex (**239**) to give (**240**) (equation 57).[344] Simple treatment of 1,1,3-trisubstituted diene complexes with $AlCl_3$ results in the formation of substituted cyclopentenones (**241**) (equation 58).[345]



(55)

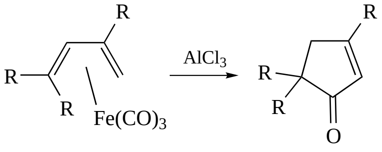


(56)



(239) **(240)**

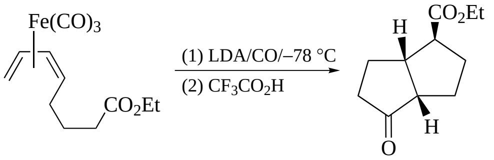
(57)



(**241**)

(58)

The η^4-diene ligand will undergo attack by strong nucleophiles (conjugate acid $pK_a >$ ca. 28) (*see Acidity Constants*) in THF/Hexamethylphosphoramide (HMPA) to afford, after protic workup, the products of addition to the diene (Scheme 67).[346] Attack occurs kinetically (−78 °C) at an internal diene position to generate the anion (**242**). This nucleophilic attack is, however, reversible. Allowing the reaction mixture to warm to 23 °C results in irreversible attack at the terminal position to afford the anionic allyl complex (**243**). Protonation of the anionic species gives the organic products shown. The anion (**244**) will undergo carbonyl insertion under an atmosphere of CO, followed by intramolecular alkene insertion to eventually afford cyclopentanone products. An intramolecular version is known as well (equation 59).[347] The alkene insertion step does not occur for cyclic dienes; however, protic workup affords the corresponding aldehydes.

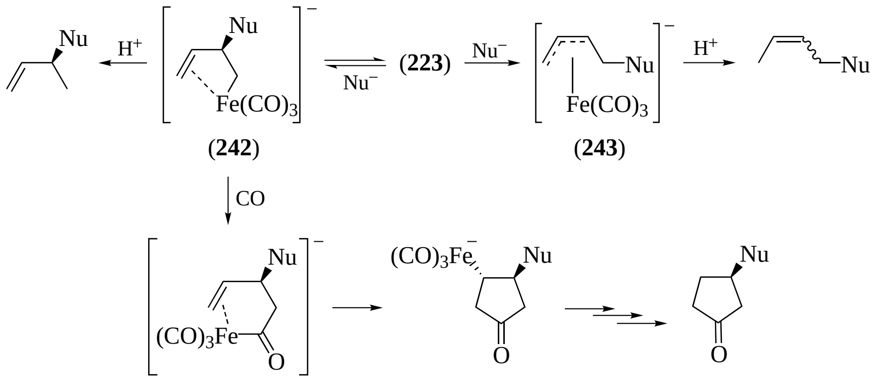


(59)

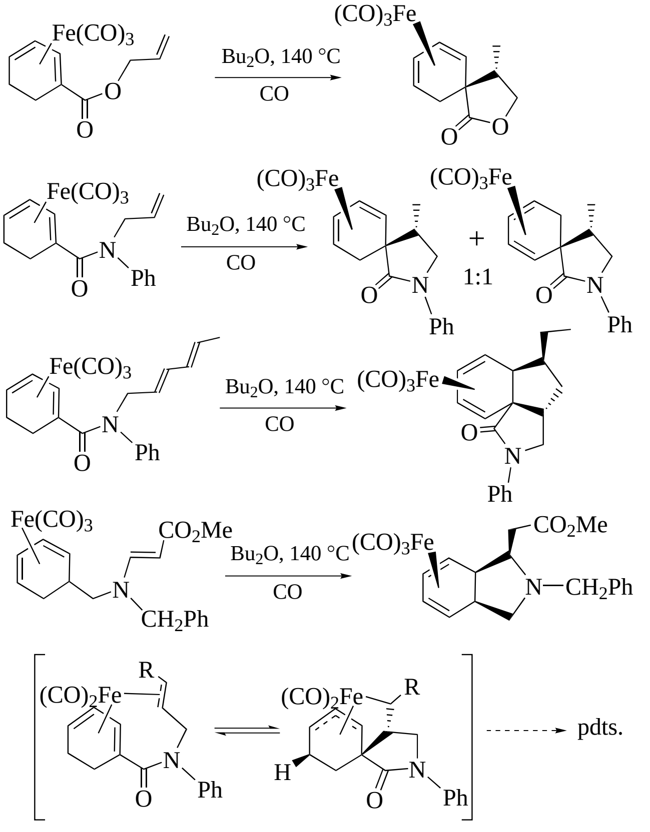
A number of intramolecular coupling reactions that involve reductive cyclization of a (cyclohexadiene)$Fe(CO)_3$ complex that bears a pendant alkene or diene have been reported.[348,349] Under CO atmosphere, this unusual cyclization presumably produces an intermediate η^3-π-allyl complex that then rearranges via hydride migration. In the case of the pendant diene, a second such process can occur (Scheme 68).

6.3.4 *Reactions Adjacent to the η^4-Diene*

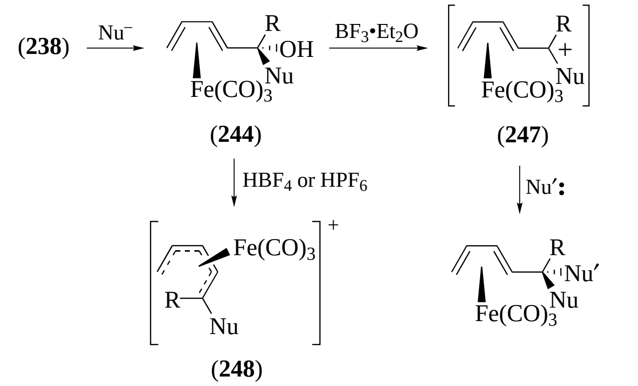
The $Fe(CO)_3$ functionality acts as a sterically bulky substituent attached to the planar diene. Reactions that create a new chiral center adjacent to the diene may occur in a diastereoselective fashion owing to approach of reagents to the complex on the side opposite to the iron center. For example, nucleophilic attack on a carbonyl at C-1 (such as **238**) to afford complexed dienols (**244**) proceeds with high diastereoselectivity for ketones, and with lesser



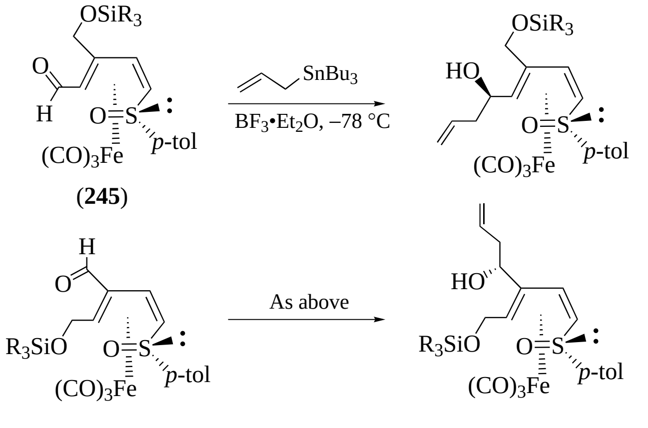
Scheme 67



Scheme 68



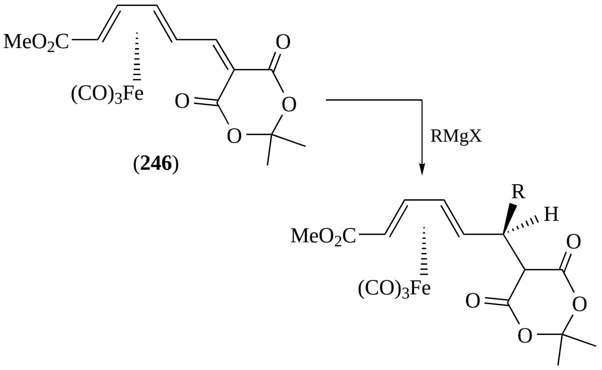
Scheme 69



Scheme 70

diastereoselectivity for aldehydes (Scheme 69).[306,307] For those nucleophilic transformations that rely on Lewis acid activation, diastereoselectivity depends on the nature of the Lewis acid.[350] Reaction at a carbonyl at C-2 (such as **240**) can also proceed in a diastereoselective fashion.[263,351] For enantiomerically pure C-2 alkyl, C-1 formyl complexes of type (**245**), nucleophilic addition is diastereoselective (*ca* 7:1) and is favored to proceed through the *s*-trans conformation; for the related C-1 alkyl, C-2 formyl complexes, addition to the *s*-cis conformation is preferred (Scheme 70).[352] Michael additions to α,β-unsaturated diene complexes (**246**) with Grignard reagents or allyl stannane proceed with excellent diastereoselectivity (equation 60).[353,354] Dihydroxylation of alkenes, homo- and hetero-Diels–Alder cycloadditions, dipolar cycloadditions, enolate-Claisen condensations (*see*

Condensation), and enolate alkylations also proceed in highly diastereoselective fashions.[306,307,355–360]

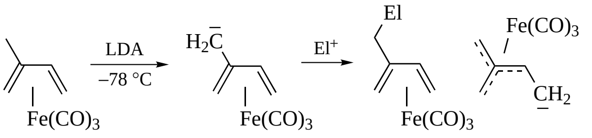


(60)

Substitution of complexed dienols (**244**) or dienol acetates with carbon or heteroatom nucleophiles, in the presence of a Lewis acid, occurs with retention of configuration (Scheme 69). (Alkyl aluminum reagents act as both nucleophile and Lewis acid in this process). This reaction is believed to proceed via stereospecific ionization, with anchimeric assistance from the iron, to generate the transoid pentadienyl cation (**247**) followed by attack of the weak nucleophile on the face opposite to iron.[361,362] The cross-conjugated pentadienyl cation can also be generated; the substitution of (2-acetoxymethyl-1,3-butadiene)$Fe(CO)_3$ (**193**) has previously been discussed (Section 6.1.1).

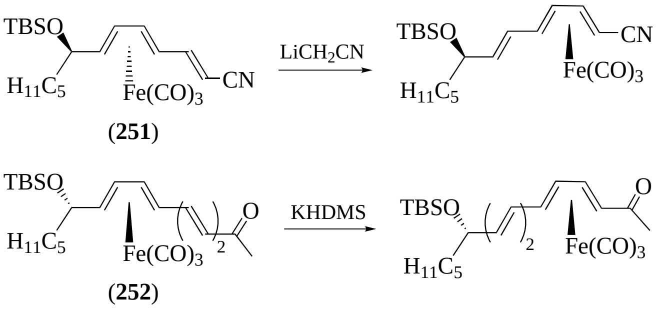
Protonation of dienol complexes (**244**) with strong acids (e.g. HBF_4, HPF_6, or $HClO_4$) generates the cisoid (η^5-pentadienyl)iron cations (**248**) (Scheme 69).[363] This reaction is believed to proceed via initial formation of the transoid pentadienyl cation, followed by isomerization to the more stable cisoid form of the cation. Computational methods on the unsubstituted cationic complex (**248**, R = Nu = H) suggest that the cisoid form is 9.2 kcal mol^{-1} more stable.[364] Protonation of an alkene that is adjacent to a diene complex can also lead to the formation of (η^5-pentadienyl)iron cations. Additionally, hydride abstraction using the trityl cation also produces (η^5-pentadienyl)iron cations; the rich chemistry of these species will be described later (Section 7.1).

Deprotonation of tricarbonyl(isoprene)iron generates anion (**249**) which will react with organic electrophiles, such as aldehydes, and alkyl, benzyl, and allyl halides, to give alkylated products (equation 61).[365] The anion is unstable above −30 °C and apparently rearranges to the trimethylenemethane anion (**250**).



(**249**) (**250**) (61)

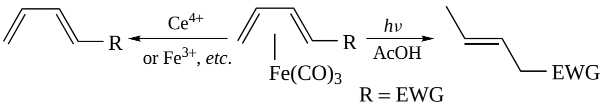
Treatment of α,β-unsaturated complex (**251**) with the basic carbanion $LiCH_2CN$ causes a 1,3-migration of the iron tricarbonyl unit rather than deprotonation, with inversion of stereochemistry (Scheme 71).[366] Related 1,5-migrations are also possible using tetraene complexes (**252**), though these proceed with stereochemical retention. Finally, other reactions that can occur adjacent to the iron diene unit include Wittig, Horner-Emmons, or Peterson olefinations, alkene cyclopropanations, and ring-closing metathesis (*see Alkene Metathesis*) catalyzed by Grubbs' ruthenium carbene catalyst.[306,307,354,367]



Scheme 71

6.3.5 *Liberation of the Ligand*

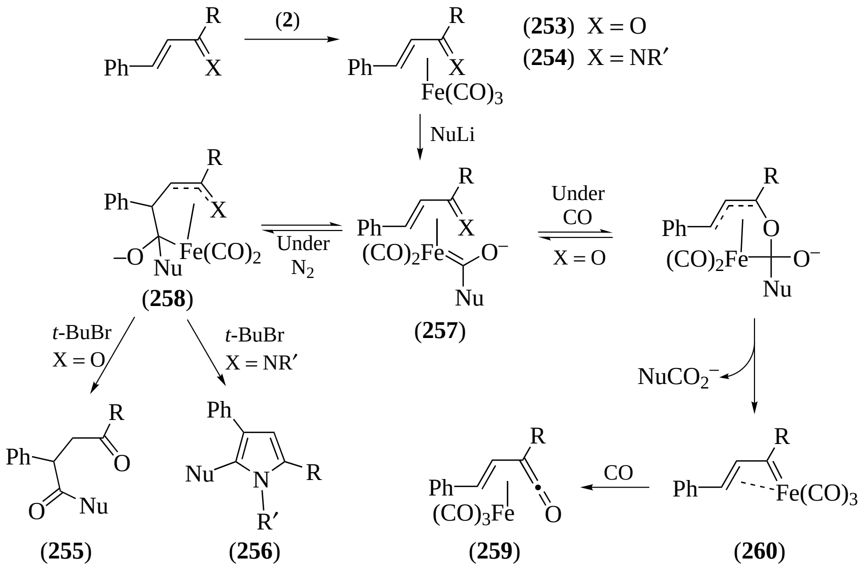
The organic ligand of acyclic diene complexes (**223** or derivatives) or cyclohexadiene complexes (**229** or derivatives) may be liberated by oxidation of the metal. Reagents useful for this transformation are CAN/methanol, basic hydrogen peroxide, $FeCl_3$, $CuCl_2$, 3-chloroperbenzoic acid, and trimethylamine *N*-oxide (equation 62).[306,307] Photochemical reduction of (diene)iron complexes in acetic acid gives the corresponding alkene. The regioselectivity for this reaction is good only if the diene is substituted by an electron-withdrawing ligand.[368] Additional reactions that liberate the organic ligand have been discussed (Section 6.3.3). The ease of complexation of the diene, versatile methodology for liberation of the diene ligand, and low cost of the metal, have made the chemistry of diene and dienyl iron complexes of great utility for the synthesis of natural products.



(62)

6.4 Heterodiene Complexes

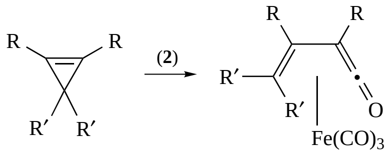
(Tricarbonyl)iron complexes of α,β-enones (**253**) and vinylimines (**254**) may be prepared by reaction of the organic ligand thermally with (**2**) or photochemically with (**1**). X-ray diffraction analysis of these complexes clearly indicates that the ligand is nearly planar and that iron is bound to all four atoms of the functionality. The heterodiene ligand may be



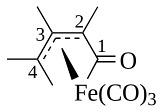
Scheme 72

displaced by treatment of either complex (**253**) or (**254**) with a suitable diene (Section 6.3.1); indeed, benzylidene acetone iron tricarbonyl (**253**, R $=$ CH_3) is a common $Fe(CO)_3$ transfer reagent in organic synthesis. As described in Section 6.3.2, if the heterodiene ligand is chiral, this ligand transfer can occur enantioselectively.[311–313] Vinylimines (**232**) and (**233**) function catalytically in this role.

The reaction of (**253**) or (**254**) with alkyllithium reagents under N_2, followed by workup with *t*-butyl bromide, generates products which have incorporated one of the carbonyl ligands, (**255**) and (**256**), respectively (Scheme 72).[369,370] This reaction probably occurs via initial attack on coordinated carbon monoxide to give the acrylate complex (**257**), followed by coupling to give a heteroallyl anion (**258**), which upon workup gives the products. If the reaction of (**253**; R $=$ H) with alkyllithium reagents is carried out in the presence of an atmosphere of CO, then vinylketene complexes (**259**) are isolated. In this case, the reaction probably proceeds via the acrylate anion (**257**) which couples to the C=O portion of the enone. Under the influence of carbon monoxide as an external ligand, a loss of carboxylate occurs to give the vinylcarbene species (**260**), which inserts a second carbon monoxide to give (**259**) (Scheme 72).[369,370] Vinylketene complexes may also be prepared by the reaction of cyclopropenes with (**2**) (equation 63).[371,372] X-ray diffraction of the vinylketene complexes indicates that the structure may best be represented as a hybrid between an η^4-diene type complex (**259**) and an η^3-allyl-η^1-acyl complex (**261**). The bond distance of (**261**) for C-1–C-2 (ca. 1.45 Å) is longer than for C-2–C-3 or C-3–C-4 (ca. 1.41 Å), the Fe–Cl distance (ca. 1.91 Å) is shorter than the Fe–C-2, Fe–C-3, or Fe–C-4 distances (ca. 2.10 Å), and the ketene C=C=O functionality is nonlinear (bend angle ca. 135°).[372]

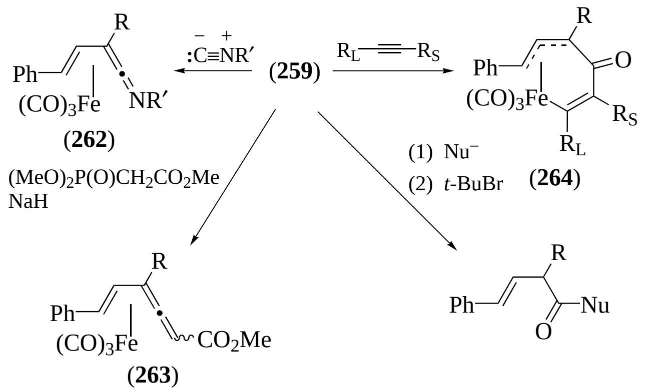


(63)



(**261**)

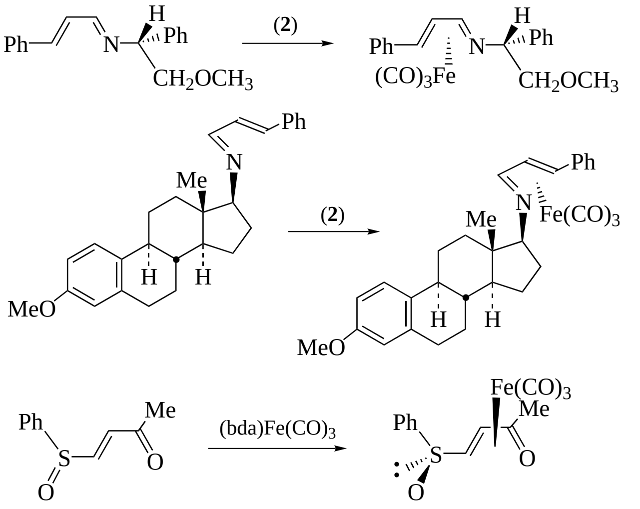
The vinylketene complexes (**259**) react thermally with isocyanides to afford η^4-vinylketenimine complexes (**262**) (Scheme 73). This reaction proceeds via initial substitution of a carbonyl ligand by the isocyanide. The isocyanide complex then undergoes intramolecular CO deinsertion, and



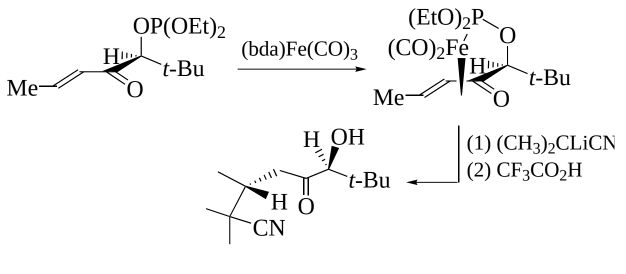
Scheme 73

reinsertion of the isocyanide.[369,370] The vinylketene complexes react with trimethyl phosphonoacetate to afford η^4-vinylallene complexes (**263**). The vinylketene ligand may be liberated by reaction with a variety of carbon and heteroatom nucleophiles, followed by workup with t-butyl bromide, to give products from addition to the ketene carbonyl carbon. As discussed in Section 5.1.3, reaction of alkynes with complexes (**259**) results in the insertion of the alkyne into the Fe–acyl bond to afford the corresponding σ-vinyl–π-allyl complexes (**264**).[373] This insertion is highly regioselective, with the larger alkyne substituent located on the vinyl carbon bound to iron.

Diastereoselective complexations affording chiral heterodiene complexes are also known (Scheme 74).[374–376] The complexation of the enantiomerically pure N-benzyl vinylimines was shown to proceed under kinetic control; equilibration to thermodynamic mixtures possessing poorer diastereomer ratios occurred upon standing. On the other hand, the diastereoselective complexation of an enantiomerically pure enone with a side chain possessing chirality and a chelating phosphite group was shown to proceed under thermodynamic control (Scheme 75).[377] The product (a single diastereomer was formed) could be transformed by nucleophilic addition at the β-position.



Scheme 74



Scheme 75

7 η^5-LIGAND COMPLEXES

7.1 Tricarbonyl(dienyl)Iron Cations[4]

7.1.1 Preparation and Structure

Tricarbonyl(dienyl)iron cations have become an important synthetic intermediate in organic chemistry and have found a significant number of applications in the area of total synthesis. These cations may be prepared and isolated or may be generated transiently and subsequently trapped by nucleophiles. (Cyclohexadiene)iron complexes (**229**) react with the trityl cation to undergo α-hydride abstraction to generate stable and isolable (η^5-cyclohexadienyl)iron cations (**265**) (equation 64).[310,333] This reaction proceeds by removal of a hydride on the cyclic diene face opposite to the iron. For substituted cyclohexadiene complexes, the regioselectivity for the removal of hydride is dictated by the position and nature of the substituents. In many, but not all, cases, the reaction is highly regioselective. (Cycloheptadienyl)iron cations can be generated in an analogous fashion. Alternatively, protonation of (cycloheptatriene)Fe(CO)$_3$ (**266**) or (cyclooctatetraene)Fe(CO)$_3$ (**230**) proceeds on the free alkene, on the face opposite to iron, and results in the formation of cationic (η^5-cycloheptadienyl)Fe(CO)$_3$ complexes (**267**) and (**268**) (Scheme 76).[378] Hydride abstraction to give acyclic (pentadienyl)iron cations is possible for acyclic dienes with a 1-methyl substituent in the *endo* position; however, removal of a hydride from an *exo* 1-methyl substituent does not occur (equation 65).[363]

The X-ray diffraction analyses of (cyclohexadienyl)iron cations have been reported.[379] These studies reveal that the five carbons of the dienyl portion of ligand are essentially coplanar, the sixth ring carbon is tilted out of this plane away from the iron atom, and one of the carbonyl ligands eclipses the methylene carbon. The ^{13}C NMR spectra of a number of substituted (cyclohexadienyl)iron cations have also been reported.[380] Carbons 2 and 4 appear furthest downfield, and the terminal carbons 1 and 5 appear furthest upfield. A

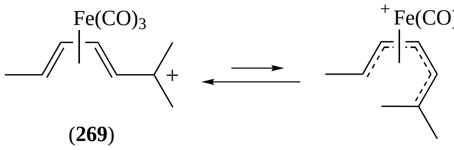
(**230**) (**268**)

Scheme 76

methoxy substituent has the greatest effect on the ^{13}C NMR chemical shift.

As described in Section 6.3.4, activation of coordinated dienols (by protonation) or coordinated dienol acetates (by treatment with Lewis acid) affords the corresponding (pentadienyl)iron cations (**248**) (Scheme 69).[363] Since the acyclic pentadienyl cationic complexes do not have the geometrical constraints of their cyclic counterparts, they can potentially adopt either a cisoid ('U') or transoid ('S', sickle) conformation. Nearly all of the (pentadienyl)iron cations prepared appear to be in the cisoid conformation by ^{1}H NMR spectroscopy. Only a single, sterically biased transoid pentadienyl cation (**269**) has been spectroscopically observed, but not isolated (equation 66).[381] Owing to their potential to undergo 'U' to 'S' conformational inversion in solution, and owing to the considerably higher reactivity of the less stable 'S' conformer, the (pentadienyl)iron cations are considerably more sensitive to moisture than their cyclic counterparts.

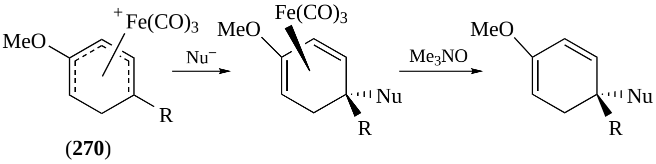


(66)

(**269**)

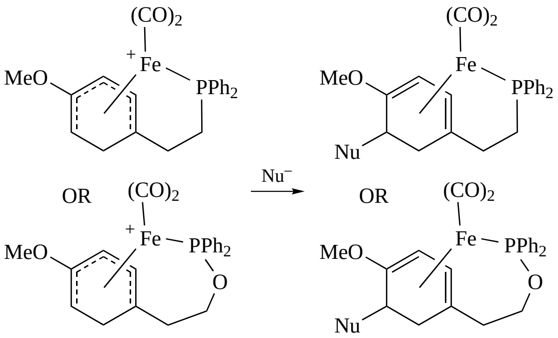
7.1.2 Reactions

The (dienyl)iron cations of type (**248**) and (**265**) are susceptible to reaction with nucleophiles. For the (cyclohexadienyl)iron cations, nucleophilic attack always occurs at a terminal carbon, on the face of the ligand opposite to the metal, to afford η^4-cyclohexadiene products. Typical nucleophiles used are malonate anions, amines, electron-rich aromatics, silyl ketene acetals, enamines, hydrides, and allyl silanes; intramolecular nucleophilic addition is also possible. The addition of highly basic organometallic nucleophiles (Grignard reagents, organolithiums) is often problematic; this may be overcome by replacing one of the iron carbonyl ligands with the poorer π-acceptor triphenylphosphine, where the diminished electron-accepting ability of the unsaturated ligand reduces the electron-transfer process that otherwise interferes with nucleophilic addition. Alternatively, softer organometallic reagents such as organozincs or organocadmiums can be used. While dialkylcuprates are effective nucleophiles with unalkylated (cyclohexadienyl)iron cations, lower order mixed cuprates R(Me$_2$S)CuLi should be employed with alkyl-substituted analogs. Regarding the regioselectivity of nucleophilic attack, for unsymmetrically substituted (cyclohexadienyl)iron cations this is dependent on the steric and electronic influence of the substituents and on the nature of the nucleophile.[310,333,382] A typical case is that of the (1-alkyl-4-methoxycyclohexadienyl)iron cation (**270**), which undergoes nucleophilic attack at the substituted terminus (equation 67).[383] When R = Me, nucleophilic addition is regioselective (as shown), however, when R is a longer alkyl chain the regioselectivity diminishes and addition to the other end of the η^5-cation system becomes competitive. This loss of regioselectivity is overcome by using the more sterically demanding isopropyl analog of (**270**). Alternatively, selectivity in the formation of the quaternary carbon is enhanced by replacing one of the carbonyl ligands with a triphenylphosphine.[384,385] On the other hand, if R possesses a terminal phosphine or phosphinite group that is capable of forming a bridged chelate complex, the regioselectivity of nucleophilic addition can be reversed (equation 68). Since these reactions (equation 67) generate 2-methoxy-1,3-cyclohexadiene complexes, and since the ligand may be readily liberated by mild oxidation of iron, this reactivity has been utilized in the synthesis of a variety of natural products.[310,333]



(**270**)

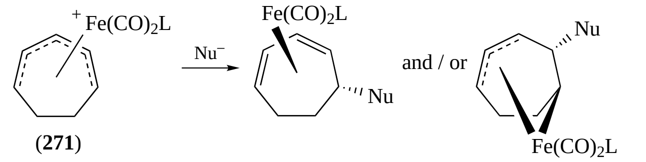
(67)



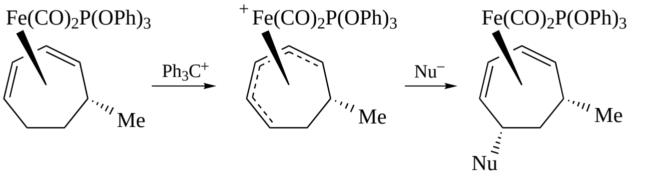
(68)

In comparison, the (cycloheptadienyl)iron cations, for example, (**271**, L = CO), are not well-behaved, tending to undergo nucleophilic attack at the terminal (C-1, C-5) as well as at internal (C-2, C-4) carbon atoms

(equation 69).[386,387] However, this limitation can be overcome by replacement of a CO ligand with triphenylphosphite (L = $P(OPh)_3$); nucleophilic addition to the terminal position of the unsaturated ligand is completely regioselective and stereoselective.[4] Treatment of this product with trityl cation selectively produces another (cycloheptadienyl)iron cation, which may undergo a second nucleophilic addition with total regioselectivity and stereoselectivity (equation 70).



(69)

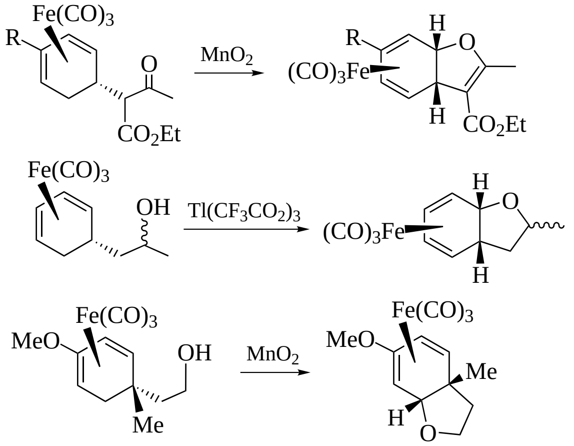


(70)

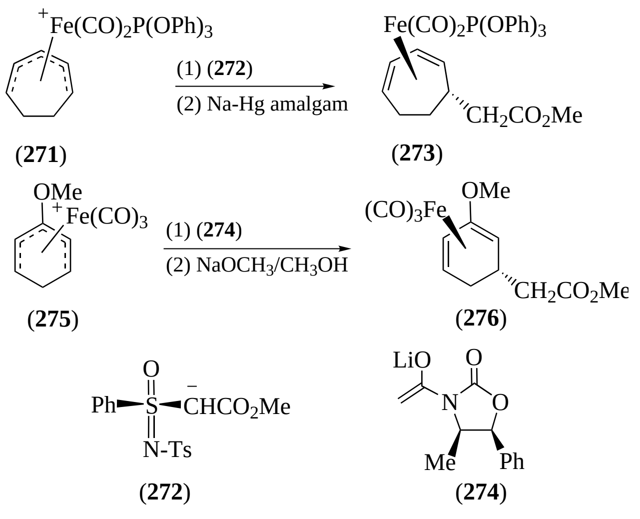
Some progress has been made in performing asymmetric variations of this chemistry. Addition of the anion of sulfoximine ester (**272**) to achiral (cycloheptadienyl)iron cation complex (**271**, L = $P(OPh)_3$), followed by desulfurization, affords enantiomerically enriched (**273**, 50% ee) (Scheme 77).[388] In a similar manner, addition of the enolate derived from a chiral *N*-acyloxazolidinone (**274**) to achiral (cyclohexadienyl)iron cation complex (**275**) and subsequent auxiliary removal affords (**276**, 70% ee).

A number of oxidative cyclizations have been formed that appear to proceed via transiently formed cyclic (cyclohexadienyl)iron cation complexes. Early examples of this methodology focused on oxygen nucleophiles (Scheme 78); more recent applications have employed aryl amines or quinone-imines used to prepare indoles and related heterocycles (Scheme 79).[389–391] This chemistry has found significant application towards the synthesis of carbazole alkaloids. Finally, related iron-mediated spiroannelations (*see Spirocyclic Compound*) have been reported, with either electron-rich aromatics or vinylogous carbamates as the nucleophilic species.[392] Isotopic labeling (*see Isotopes & Isotope Labeling*) evidence suggests that the reactions proceed through an intermediate vinyl-substituted η^5-(cyclohexadienyl) iron cation, (**277**) (Scheme 80).

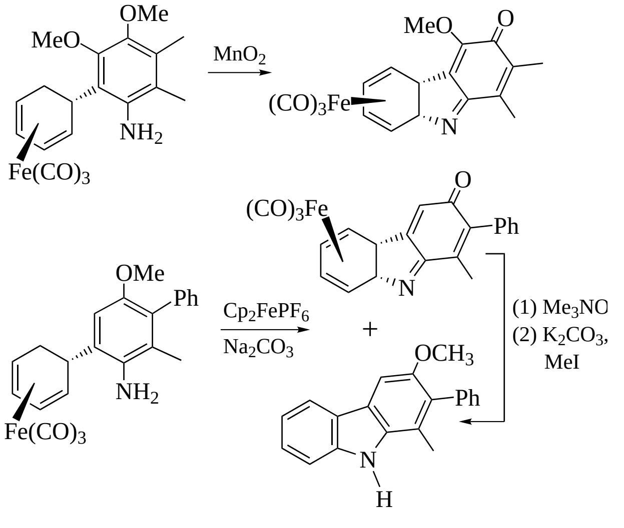
The reactivity of acyclic (pentadienyl)iron cations with carbon and heteroatom nucleophiles has been examined. Nucleophilic attack may occur on either the cisoid or transoid conformation of the ligand. In general, it has been found that attack by weak nucleophiles (water, alcohols, weakly basic



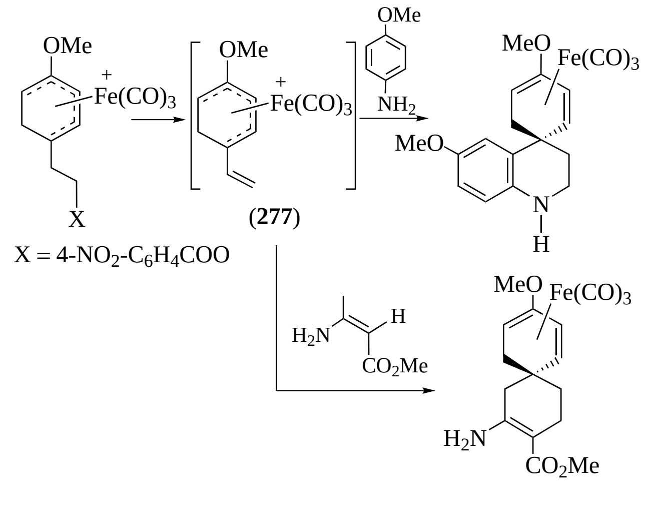
Scheme 78



Scheme 77

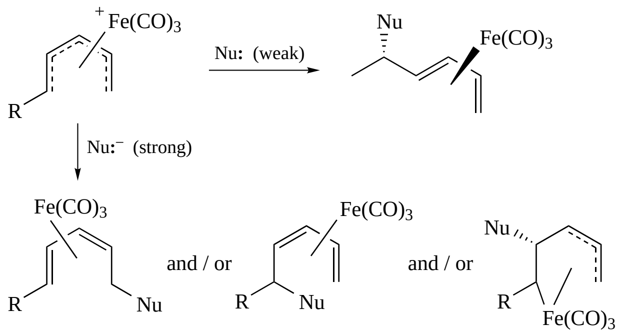


Scheme 79



Scheme 80

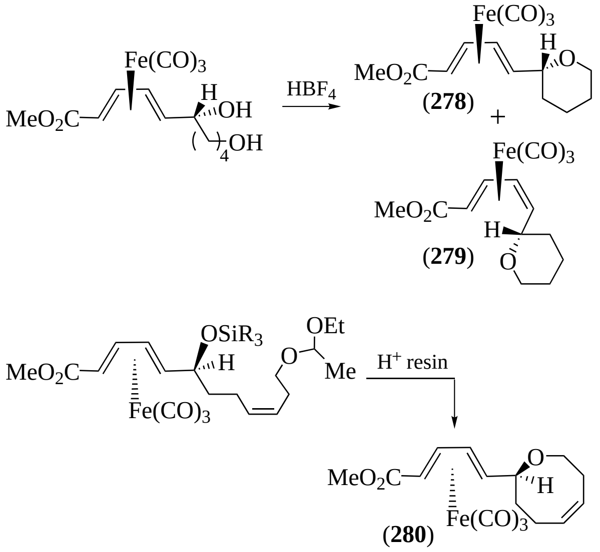
amines, electron-rich aromatics, or allylsilanes) occurs on the less stable, and therefore more reactive, transoid conformer of the pentadienyl cation.[393] Conversely, strong nucleophiles (malonate, hydride reagents, and organocuprates) are known to react with the more stable cisoid conformer. In general, attack by the stronger nucleophiles usually occurs at the terminal position (C-1, C-5) of the ligand to afford *cis* diene products;[394] however, several examples of attack at the internal carbons (C-2, C-4) have been noted (equation 71).[395] Attack at the more substituted terminal position of the ligand (to give the less-substituted η^4-iron diene complex) is significantly favored when one of the carbonyl ligands is replaced by triphenylphosphine.[396]



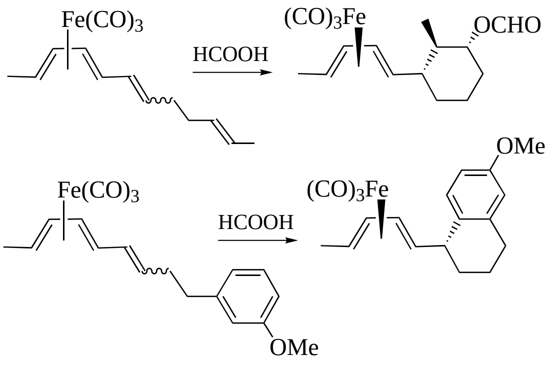
(71)

As discussed earlier (Section 6.3.4), acyclic (pentadienyl)iron cations are intermediates in reactions involving protonation or Lewis acid activation of iron dienol or dienol acetate complexes. With appropriate functionalization, these cations may also be trapped intramolecularly (Scheme 81). In the case of the formation of tetrahydrofurans (**278**) and (**279**), equilibration of the transoid and cisoid cations is observed.[397] However, this equilibration is not observed in the stereoselective cyclization to provide (racemic) oxocene (**280**).[398] Analogous intramolecular cyclizations of sulfur and nitrogen nucleophiles have also been reported.[399] Cyclizations may also be initiated by protonation of an alkene; thus far either tethered alkenes or an electron-rich aromatic have been shown to participate in this diastereoselective process (Scheme 82).[400]

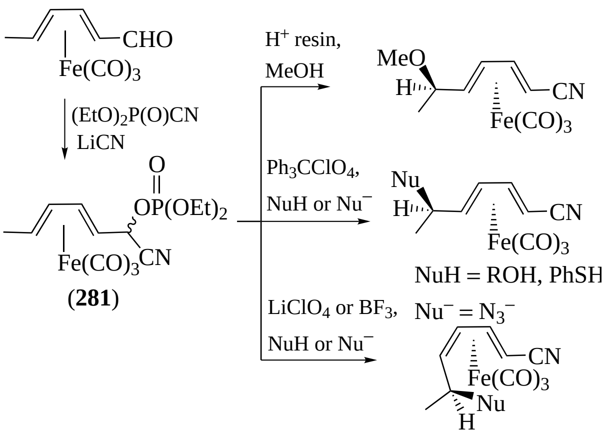
A variation on the theme of generating an acyclic (pentadienyl)iron cation by activation of a leaving group adjacent to an η^4-iron diene complex has led to the development of a highly diastereoselective 1,5-nucleophilic substitution with concurrent 1,2-migration of the $Fe(CO)_3$ fragment (Scheme 83).[367] Conversion of an iron dienal complex into the unstable *O*-diethylphosphoryl cyanohydrin (**281**) provided the required substrate for the substitution/migration reaction, which occurs stereospecifically depending on the reaction conditions. Since the nitrile of the product can be readily reduced to the corresponding aldehyde, an iterative process is possible and can produce multiple and adjacent chiral centers. The process can also be performed on enantiomerically pure material without any loss of stereochemical fidelity.



Scheme 81



Scheme 82



Scheme 83

7.1.3 Cross-conjugated Dienyliron Cations

Dehydration of (2-hydroxymethyl-1,3-butadiene)iron complexes or (hydroxymethyltrimethylenemethane)iron complexes with fluorosulfonic acid/liquid sulfur dioxide generates the corresponding (cross-conjugated dienyl)iron cations (**194**) (equation 72).[276] The ^{1}H and ^{13}C NMR spectral data for these cations favor an η^4-TMM-methyl cationic structure (**282**) over an η^4-isoprenyl cationic structure (**283**). These cations react with water or alcohols to afford butadiene products via nucleophilic attack at C-5. As indicated earlier (Section 6.1.1), the cross-conjugated dienyl cations are believed to be intermediates in the substitution of (**193**) with weak carbon nucleophiles (Scheme 53). In these cases, nucleophilic attack occurs on C-4 to give predominantly TMM products.[263]

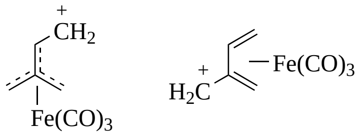
(**194**)

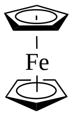


(**282**) (**283**)

7.2 Ferrocene and its Derivatives

The discovery of ferrocene and the establishment of its structure in the 1950s mark the beginning of modern organometallic chemistry. Today ferrocene chemistry is ubiquitous, and numerous significant applications are to be found in the areas of homogenous catalysis, asymmetric organic synthesis, and materials science. Owing to space limitations, it is not possible here to provide a complete listing of these applications; the reader should seek out more comprehensive sources, such as the 1995 nomograph edited by Togni and Hayashi.[401] There are also a number of more recent review articles available.[402–411]

The reaction of cyclopentadienylmagnesium bromide with $FeCl_3$ was reported by Kealy and Pauson to afford the orange crystalline $Fe(C_5H_5)_2$ (mp 173 °C), which they formulated as a bis-σ-bonded complex.[412] A similar complex was reported by Miller, Tebboth, and Tremaine.[413] This compound was subsequently shown to be the first recognized 'sandwich' complex (*see Sandwich Compound*), and was termed ferrocene (*see Ferrocene*) by Whiting because of its aromatic character.[414] Ferrocene (**284**) has been shown to assume a D_{5h} structure by gas-phase electron diffraction,[415] and is only twisted by 9° from D_{5h} below its Λ-point (164 K) in the solid state. The lengths of the Fe–C bonds and the C–C bonds are 2.064 and 1.440 Å, respectively, and the hydrogen atoms are bent out of the cyclopentadienyl plane towards the iron atom by about 4°. The barrier to rotation of the cyclopentadienyl ligands with respect to each other is an extremely low 3.8 kJ mol^{-1}. Owing to the small energy difference between eclipsed (D_{5h}) and staggered (D_{5d}) conformations, substituted ferrocenes have been found to adopt both conformations.[416] Ferrocene gives a single signal in ^{1}H (4.04 ppm), ^{13}C (68.2 ppm) and ^{57}Fe (+1535.2 ppm with respect to $Fe(CO)_5$) NMR spectra.[32,318,417] The compound is air and water stable and has a $\Delta H_f°$ of 158 ± 4 kJ mol^{-1}.



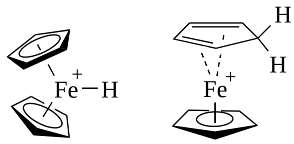
(**284**)

There are numerous methods for the preparation of ferrocene, the most common being the reaction of alkali cyclopentadienyl anions with $FeCl_2$.[418] Ferrocene itself is commercially available and considerably inexpensive. The preparation of substituted ferrocenes will be discussed in subsequent sections.

7.2.1 Electrophilic Attack

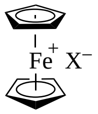
Because it is an electron-rich compound, ferrocene reacts with electrophiles. The reaction of (**284**) in strong acid affords the protonated species $[(C_5H_5)_2FeH]^+$ (**285**). The hydrogen is attached to iron, as evidenced by an upfield signal in the ^{1}H NMR spectrum at ca. −12 ppm.[419] In the case of substituted ferrocenes, the two Cp ligands are tilted with restricted rotation about the Cp–Fe axes.[420] The ring protons of (**284**) undergo exchange, even in weakly acidic solution. Since (**285**) is formed in substantial quantities only in strongly acidic media,

it seems unlikely that it is involved in proton exchange, and that the σ-ligand complex (**286**), formed by direct protonation on the cyclopentadienyl ligand, is the intermediate species. In addition, H/D exchange of (**284**) occurs at slower rates in highly acidic solution.[421]



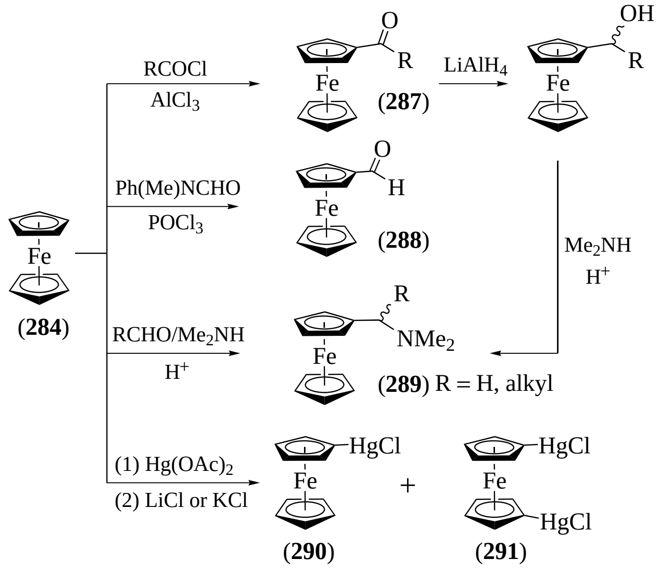
(**285**) (**286**)

Ferrocene reacts with acetyl chloride and aluminum chloride to afford the acylated product (**287**) (Scheme 84). The Friedel–Crafts acylation of (**284**) is about 3.3×10^6 times faster than that of benzene.[419] Use of these conditions it is difficult to avoid the formation of a disubstituted product unless only a stoichiometric amount of $AlCl_3$ is used. Thus, while the acyl substituent present in (**287**) is somewhat deactivating, the relative rate of acylation of (**287**) is still rapid (1.9×10^2 faster than benzene). Formation of the diacylated product may be avoided by use of acetic anhydride and $BF_3{\cdot}Et_2O$. Electrophilic substitution of (**284**) under Vilsmeyer formylation, Mannich aminomethylation, or acetoxymercuration conditions gives (**288**), (**289**), and (**290**/**291**), respectively, in good yields.[422] Racemic amine (**289**) (also available in two steps from (**287**)) is readily resolved, providing the classic entry to enantiomerically pure ferrocene derivatives that possess central chirality and/or planar chirality. Friedel–Crafts alkylation of (**284**) proceeds with the formation of a mixture of mono- and polyalkyl-substituted ferrocenes. The reaction of (**284**) with other electrophiles (e.g. NO_2^+) is not as successful, owing to facile oxidation of ferrocene to the ferricinium cation (**292**) (also known as the ferricenium or ferrocenium cation).

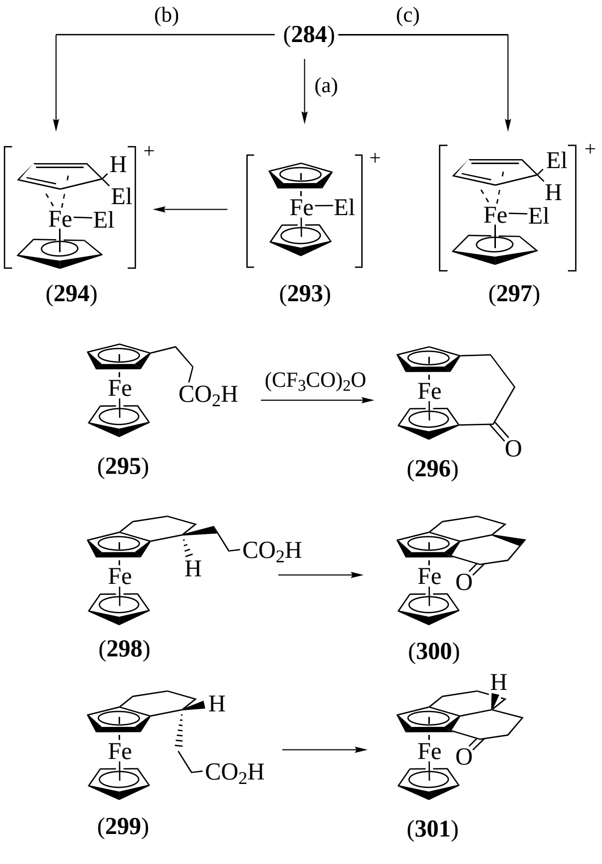


(**292**)

There are a number of pathways possible for the electrophilic substitution of (**284**) (Scheme 85). Pathway (a) involves electrophilic attack at iron to generate (**293**). This pathway is suggested by the results of protonation of ferrocene. Subsequent transfer of the electrophile to the *endo* face of the Cp ligand gives (**294**). Alternatively, direct electrophilic attack on the *endo* face of the ligand, pathway (b), could give (**294**). The fact that facile intramolecular acylation of 3-ferrocenylpropionic acid (**295**), a compound which is constrained to suffer only attack from the *endo* face, gives [3]ferrocenophane (**296**) suggests that the *endo* attack route is feasible.[423] A third possibility, path (c), involves direct electrophilic attack on the less hindered *exo* face of the Cp ligand to give (**297**) followed by loss of a proton.



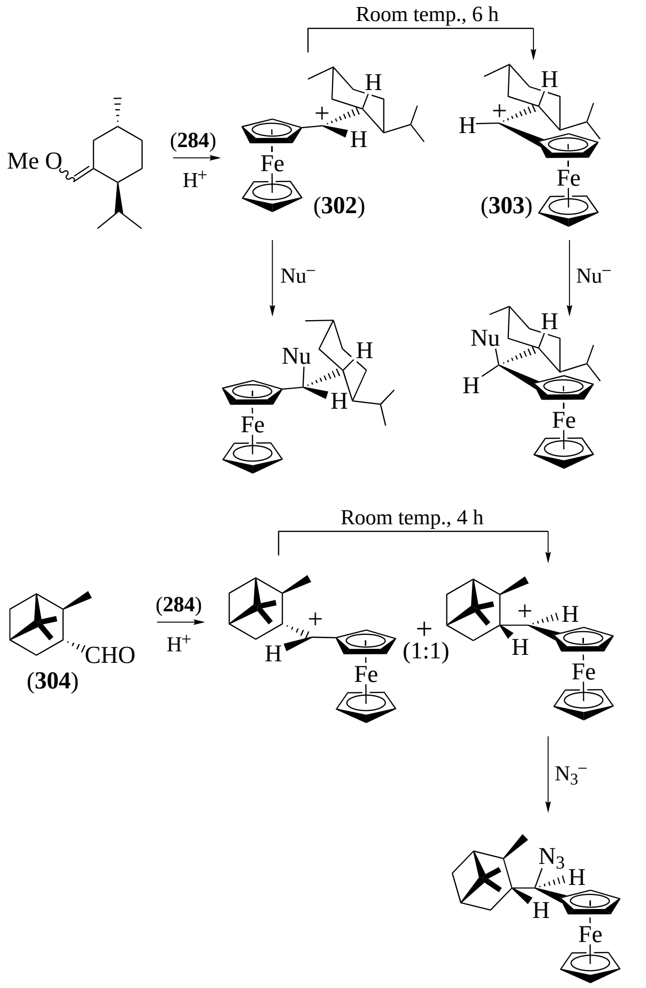
Scheme 84



Scheme 85

The relative rates of intramolecular cyclization of the *exo* and *endo* isomeric carboxylic acids (**298**) and (**299**) to give (**300**) and (**301**), respectively, is ca. 4 (k_{exo}/k_{endo}).[424] If it is assumed that electrophilic attack, and not loss of a proton, is the rate limiting step, then these results imply that there may not be a preference for *endo* attack in intermolecular acylation reactions. It has been proposed that the direction of electrophilic attack is dependent on the strength of the electrophile: for strong electrophiles (e.g. RCO^+), the rate-determining step is attack from the *exo* face (pathway c); for weaker electrophiles (e.g. $AcOHg^+$), attack from the *endo* face (pathway b) is followed by slow loss of the proton. In agreement with this analysis, the kinetic isotope effect (*see Isotope Effect*) for acetoxymercuration of (**284**) is $k_H/k_D = 3.2$ while the isotope effect for acylation of (**284**) is $k_H/k_D = 1.0$.[425]

Reaction of (**284**) with an aldehyde, ketone, or enol ether in the presence of acid results in an electrophilic substitution that produces α-ferrocenylalkyl carbocations that may be trapped by nucleophiles (azides, amines, thiols). This chemistry may be used to prepare enantiomerically pure ferrocene derivatives in a manner that avoids resolution procedures (Scheme 86).[401] For example, the enol ether from (-)-menthone affords a kinetic carbocation (**302**) that may be trapped or allowed to rearrange to the more thermodynamically stable cation (**303**) and then trapped, thus offering a means of controlling the configuration of the stereocenter adjacent to the ferrocene unit. Use of an enantiomerically pure aldehyde derived from α-pinene (**304**) affords a 1:1 carbocationic mixture that similarly isomerizes to a single cation.



Scheme 86

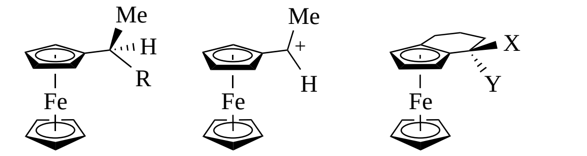
7.2.2 Oxidation

Oxidation of ferrocene gives the 17-electron ferricinium ion (**292**) that is deep red in concentrated solutions. This has been shown electrochemically to be a reversible oxidation with $E_{1/2}$ of 0.34 versus SCE (*see* ***Electrochemistry: Applications in Inorganic Chemistry***). The reaction may be used in the quantitative determination of ferrocene and has been suggested by the IUPAC Commission on Electrochemistry as a standard for measuring redox potentials (*see Redox Potential*) in nonaqueous solutions.[426] Ferrocene (**284**) and the ferricinium cation (**292**) undergo rapid electron exchange which is first order in both with an E_a of $21 \pm 4\,kJ\,mol^{-1}$. The admixture of ferrocene or substituted ferrocenes with tetracyanoquinodimethane (TCNQ) generates charge-transfer salts. Certain of these salts display semiconductor behavior (*see* ***Semiconductors***).[427]

7.2.3 Reactions at the Side Chains

The solvolysis of (1-acetoxyethyl)ferrocene (**305**) in 80% aqueous acetone proceeds at a rate which is ca. 6.5 times faster than the solvolysis of trityl acetate.[428] The rapid rate of this S_N1 solvolysis is attributed to the tremendous stability of the intermediate α-ferrocenylcarbocation (**306**). A review of the relevant literature through 1979 concerning this species has been published.[429] The solvolysis occurs in a stereospecific fashion. Thus, the (*R*)-acetate (**305**) upon solvolysis gives the (*R*)-alcohol (**307**) and acetylation of (*R*)-(**307**) gives (*R*)-(**305**). The acetate (*R*)-(**305**) can be converted into the trimethylammonium salt (*R*)-(**308**) via (*R*)-(**289**), and subsequent solvolysis gives (*R*)-(**305**). Thus, the solvolysis and aminolysis reactions must occur with retention of configuration. It has been suggested that the solvolysis occurs by neighboring group participation of the iron atom, and thus the net inversion is due to preferential ionization of the acetate opposite to iron, followed by rapid nucleophilic attack at the carbocation on the face opposite to the bulky ferrocene substituent. In accord with this proposal, solvolyses of both the *exo* and *endo* acetates (**309**) and (**310**) affords the *exo* alcohol (**311**). However, the solvolysis of (**309**) occurs 2500 times faster than solvolysis of (**310**). The activation entropies for solvolysis of (**309**) and (**310**) are similar, so the

difference in rate must not be due to steric hindrance effects on the departure of the *endo* acetate functionality.

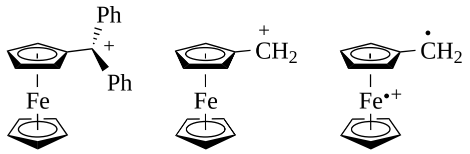


(**305**) R = OAc
(**307**) R = OH
(**308**) R = NMe_3^+
(**306**)
(**309**) X = OAc, Y = H
(**310**) X = H, Y = OAc
(**311**) X = OH, Y = H

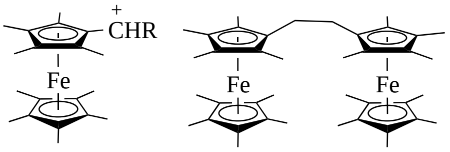
The α-ferrocenyl carbocation complexes are also generated by dissolution of the corresponding alcohols or alkenes in acid (e.g. conc. H_2SO_4 or CF_3CO_2H); the cationic species are detectable by NMR. For cation (**306**) in CF_3CO_2H the signals of the substituted Cp ligand appear as a series of four distinct signals (4.49–6.36 ppm). The presence of four signals indicates that there is restricted rotation, on the NMR timescale, about the Cp to α-C bond. The barrier to rotation is 84.0 kJ mol^{-1}, which is consistent with the stereoselective solvolysis results.

A number of models to explain the stabilizing effect of the α-ferrocenyl substituent have been proposed.[429] The most acceptable model maintains a planar cyclopentadienyl ligand; however, the carbocation substituent is displaced out of the cyclopentadienyl plane toward the iron metal. X-ray diffraction analysis of the α-ferrocenyl carbocation (**312**) is consistent with this model. The diphenylmethyl substituent is bent out of the Cp plane by 20.7° and each of the two Cp rings are planar tilted by 9.3° with respect to being parallel. The α-C–Fe distance (2.715 Å) is considerably longer than normal Fe–C bond distances (ca. 2.1 Å).[430] Extended Hückel calculations of the parent α-ferrocenyl carbocation (**313**) indicate that the carbocation is tilted out of the Cp plane in the lowest energy structure. The positive charge on the iron metal is +0.5, with the remainder of the positive charge being distributed on the carbon atoms. The ground state is determined by computation to be a singlet state (*see Singlet State*); however, positioning the carbocation atom in the plane of the cyclopentadienyl ligand (cf. **314**) results in a triplet ground state.[431] Nonamethylferrocenyl carbocations (**315**) may be prepared from the corresponding carbinols. The cation (**315**; R = H) slowly undergoes dimerization in the solid state and more rapidly in solution to afford the bisferricinium cation (**316**). Cations (**315**) with greater steric hindrance (e.g. R = mesityl) give ^{1}H NMR and Mössbauer spectra which are consistent with the presence of both singlet and triplet species.[432]

Ferrocenyl ketones (**287**) and ferrocenyl aldehyde (**288**) readily undergo a number of classic organic transformations, such as aldol, Knoevenagel, and Wittig reactions. Conversion of (**288**) into the dimethylaminoacetonitrile (**317**)

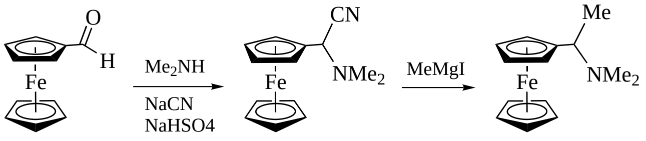


(**312**) (**313**) (**314**)



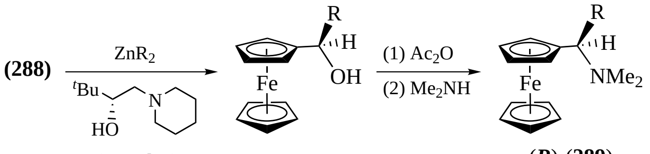
(**315**) (**316**)

followed by treatment with MeMgI provides another approach to the Ugi-amine (**289**, R = CH_3), which is resolved by using (*R*)-(+)-tartaric acid (equation 73).[4] The preparation and resolution of this compound allowed for the development of chiral ferrocene-based ligands. Another approach involves asymmetric alkylation of (**288**), leading to chiral secondary alcohols with excellent selectivities (up to 99% ee), and is accomplished with dialkylzincs in the presence of a chiral amino alcohol (equation 74).[403] As described above, this can be used as an approach to chiral amines by conversion to the corresponding acetate and subsequent aminolysis in a stereoretentive manner. Alternatively, (**288**) can be converted into an enantiomerically pure hydrazone and then selectively alkylated with an organolithium nucleophile. After hydrogenation of the product hydrazine, acetylation gives *N*-acetylamines in high optical purity (up to 94% ee) (equation 75).[403] Finally, asymmetric reduction (with BH_3 and the Corey/Bakshi/Shibata catalyst (CBS) catalyst) of ferrocenyl ketones and diketones (*see Diketones*) can also be readily accomplished.[433,434]



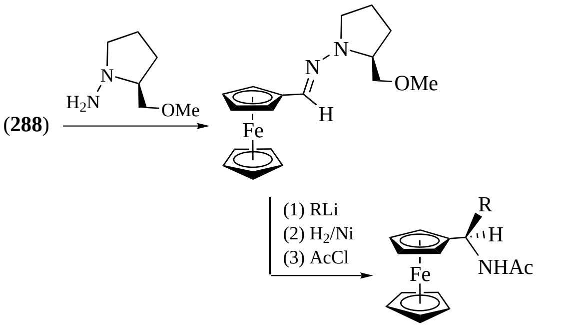
(**288**) (**317**) (**289**)

(73)



(5 mol%) (***R***)-(**289**)

(74)



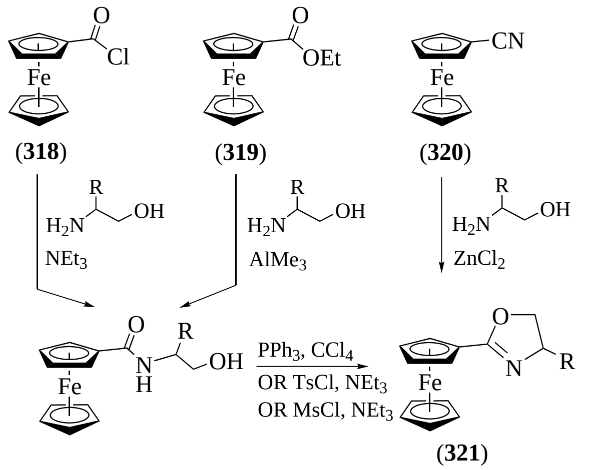
(75)

Ferrocenoyl chloride (**318**), ethyl ferrocenecarboxylate (**319**), and cyanoferrocene (**320**) are all used as starting materials for the synthesis of 2-ferrocenyloxazolines (**321**) (Scheme 87). Chirality may be incorporated into the oxazoline ring, and these important chiral compounds have been used to prepare a great number of ferrocene derivatives that are used as catalysts in asymmetric synthesis.[404]

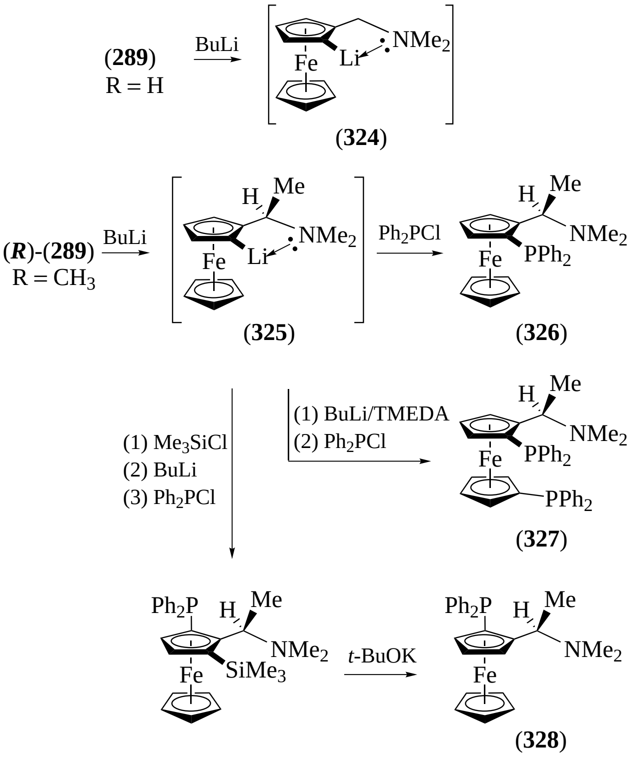
7.2.4 *Metalation and Metalation-derived Ferrocenes*

Ferrocene is weakly acidic and treatment of (**284**) with *n*-butyllithium affords the lithiated species (**322**) (equation 76). In the presence of *N*,*N*,*N'*,*N'*-tetramethylethylenediamine TMEDA), treatment of (**284**) gives the 1,1′-dilithiated species (**323**).[435] A number of other metalated ferrocene derivatives containing a M–C bond (M = B, Cu, Si, P, Ge, As, Sn) can be prepared from (**322**) and (**323**).[401] Lithiation of alkyl-substituted ferrocenes occurs both homo- and heteroannularly, while the lithiation of *N*,*N*-dimethylaminomethylferrocene (**289**, R = H) is directed to the 2-position by chelation with the nitrogen lone pair (*see Lone Pair*), to give (**324**) (Scheme 88).[435] Anion (**324**) and products generated by the addition of appropriate electrophiles are planar chiral. For analogs bearing a chiral center, such as (*R*)-(1-dimethylaminoethyl)ferrocene (**289**, R = Me), this directed lithiation can occur with high diastereoselectively, and (**289**, R = Me) is preferentially converted to the (*R*, *R*)-lithiated derivative (**325**, 96:4 dr). This is a highly significant transformation, as it created a multitude of opportunities for the development of new chiral catalysts using compounds related to this type of planar chiral ferrocene as bidentate ligands. For example, chiral ferrocenyl bis- and monophosphines (**326**, PPFA) and (**327**, BPPFA) are prepared using this methodology. The diastereomer (**328**) may be prepared by formation of (**325**) and blocking this site toward further lithiation with a removable silyl group. Subsequent lithiation, transmetalation (*see Transmetalation*), and deprotection gives (**328**).[401,405]

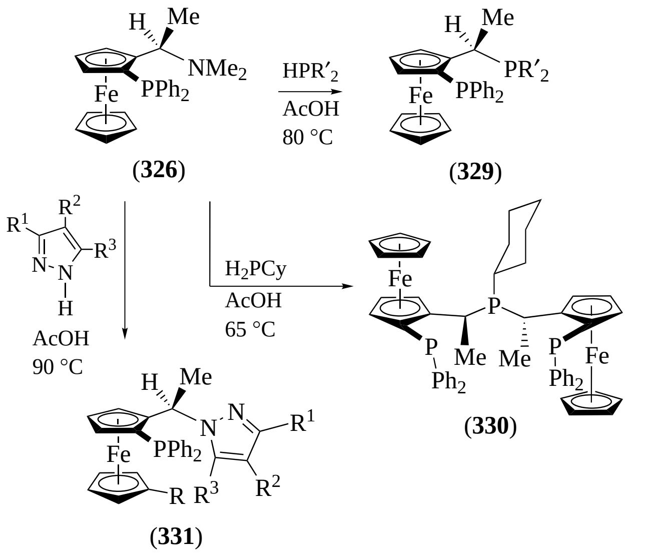
Additional ligand families can be prepared via further modification of ferrocenes (**326**), (**327**), or (**328**). Retentive S_N1-like displacement of the dimethylamino group with secondary phosphines affords ferrocenyl bisphosphines (**329**, Josiphos), and the use of primary phosphine gives the tridentate (*see Tridentate Ligand*) bisferrocene (**330**, Pigiphos) (Scheme 89).[401] Additionally, pyrazoles of type (**331**) are available, or a two-step process via acetate (**332**) provides ferrocenes with hydroxylated or aminated side chains (**333**) (Scheme 90). Using iodine as an electrophile for anion (**325**) affords iodoferrocene (**334**) that leads to a family of *trans*-chelating diphosphine bisferrocenes by means of a nickel-catalyzed coupling process (**335**, TRAP). Finally, double asymmetric reduction of the ferrocene diketone (**336**)



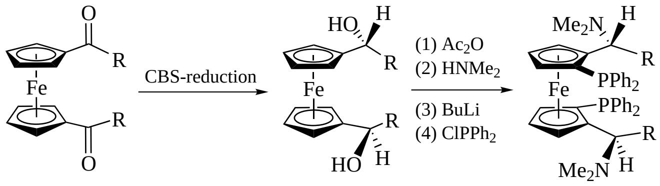
Scheme 87



Scheme 88

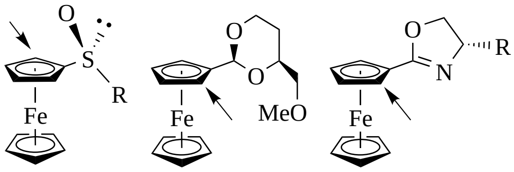


Scheme 89

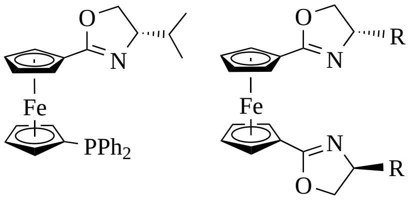


(336) (337)

(77)

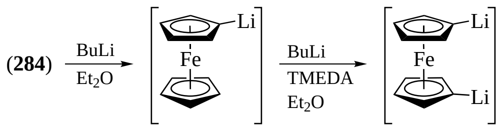


(338) (339) (321)



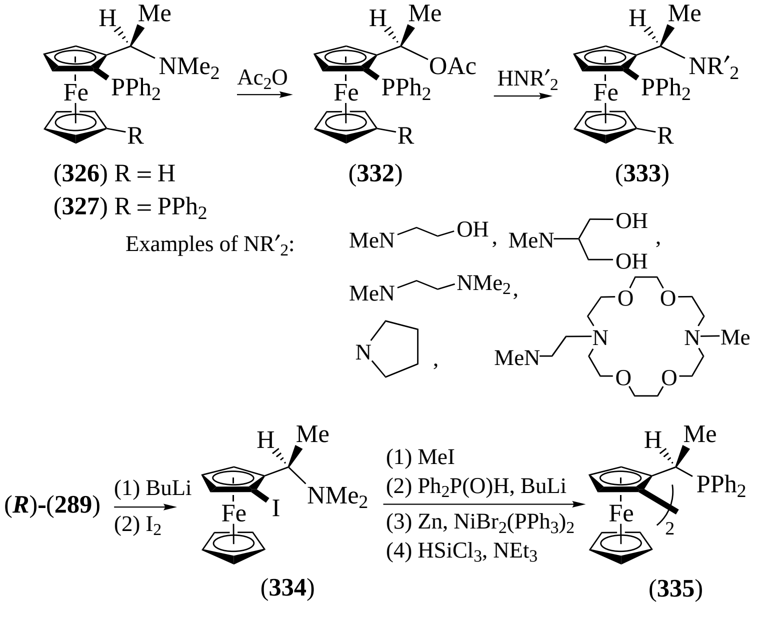
(340) (341)

and subsequent manipulation of the product diol produces a family of C_2-symmetric ferrocene bis-aminophosphines (**337**) (equation 77).[436]



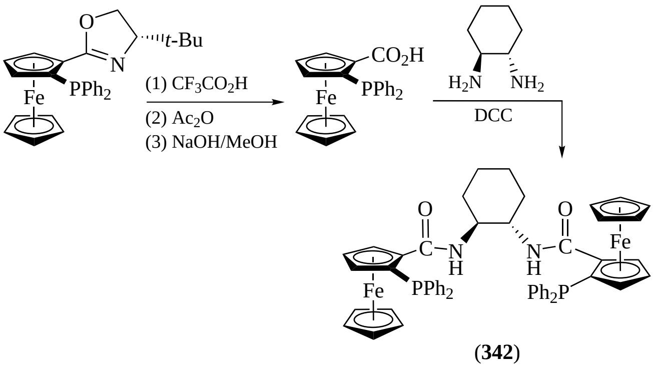
(322) (323) (76)

Many of the ferrocene ligand families described above are derived from a resolved chiral precursor (i.e. **289**). Efforts to prepare planar chiral ferrocenes also employ other strategies that rely on a directed metalation (*see Orthometalation*). Sulfoxide (**338**), acetal (**339**), and oxazolines of type (**321**)

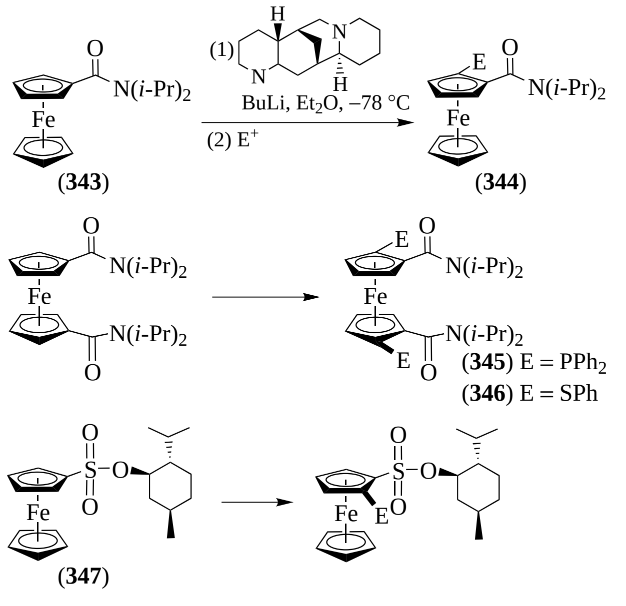


Scheme 90

are all selectively metalated at the indicated position and are trapped with electrophiles; for (**340**) and (**341**) good selectivity depends greatly on conditions (lithiating agent, solvent, stoichiometry).[407] The numerous derivatives of oxazoline (**321**) prepared in this manner are also used as ligands in asymmetric synthesis, particularly those that possess phosphorus or sulfur atoms on the ferrocene ring adjacent to the oxazoline.[404] These derivatives are further elaborated into still more variations; an example is bisferrocene (**342**) (equation 78). A direct nonauxiliary based approach is performed by use of (-)-sparteine to mediate enantioselective deprotonation of N,N-diisopropyl ferrocenecarboxamide (**343**) to produce (**344**) (Scheme 91).[437] Similarly, the C_2-symmetric bisphosphine (**345**) or bissulfide (**346**) can be prepared this way with high enantioselectivity by sequential deprotonations, while a matched chiral-directed metalation of (-)-menthylferrocenesulfonate (**347**) proceeds with a diastereoselectivity of *ca.* 90:10.[438,439]

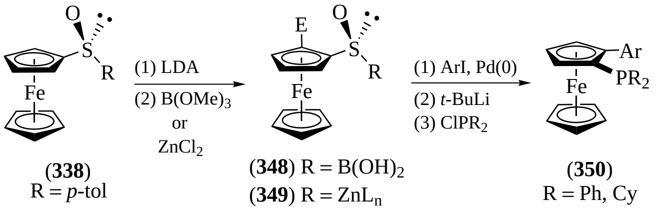


(78)

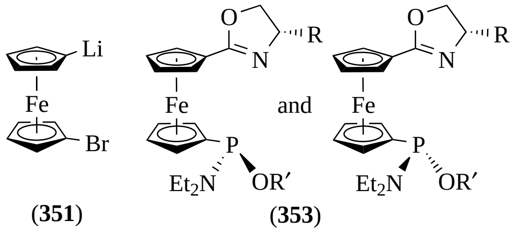


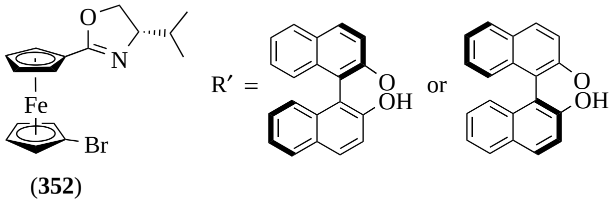
Scheme 91

Metalation of sulfinylferrocene (**338**) to give the lithiated species, followed by transmetalation to give either the isolable boron analog (**348**) or the nonisolable zinc analog (**349**), is an approach used to access yet another class of ferrocene derivatives (equation 79).[440–442] Palladium-catalyzed coupling of (**348**) or (**349**) with aryl iodides affords planar chiral aryl ferrocenes that are converted by standard transformations into planar chiral monophosphine aryl ferrocenes (**350**) that are also useful ligands in asymmetric catalysis. With appropriate *ortho*-substitution on the aryl ring, ferrocenes that possess axial chirality as well as planar chirality are prepared; if the *ortho*-substitutent is a second phosphine unit, access to a bisphosphine aryl ferrocene is achieved.[443]

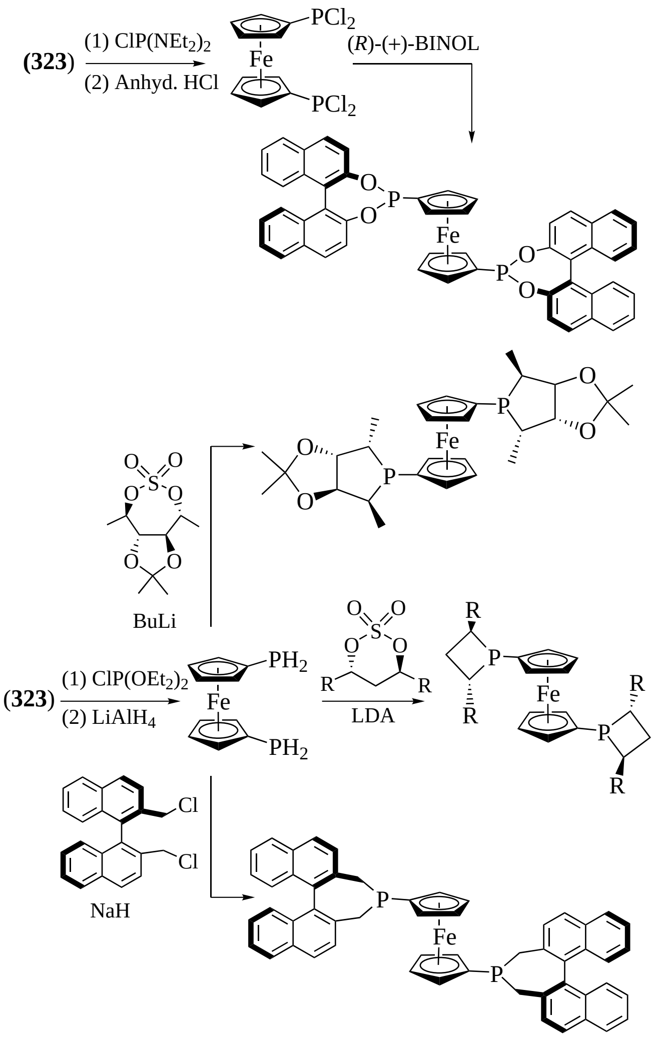


(79)



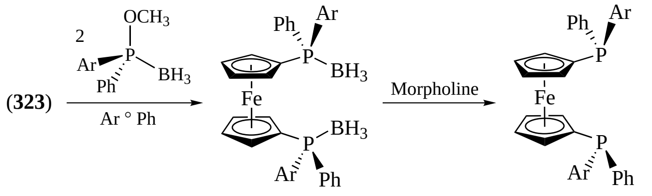


Lithioferrocene (**322**) or dilithioferrocene (**323**) can also be prepared, and then utilized *in situ*, from the corresponding halo- or dihaloferrocenes by halogen-metal exchange with alkyl lithiums. Alternatively, monolithiation of 1,1′-dibromoferrocene gives rise to anion (**351**), which may be reacted with an electrophile in order to afford additional ferrocene derivatives. In this way, monophosphine oxazoline ferrocene (**340**) is prepared from bromo oxazoline ferrocene (**352**), a compound that also is used to prepare chiral-at-phosphorus ferrocenes (**353**).[444,445] Other chiral-at-phosphorus ferrocenes (**354**) are made from (**323**) and a phosphite borane as the electrophile (equation 80).[446,447] The phosphorus atoms may also be contained in a ring that possesses chirality; the sequences used to prepare this family



Scheme 92

of ferrocene ligands also begin with (**323**) (Scheme 92).[448–451]



(80)

7.2.5 *Ferrocenes from Chiral Cyclopentadienylides*

There are a number of examples of chiral ferrocene derivatives prepared by reaction of substituted cyclopentadiene anions with $FeCl_2$ or a monocyclopentadienyl iron species rather than using the strategy of introduction and modification of a side chain on ferrocene itself. Addition of methyl lithium to chiral fulvene (**355**) produces the chiral cyclopentadienylide which reacts with Cp*Fe(acac) to give the heteroleptic (*see Heteroleptic Compound*) metallocene (*see Metallocene Complexes*); replacement of the chiral auxiliary gives (**356**), the monoCp* analog of Ugi-amine (**289**) in 75% ee (Scheme 93).[452] Similarly, chiral dianion (**357**) is converted into (**358**) or (**359**).[453] Also, mannitol-derived cyclopentadienylide (**360**) and chiral cyclopentadienylide (**361**) produce C_2-symmetric ferrocenes (**362**) and (**363**) (Scheme 94).[454,455] Both heteroleptic ferrocene analogs and C_2-symmetric ferrocenes are available in high optical purity by the use of (-)-sparteine-mediated deprotonation (equation 81).[456]

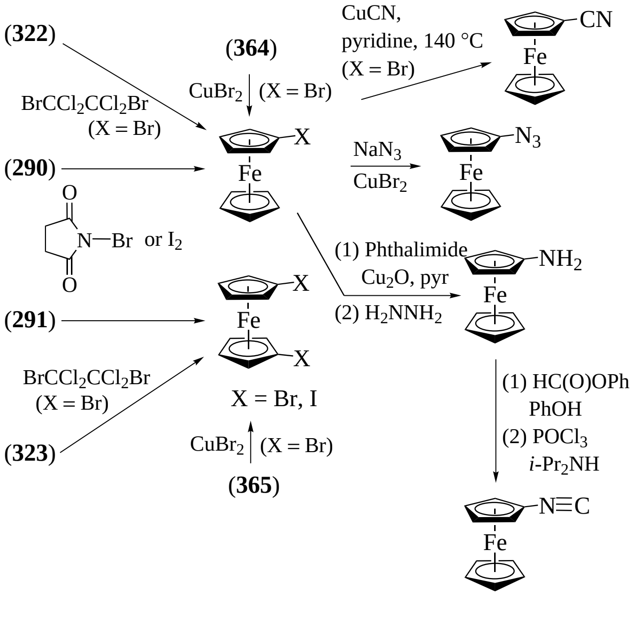


Scheme 96

7.2.6 Heteroatom-substituted Ferrocenes

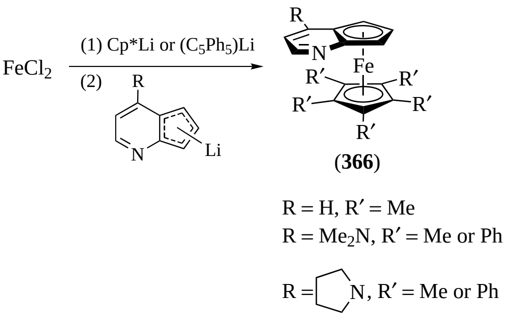
Some aspects of the preparation of heteroatom-substituted ferrocenes have previously been discussed (Section 7.2.4); a review article that covers this topic through 1994 is available and offers a more complete treatment than can be presented here.[401] Borylation and diborylation of ferrocene is readily accomplished using BBr_3 or BI_3; the haloborylferrocenes provide access to a large number of aminoboryl-, alkylboryl-, thioboryl-, and boronateferrocenes by treatment with amines, alkylstannanes, thiols, and alcohols, respectively (Scheme 95). Methyl- and phenylbromoborylferrocene are available by direct addition of Br_2BMe or Br_2BPh to ferrocene.[457] Ferrocene boronic acid (**364**) and ferrocene diboronic acid (**365**) are both commercially available, and are prepared by treatment of lithio- or dithioferrocene (**322**, **323**) with trialkylborates followed by hydrolysis. These boronic acids can undergo Suzuki couplings to provide aryl-substituted ferrocenes or be converted into the ferrocenyl acetates.[401,458]

Mercurioferrocenes (**290**) and (**291**) are separable by Soxhlet extraction and these may be used to prepare bromoferrocene or dibromoferrocene or the iodo analogs. Alternatively, these halogenated ferrocenes are prepared from the ferrocene boronic acids or from anions (**322**) or (**323**).[401] Bromoferrocene is the starting material for cyanoferrocene, azidoferrocene, or aminoferrocenes, generally in the presence of a copper salt. Aminoferrocene can be acylated to produce an amide, or converted to isocyanoferrocene by a formylation/dehydration sequence (Scheme 96).[459] The 1,1′-diisocyanoferrocene is available from the bis(acyl)azide, itself derived from ferrocene dicarboxylic acid.[460]

Hydroxyferrocene is prepared by hydrolysis of ferrocene acetate, and it undergoes many of the same organic transformations (alkylation, silylation, acylation, acetal formation) that are carried out with phenol. Access to thioferrocene or dithioferrocene is easily accomplished by treatment of anions (**322**) or (**323**) with elemental sulfur, and a number of alkylated and metalated derivatives are known. Finally, a great number of coordination compounds that possess a transition metal center directly bound to the ferrocene unit are known; this topic is beyond the scope of this review.[401]

A series of planar chiral pyridine-fused ferrocene analogs (**366**) have been prepared and the enantiomers are resolved by chiral High performance (pressure) liquid chromatography (HPLC) (*see High Performance Liquid*

Chromatography) (equation 82).[408] These complexes are used as enantioselective nucleophilic catalysts for reactions such as the rearrangements of *O*-acylated azlactones, oxindoles, and benzofuranones, and the kinetic resolution of secondary alcohols via acylation. X-ray crystal structures have been obtained for *N*-acylated derivatives of (**366**), allowing for characterization of a likely intermediate along the catalytic pathway.

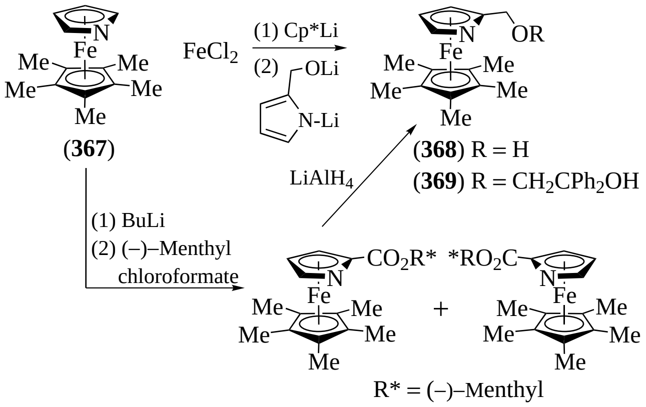


(82)

7.2.7 Heteroferrocenes

Ferrocene analogs that possess a heteroatom in place of one carbon atom have been known for some time. The most common of these heteroferrocenes are the azaferrocenes and the phosphaferrocenes, though complexes having sulfur, boron, arsenic, antimony, bismuth, and nickel atoms are known.[4,461] Review articles that are either comprehensive (in the case of phosphaferrocenes), or cover aspects of this chemistry (in the case of azaferrocenes), are available; space restrictions for this review do not permit complete coverage of these areas.[409,462] Instead, recent developments in the area of planar chiral heteroferrocenes, especially as it relates to asymmetric catalyst design, will be the primary focus here.

The parent azaferrocene is obtained in two steps by the reaction of (**6c**) with pyrrole to give CpFe-NC_4H_4, followed by photodecarbonylation.[463] Preparation of the Cp* analog (**367**) is carried out by successive treatment of $FeCl_2$ with Cp*Li and potassium pyrrolide.[464] Heteroferrocenes that possess a substituent in the 2- or 3-position are planar chiral, and a racemic mixture of 2-substituted azaferrocene (**368**) is similarly obtained by replacing potassium pyrrolide with the dilithium salt of pyrrole-2-methanol (Scheme 97). Enantiomerically pure (**368**) is obtained by 2-lithiation of (**367**) and conversion to the diastereomer esters that are chromatographically separable. Reduction affords the desired enantiomerically pure azaferrocene, which upon silylation is used as an enantioselective nucleophilic catalyst for the addition of alcohols to ketenes.[464,465] Alcohol (**369**) is used as a ligand in the enantioselective addition of organozinc reagents to aldehydes.[466] A related C_2-symmetric bisazaferrocene is resolved by chiral HPLC and is used as an enantioselective alkene Cu(I)-cyclopropanation catalyst with diazoesters; an X-ray crystal structure is available for this bidentate ligand in

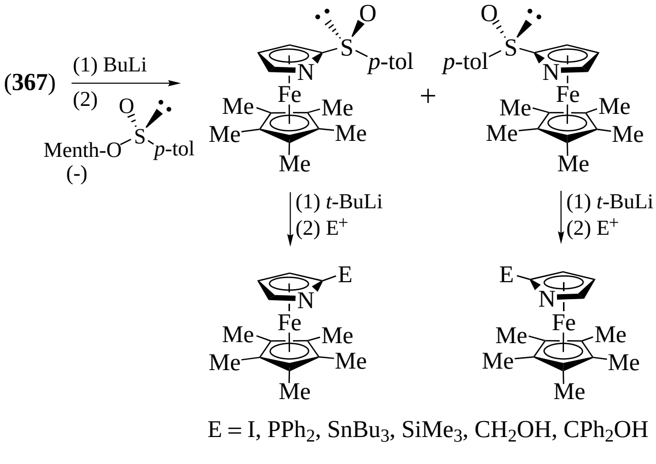


Scheme 97

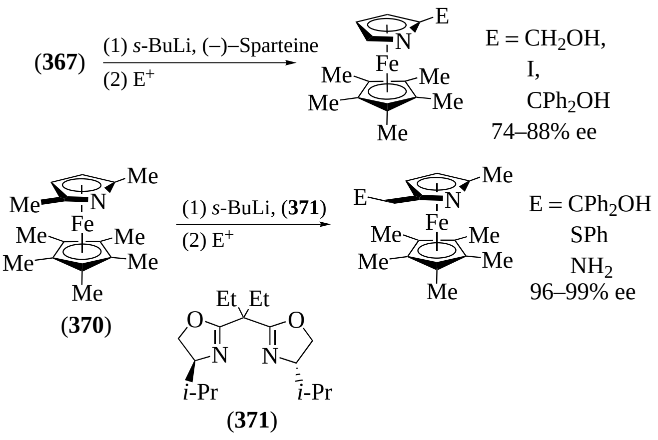
a Cu(I) complex (styrene occupies the other positions of this square-planar complex).[467]

Another approach to enantiomerically pure planar chiral azaferrocenes involves 2-lithiation of (**367**) followed by addition of (-)-menthyl-(*S*) – *p*-toluenesulfinate. The diastereomeric sulfoxides thus obtained are chromatographically separable, and treatment of each diastereomer with *t*-BuLi produces an enantiomerically pure planar chiral anion that may be trapped with an electrophile (Scheme 98).[468] Finally, in order to obviate the need for performing a resolution or a chromatographic separation, chiral ligand-mediated enantioselective deprotonations have been investigated. Lithiation of (**367**) in the presence of (-)-sparteine followed by addition of an electrophile gives the 2-substituted azaferrocene in good enantioselectivities (Scheme 99).[469] However, lateral lithiation of (**370**) mediated by *S*-valine-derived bis(oxazoline) (**371**) provides planar chiral products with excellent enantioselectivity.

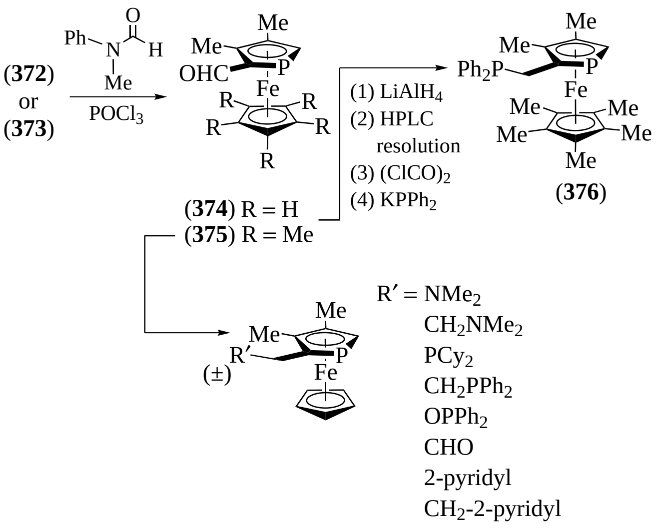
Unlike the azaferrocenes, direct lithiation of phosphaferrocenes does not occur as the strong nucleophile attacks the



Scheme 98

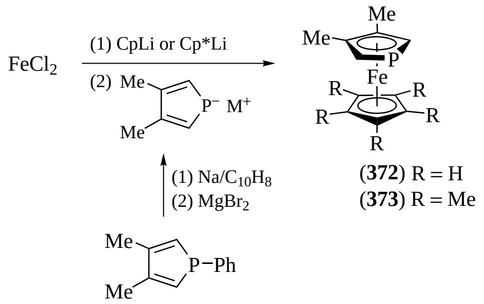


Scheme 99



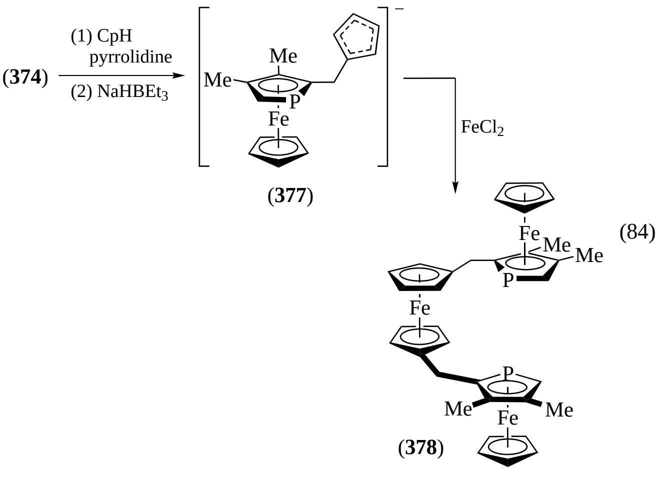
Scheme 100

phosphorus atom. Instead, electrophilic substitution reactions such as acylation and formylation are possible and have been used as an entry into planar chiral systems of this class of heteroferrocenes. The achiral complex (**372**) derived from the anion of 3,4-dimethylphosphole has long been known, and the Cp* analog (**373**) has been recently prepared (equation 83) and was shown to catalyze epoxide ring opening in the presence of trimethylsilyl chloride.[470]



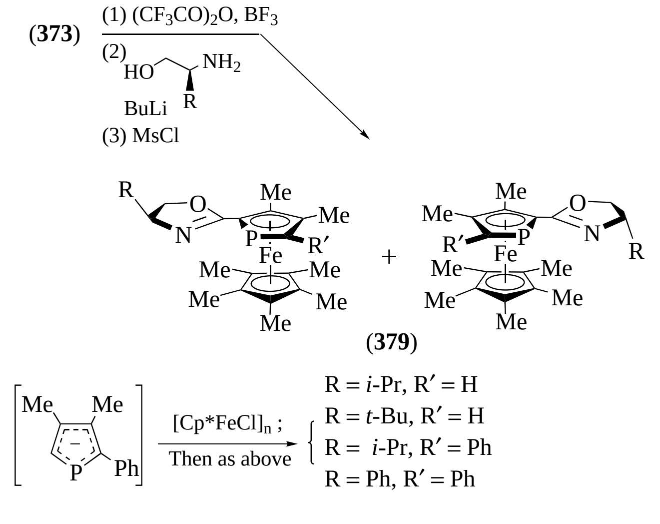
(83)

Vilsmeier formylation of (**372**) and (**373**) proceed smoothly, leading to planar chiral racemic aldehydes (**374**) and (**375**) which can be converted into a number of derivatives by standard methodologies (Scheme 100).[409,471,472] Addition of methyl Grignard to (**374**) is highly diastereoselective, which is in contrast to $LiAlH_4$ reduction which occurs in a stereorandom manner. Acid-promoted nucleophilic substitution of the Grignard-derived secondary alcohol can occur with inversion or retention, depending on the conditions; the intermediate fulvene-like cation slowly undergoes *E*-*Z*-isomerization.[473] Resolution of (**374**) is achieved by chromatographic separation of the diastereomeric aminals, and resolution of the primary alcohol derived from (**375**) is accomplished via chiral HPLC. The latter compound is converted into a bisphosphine (**376**) that is used as a ligand in asymmetric hydrogenations or enantioselective isomerizations of allylic alcohols to β-substituted aldehydes. Condensation of resolved aldehyde (**374**) with cyclopentadiene followed by reduction gives phosphaferrocene cyclopentadienide (**377**) which forms the unique 1,1′-bisphosphaferrocenyl ferrocene (**378**) (equation 84).[474] This complex acts as a bidentate ligand; an X-ray crystal structure of the $Mo(CO)_4$ complex has been obtained, and the ligand has also been used in a palladium-catalyzed asymmetric allylic substitution.



(84)

Planar chiral phosphaferrocene-oxazolines (**379**) constitute another family of complexes that are useful as ligands in asymmetric catalysis. Preparation of these takes advantage of a modified Friedel–Crafts acylation of (**373**) and an unusual conversion of the resulting trifluoromethyl ketone into an amide that is then cyclized to an oxazoline. The diastereomeric complexes thus formed are chromatographically separable and are used in a palladium-catalyzed asymmetric allylic substitution. Modification of this complex by using the anion derived from 3,4-dimethyl-2-phenylphosphole gives more



Scheme 101

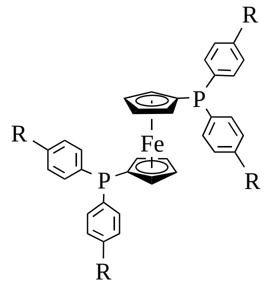
substituted analogs (**379**, R′ = Ph) that are used in the copper-catalyzed enantioselective conjugate addition of diethyl zinc to acyclic enones (Scheme 101).[475]

7.2.8 Supported Ferrocenyl Phosphine Ligands

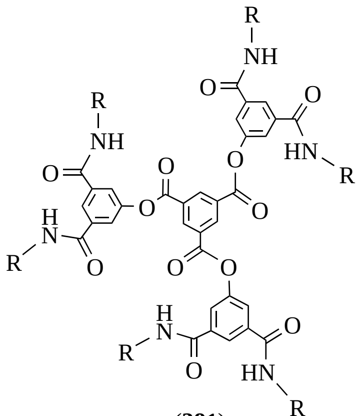
The tremendous growth of the use of enantiomerically pure ligands in homogeneous asymmetric catalysis as led to significant efforts to immobilize the active catalysts in order to recycle them or prevent (or minimize) metal leaching into products. Both achiral and chiral ferrocenyl phosphines are among those catalysts that have been utilized in this context, and detailed descriptions of this research have appeared in a number of review articles.[405,476,477]

One approach that is taken is to place the catalytic 1,1′-bisphosphine ferrocene unit in the core of carbosilane dendrimers (**380**). NMR evidence reveals that addition of $PdCl_2$ affords a bidentate palladium complexes with *cis* stereochemistry, and when used in conjunction with catalytic amounts of a palladium source (**380a–c**) acts as ligand and catalysis of allylic alkylation reactions is observed. Product regioselectivity is affected by the size of the dendrimeric system. A similar ferrocenyl dendrimer (**380d**) is used as a ligand in rhodium-catalyzed hydrogenations; catalyst activity, level of leaching, and recyclability all compared favorably to nondendrimeric 1,1′-bisphosphine ferrocene dppf ligand.

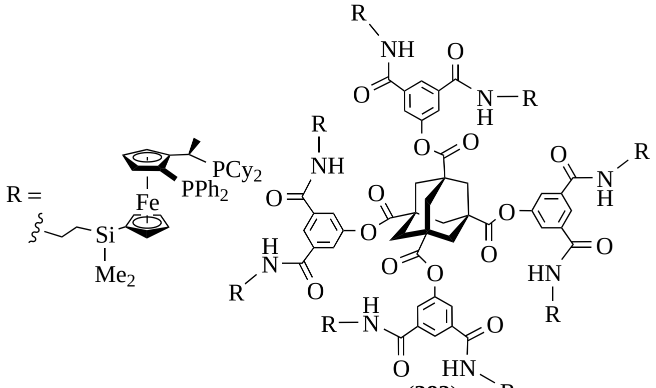
A second strategy is to place multiple chiral Josiphos-type (**329**) units along the exterior of dendrimers, and successful applications for rhodium-catalyzed asymmetric hydrogenation utilize cores composed of benzene-1,3,5-tricarboxylic acid esters (**381**), adamantane-1,3,5,7-tetracarboxylic acid esters (**382**), and cyclophosphazenes (*see Phosphazenes*) (**383**).[478] Enantioselectivities are excellent and these dendrimeric materials can be recovered by filtration through a nanofiltration membrane.



(**380a**) R = $(CH_2{=}CHCH_2)_3SiCH_2CH_2$–
(**380b**) R = $[(CH_2{=}CHCH_2)_3Si(CH_2)_3]_3SiCH_2CH_2$–
(**380c**) R = $[(R_3SiCH_2CH_2CH_2)_3Si(CH_2)_3]_3SiCH_2CH_2$–
(**380d**) R = $(Me_3SiCH_2CH_2CH_2)_3SiCH_2CH_2$–



(**381**)

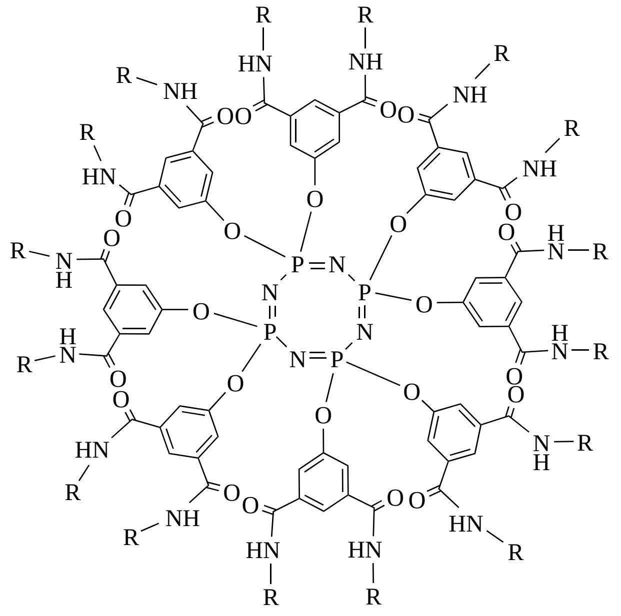


(**382**)

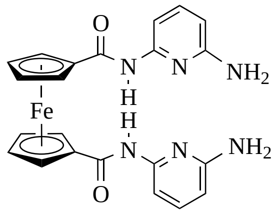
Other means of immobilizing ferrocenyl phosphine ligands include covalent (*see Covalent Bonds*) attachment to either silica gel (*see Silica*) or solid support poly(ethylene glycol) (TantaGel), or confinement within mesoporous MCM-41.[405]

7.2.9 Ferrocene Derivatives as Receptors

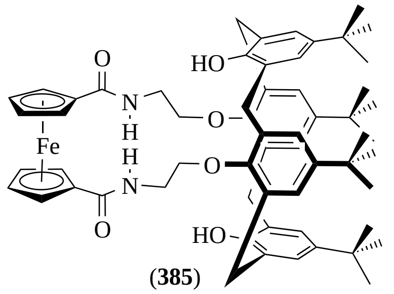
As the synthetic community embraced the fields of supramolecular chemistry and molecular recognition, active research areas developed that included the use of ferrocene



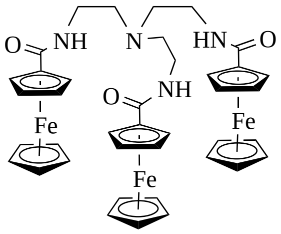
(**383**)



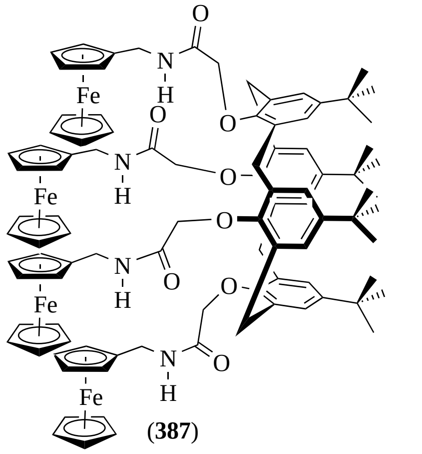
(**384**)



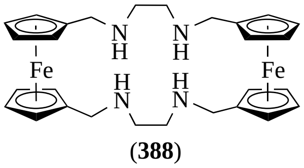
(**385**)



(**386**)



(**387**)



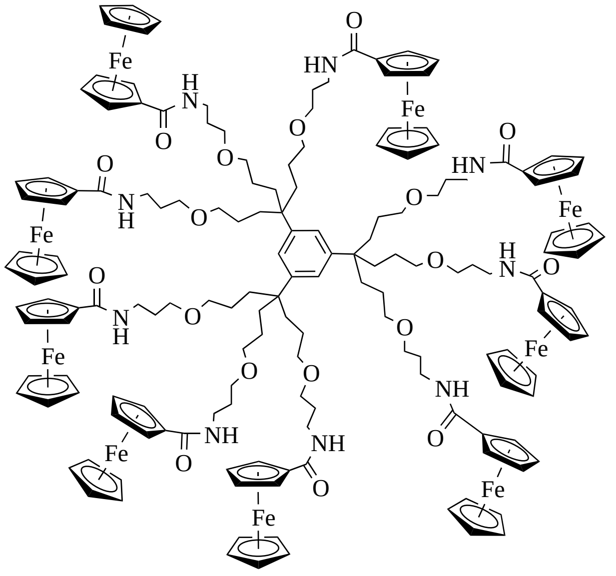
(**388**)

derivatives as receptors and sensors. Though results mostly involve the selective binding for particular anionic species as a result of redox properties (*see Redox Properties & Processes*) of the ferrocene unit, some efforts have studied selective binding of dicarboxylic acids through hydrogen bonding (*see Hydrogen Bonding*). Some recent and thorough reviews that either focus on or simply include the role of ferrocene derivatives in this chemistry are available and should be consulted for a more complete discussion than will be presented here.[479–481]

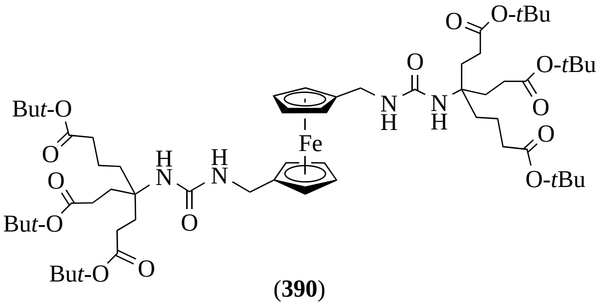
A number of synthetic receptors based on elaboration of ferrocenecarboxamide or ferrocenyl amines are known; since the ferrocene unit or units are neutral they do not bind with anions. Instead, oxidation to the positively charged ferrocenium ion is induced, and electrostatic binding can occur. Examples include complexes (**384–387**) that selectively bind $H_2PO_4^-$, complex (**388**) that discriminates for sulfate over phosphate (pH 4, in aqueous THF), and dendrimeric complex (**389**) that also registers a cathodic shift (and oxidation to ferrocenium) upon addition of $H_2PO_4^-$. Variations on complex (**386**) that utilize a cyclotriveratrylene scaffold bind $H_2PO_4^-$ as well as ATP^{2-}, and a ferrocene-zinc metalloporphyrin (*see Porphyrin*) receptor that is ringed with ferrocenyl amide units is also known.[480] Finally, 1,1′-ferrocenedicarboxamides equipped with carbon chains that terminate with phosphine units are known; complexation of the phosphines to metal centers [$Mo(CO)_4$, $Cr(CO)_4$, Rh(CO)Cl, $Ru(bpy)_2Cl$] strengthens anionic binding.[480] A number of polyferrocene aza- and oxomacrocycles (*see Macrocycle*) exist a well, and ferrocene boronic acid (**364**) exhibits selectivity for fluoride in the presence of a number of other anions.[480]

Urea-substituted ferrocenes are also capable of binding anions. In the case of (**390**), the presence of bulky *t*-butyl groups appears to reverse the selectivity of binding, where chloride is instead favored over $H_2PO_4^-$.[482] Enantiomerically pure (**391**) (prepared by diastereoselective nucleophilic addition to a chiral ferrocene oxime) binds a racemic mixture of the carboxylate anion, tetrabutylammonium 2-phenylbutyrate. While the binding constant of (*R*)-carboxylate is greater than that of its enantiomer, the difference is only moderate but does suggest an opportunity for the design of chiral receptors than can bind enantioselectively.[483]

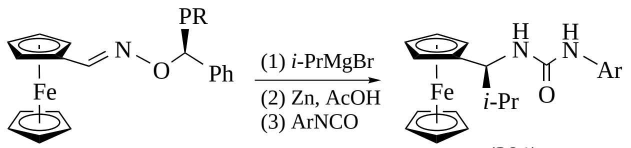
A series of ferrocene derivatives that bear two dipeptide chains are available from 1,1′-bis(chlorocarbonyl)ferrocene (**336**, R = Cl).[484] The compounds form highly ordered



(**389**)

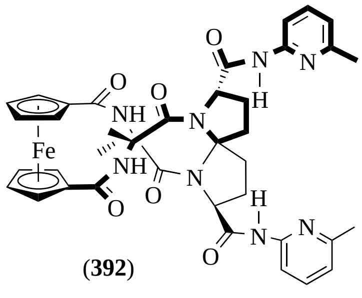


(**390**)



(**391**)

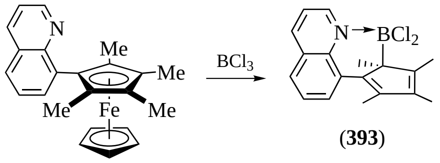
assemblies in the solid state that results from interchain hydrogen bonding. One of these compounds, (**392**), selectively recognizes dicarboxylic acids.[485]



(**392**)

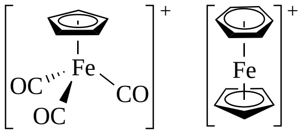
7.2.10 *Ligand Displacement*

Ferrocene was originally found to be stable to hydrogenation under conditions that effect the reduction of benzene. It was subsequently found that the reductive liberation of the Cp ligand could be effected by use of 10% Pd/C in CF_3CO_2H at 1–2 atm H_2. For 1,2-disubstituted ferrocenes the predominant products are *trans* 1,2-disubstituted cyclopentanes.[486,487] It has been variously suggested, but not proven, that this reaction proceeds via either protonation on Fe or on the Cp ligand. Use of this method for organic synthesis may be limited, since the yields are variable and planar chiral ferrocenes afford racemic cyclopentane products. Indeed, attempted liberation of the Cp ligand of ferrocenes is not commonly encountered. Reductive cleavage of ferrocene itself with lithium/$EtNH_2$ is known, but one report of the analogous transformation on a more substituted ferrocene required lithium di-*tert*-butylbiphenylide but proceeded in poor yield.[488,489] In a unique example of decomplexation, organoborane (**393**) is formed upon treatment of a quinoline-substituted ferrocene with BCl_3 (equation 85).[490] Finally, nitro-2-ferrocenyloxazolines are quite light-sensitive and can be readily photo-decomplexed to give the corresponding nitrofulvalenes.[491]



(**393**) (85)

The $[Cp(CO)_3Fe]^+$ cation (**394**) can be prepared from ferrocene by treatment with carbon monoxide, $AlCl_3$, Al powder, and water.[492] One Cp ligand of ferrocene may also be replaced by an arene to form the $(\eta^6$-arene)$FeCp^+$ cations (**395**) by treatment of ferrocene with the arene in the presence of $AlCl_3$, Al powder, and water (ratio of 1:1:3:1:1). The Al powder is present to prevent oxidation of ferrocene to the ferricinium cation (**292**).[493] The chemistry of these $(\eta^6$-arene)iron cations will be discussed later (Section 8.1.1). Treatment of ferrocene with $AlCl_3$ in the absence of a good ligand leads to partial decomposition and formation of unusual bridged ferrocenophanes.[493]



(**394**) (**395**)

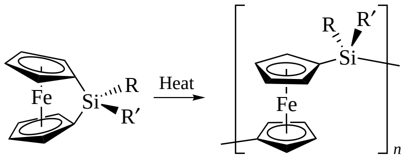
7.3 Ferrocenophanes

Bridged ferrocenes, or ferrocenophanes, have been known for many years. These compounds, in which the two Cp rings are linked by carbon and/or heteroatom chains, are

more than merely a scientific curiosity; many provide access to ferrocenyl polymers that have great value in materials science. A recent review of ferrocenophanes that possess only carbon bridges should be consulted for greater detail than can be provided here.[410] Information regarding multinuclear ferrocenes (biferrocenes, etc.) is also incorporated in that review, however that material will not be included here. While a detailed discussion of the synthesis and properties of the ferrocene-based polymers that are often derived from ferrocenophanes is also beyond the scope of this presentation, thorough recent reviews of this topic are available.[100,411]

7.3.1 Mononuclear [1]Ferrocenophanes

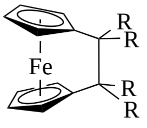
[1]Ferrocenophanes, that is, ferrocenes with two Cp rings connected by a single carbon atom bridge are unknown. Apparently this system would cause the Cp rings to distort too far from planarity to provide stability. However, there are numerous examples of heteroatom chains of one atom length that are known; larger atomic radii presumably results in less tilting of the Cp rings and therefore increased stability. Silaferrocenophanes may be the most important of this class of complexes, as poly(ferrocenylsilanes) are prepared from them by thermal ring-opening polymerization (equation 86).[411] Also known are [1]ferrocenophanes with boron, oxygen, sulfur, germanium, phosphorus, and tin linkers.[100] Typically these are prepared by treatment of dilithioferrocene (**323**) with the appropriate dihalide (Me_2SiCl_2, $PhPCl_2$, etc.). X-ray structures are available for some of these complexes, and tilt angles vary from *ca.* 27° for the phosphaferrocenophanes to 17° for the germanium analog.



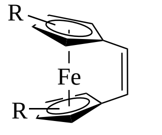
(86)

7.3.2 Mononuclear [2]Ferrocenophanes

Though considerably strained, [2]ferrocenophanes (**396**) can be prepared, in modest yield, by condensation of the appropriate biscyclopentadienyl dianion with $FeCl_2$.[423] X-ray analysis of (**396**, R = Me) shows that the strain imposed by short two atom carbon bridge is significant – a tilt angle of 23° and a ring twist angle of 26° are observed. This large tilt angle is manifested in an increased Lewis basicity, and the iron atom more readily forms adducts with Lewis acids and is more readily protonated than less-strained ferrocenophanes. Ring-opening polymerization of these complexes are possible, though initiation requires a higher temperature than the [1]silaferrocenophane analog (300 °C vs. 130–220 °C). The unsaturated analog (**397**, R = H) is prepared by subjecting ferrocene dialdehyde to McMurry coupling conditions ($TiCl_3$, Zn/Cu), and the X-ray structure shows the same 23° tilt angle observed in the saturated analog. Polymerization to give the poorly characterized poly(ferrocenylenevinylene) is accomplished by ring-opening metathesis polymerization (ROMP) (*see Ring Opening Metathesis Polymerization Reactions*). More highly substituted analogs (**397**, R = alkyl) are directly polymerized, and owing to their higher solubility these polymers are better characterized.[100]

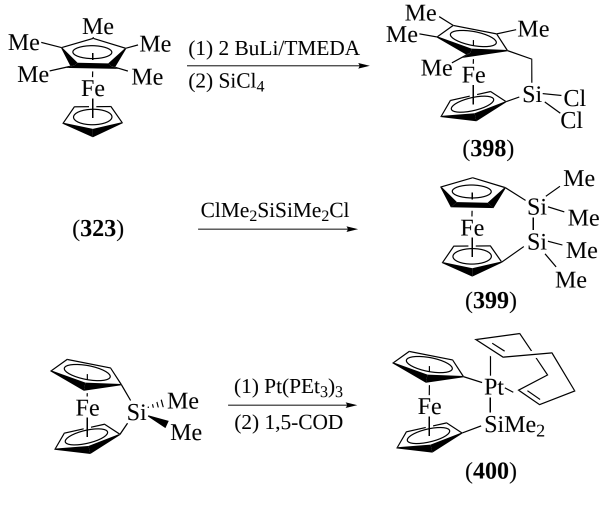


(**396**)



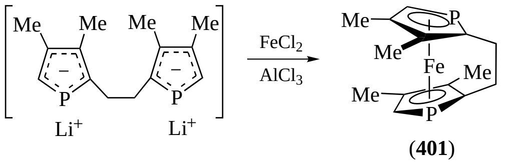
(**397**)

The dianion derived from the monoCp* analog of ferrocene is used with $SiCl_4$ to prepare a sila[2]ferrocenophane (**398**), and similarly treatment of dilithioferrocene (**323**) with $ClMe_2SiSiMe_2Cl$ affords the [2]disilaferrocenophane (**399**) (Scheme 102). However, unlike the [1]silaferrocenophane, (**399**) is resistant to polymerization, and this lack of reactivity may be correlated with the observed tilt angle of only 4°.[494] On the other hand, treatment of [1]silaferrocenophane with $Pt(PEt_3)_3$ results in an oxidative addition to produce a [2]-platinasilaferrocenophane (**400**); an exchange of ligands produces a complex which functions as a catalyst for ring-opening polymerization of [1]silaferrocenophanes.[495,496] It is also possible to prepare a diphospha[2]ferrocenophane; (**401**) is prepared from the diphospholide and $FeCl_2$ in the presence of $AlCl_3$ (equation 87).[497] The tilt angle, 20°, is observed to



Scheme 102

be similar to (**396**) and (**397**).



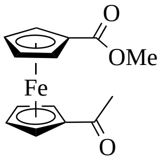
(**401**)

(87)

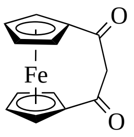
7.3.3 *Mononuclear [3]Ferrocenophanes*

This class of ferrocenophanes is probably the most-studied, and there are numerous examples that span from the simple mono-bridged [3]-ferrocenophane (prepared from treating the dianion derived from biscyclopentadienyl propane with $FeCl_2$) to the tetra-bridged [3][3][3][3]ferrocenophanes. The pentabridged compound remains unknown.

The facile intramolecular acylation of 3-ferrocenylpropionic acid (**295**) to give keto[3]ferrocenophane (**296**) has already been described (Section 7.2.1), and intramolecular Claisen condensation of (**402**) gives 1,3-diketo[3]ferrocenophane (**403**) (tilt angle, 10°); both of these compounds are used to prepare other [3]ferrocenophanes. An enantiomerically pure C_2-symmetric ferrocenophane (**404**; tilt angle, 6.5°) is made by a sequence that includes a Friedel–Crafts acylation to form a mono-bridged [3]-ferrocenophane and a subsequent intramolecular acylation to install the second bridge (Scheme 103).[498,499]

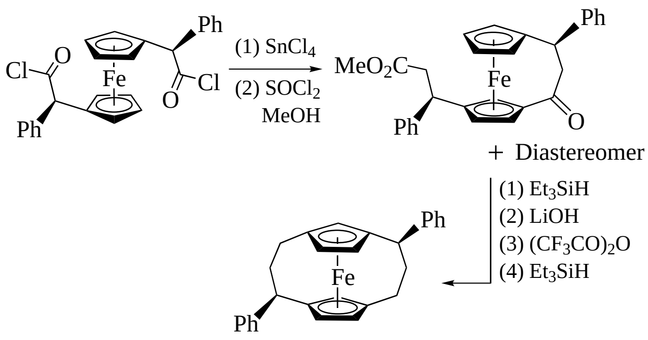


(**402**)



(**403**)

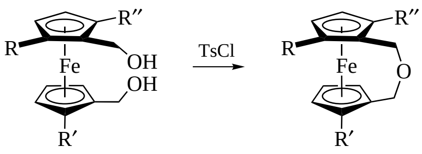
Enantiomerically pure [3]oxaferrocenophanes (**405**) are available as well, from tosyl chloride-induced dehydration of diols (equation 88).[500,501] Tilt angles for these complexes as



(**404**)

Scheme 103

determined from X-ray structures are in the 11–12° range.



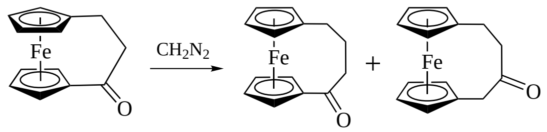
(**405**) (88)

R = Me_3Si; R′, R′ = H

R, R′ = H; R″ = 
R = H; R′ = R″ = Me_3Si

7.3.4 *Mononuclear [m]Ferrocenophanes (m ≥ 4)*

As in the case of [3]ferrocenophanes, there are numerous examples of [4]- and [5]ferrocenophanes. While the saturated complexes may be prepared from the usual route of treating the corresponding dicyclopentadienide with $FeCl_2$, other approaches may be taken. For example, the reaction of keto[3]ferrocenophane (**296**) with diazomethane results in ring-expanded keto[4]ferrocenophanes (**406a,406b**) (equation 89).



(89)

(**296**) (**406a**) (**406b**)

Unsaturated [4]- and [5]ferrocenophanes, with one or two alkenes in the bridge are readily prepared. Perhaps the most rapid entry to unsaturated [4]ferrocenophanes is via Ring-closing metathesis (RCM) of 1,1′-bispropenylferrocene (Scheme 104).[502] Enantiomerically pure analogs are available if analogs bearing chiral centers are utilized. Similarly, racemic 1,1′-diphospha[4]ferrocenophanes have been prepared.[503] An alternative approach uses the 1,1′-bis(trimethylsilylalkynyl)ferrocene that can be obtained from a Sonogashira-type coupling of 1,1′-diiodoferrocene.[504] Axially chiral (**407**) and helically chiral (**408**) ferrocenophanes are known as well.[489,505] The latter, prepared by reaction of the corresponding helical dianion with $FeCl_2$, has been resolved. X-ray diffraction analysis of (**408**) indicates that the two cyclopentadienyl groups are staggered and tilted by 19.8° with respect to being parallel.

Scheme 105

7.3.5 *Multiply-bridged [m]^{n}Ferrocenophanes*

Numerous di-, tri-, and tetra-bridged ferrocenophanes have been prepared from (**296**) and (**406a**) using acylation or formylation of the ferrocenophane as the first step, and intramolecular acylation to form the bridging chain. An early attempt of the preparation of [3]^4- and [3]^5-ferrocenophanes (**409**) and (**410**) from (1,2,4)[3]^{3}ferrocenophane (**411**; R = $CH_2CH_2CO_2H$), using this type of intramolecular acylation, failed owing to a novel rearrangement to (**412**) (Scheme 105). It is speculated that the intraring distance – in (**411**; R = H) the average Fe–C_{ring} is 1.99 Å – is too short to allow for *endo* attack of the acylium ion in a heteroannular fashion. Notably, the intramolecular acylation of the one-carbon homolog (**413**; R = $CH_2CH_2CO_2H$) to give (**414**) occurs in reasonable yield.[506] The pentabridged [4]^5-, [5]^5-, [4]^4[3]-, and [3]^4[4]ferrocenophanes (**415**), (**416**), (**417**), and (**418**) have been prepared.[506–509] These examples represent a class of compound in which a metal atom is completely surrounded by a hydrocarbon 'cage'. Attempted reduction of the bridged ferrocene (**411**; R = H) results in chain scission to give (**419**).[486]

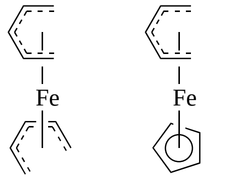
(**419**)



(**420**) (**421**)

7.4 'Open' and 'Half-open' Ferrocene[510]

Acyclic analogs of ferrocene, (**420**), can be prepared by reaction of the corresponding pentadienyl anion with $FeCl_2$. The mixed-sandwich complexes (**421**), with one cyclopentadienyl ligand and one 'open' pentadienyl ligand (*see Pentadienyl Ligand*), can be prepared by reaction of $FeCl_2$ with a 1:1 mixture of cyclopentadienyl anion and pentadienyl anion. This results in the formation of a nearly statistical, but separable, mixture of (**284**), (**420**), and (**421**) (1:1:2 ratio). X-ray diffraction analysis of (**420**) indicates that it adopts a *gauche*-eclipsed conformation, and that the average Fe–C distance (2.089 Å) is longer than that of ferrocene itself. Rotation of the two ligands with respect to each other is not as facile as for ferrocene. The barrier for rotation in the 'open' ferrocenes is $>35\,\mathrm{kJ\,mol^{-1}}$. The pentadienyl ligand may act as a better σ-acceptor ligand than the cyclopentadienyl ligand, thus resulting in more metal–ligand orbital mixing. Oxidation of (**420**) and (**421**) occurs at lower potential ($E_{1/2} = 0.11$ and 0.29 versus SCE respectively,

dimethoxyethane/$Bu_4N^+ClO_4^-$) than that of ferrocene, and these oxidations are not reversible owing to coupling of the pentadienyl ligands.

8 η^6-LIGAND COMPLEXES

This subject has been thoroughly reviewed, and readers should consult these articles for comprehensive information.[4,493,511]

8.1 Cationic η^6-Arene Complexes (*see Arene Complexes*)

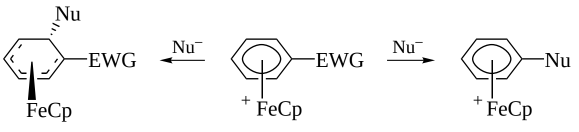
8.1.1 Preparation and Structure

As previously indicated, the reaction of ferrocene with arene, $AlCl_3$, Al powder, and water affords (η^6-arene)(η^5-cyclopentadienyl)iron cations (**395**).[493] These cations can also be formed by the reaction of (**6a**) with arenes in the presence of $AlCl_3$,[512] as well as by hydride abstraction from (η^5-cyclohexadienyl)FeCp complexes; however, since these are usually prepared by reduction of cations (**395**), this latter methodology is of little synthetic utility. A wide variety of aromatic compounds can be accommodated in these complexes;[513] however, complexation of polycyclic aromatic hydrocarbons, such as naphthalene, phenanthrene, anthracene, or pyrene, proceeds with partial hydrogenation.[514] Photochemical exchange of a complexed arene ligand by a more basic arene has been effected for the *p*-xylene and chlorobenzene complexes in MeCN as solvent.[515] The labile (*see Labile*) $(MeCN)_3FeCp^+$ cation is believed to be an intermediate in this ligand exchange. The preparation of substituted (arene)$FeCp^+$ by modification reactions will be discussed in the following section.

The crystal structures of a number of (arene)$FeCp^+$ cations have been reported.[516] In general, the planes defined by the arene and cyclopentadienyl ligands are essentially parallel. The Fe–arene centroid distance is in the range 1.52–1.60 Å, while the Fe–Cp centroid distance is 1.62–1.79 Å. The arene C–C bond distance increases upon complexation to 1.39–1.44 Å. An upfield shift is observed for the ^{13}C NMR signals of the complexed arene ring.[32]

8.1.2 Reactions

As might be expected for a polyene metal cation, the arene ligand in complexes (**395**) is unreactive toward normal Friedel–Crafts substitution. In turn, the $FeCp^+$ adjunct acts as a good electron-withdrawing group and facilitates attack by hydride and carbanion nucleophiles on the benzene ligand to form (η^5-cyclohexadienyl)FeCp complexes.[493,513,516] For $LiAlH_4$ as nucleophile and at low temperature this reaction has been shown to proceed via initial electron transfer to afford the 19-electron complex (*see Nineteen Electron Configuration*), which is characterized by ESR (Section 8.2), followed by hydrogen atom transfer.[517] Nucleophilic attack occurs on the *exo* face of the arene ligand. For arenes substituted with electron-withdrawing groups (e.g. **422**, Electron-withdrawing group (EWG) = NO_2, Cl, CO_2R), nucleophilic attack by hydride, cyanide, organometallics, or enolates occurs at the position *ortho* to the substituent to give neutral cyclohexadienyl complexes (**423**) (equation 90).[518] In contrast, reaction of complexes (**422**; EWG = Cl or NO_2) with stabilized nucleophiles, such as amines, alkoxides, thiolates, or β-dicarbonyl anions, results in displacement of chlorine or nitrite to give the substituted arene cations (**424**).[516,519] Sequential substitution of the two chlorines of (*o*-dichlorobenzene)$FeCp^+$ are known,[520] and this methodology is used to prepare polycyclic compounds.

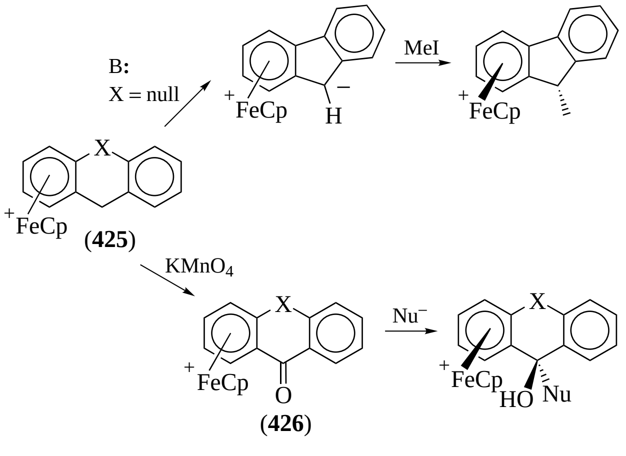


(**423**) (**422**) (**424**) (90)

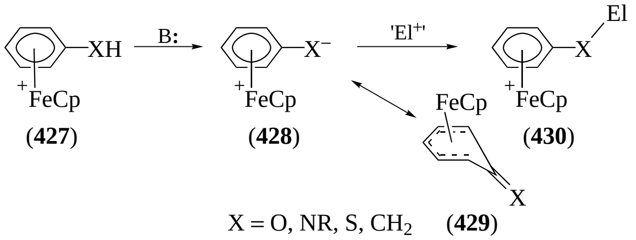
EWG = Cl, NO_2, CO_2R ; Nu^- = H^-, RLi, ^-CN

EWG = Cl, NO_2 ; Nu^- = R_2NH, RO^-, ArS^-, $NaCH(COR)_2$

The (η^6-arene)(η^5-cyclopentadienyl)iron cation is stable to strong oxidants (e.g. conc. H_2SO_4, HNO_3, peroxides (*see Peroxide*), and permanganate); however, toluene and other alkyl-substituted arene cations are oxidized with hot permanganate to give the corresponding benzoic acid complexes.[513] Oxidation of a CH_2Ar side chain (e.g. **425**) gives the corresponding diaryl ketone complex (**426**) (Scheme 106).[521] Nucleophilic addition to ketones of the type (**426**) occurs *exo* to the metal in a highly diastereoselective fashion.



Scheme 106



Scheme 107

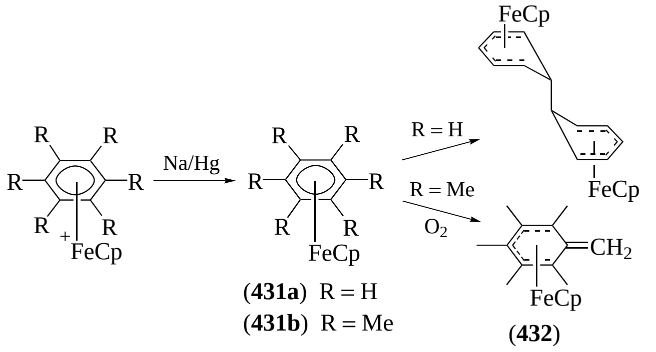
The protons of OH, NHR, SH, or CH groups attached to a complexed arene exhibit enhanced acidity (e.g. **427**) (Scheme 107). Deprotonation generates the corresponding zwitterionic species (**428**), which might also be drawn as (**429**). The X-ray diffraction structure of the product generated by deprotonation of (η^6-fluorene)FeCp cation indicates that all six carbons of the aryl ring are bonded to iron.[522] Reaction of the deprotonated species (**428**) with electrophiles results in the formation of the substituted arene complex (**430**).[493,516,523,524] Reaction of the conjugate base of (η^6-fluorene)FeCp$^+$ cation with iodomethane or methyl fluorosulfonate results in formation of a new C–C bond on the face of the ligand opposite to the metal (Scheme 106).[522]

Decomplexation of cationic arene iron Cp complexes to afford the functionalized arene may be carried out by heating in a donor solvent (*N,N*-dimethylformamide (DMF) or Dimethylsulfoxide (DMSO)). For less robust systems, irradiation by sun or UV lamp is efficient, often in the presence of an exogenous ligand such as triphenylphosphine.[4,493,525]

8.2 Nineteen-electron Neutral η^6-arene Complexes

This area has been the subject of several reviews by Astruc.[526–528] Electrochemical reduction of (η^6-arene)FeCp$^+$ cations (**395**) generates the corresponding 19-electron neutral η^6-arene complexes (**431**) (Scheme 108). These 19-electron complexes are unstable with respect to dimerization unless the arene ligand is peralkyl substituted. The arene ligand may be electrocatalytically liberated in ethanol solution via the intermediacy of the unstable 19-electron complex (**431b**).[529]

The (η^6-hexamethylbenzene)FeCp complex (**431b**) is a green–black sublimable solid. The X-ray diffraction structure of (**431b**) indicates that the arene and Cp rings are planar and parallel; however, the Fe–Cp centroid distance is an extremely long (1.79 Å) and the Fe–arene centroid distance is 1.58 Å.[530] The Mössbauer spectrum of (**431b**) indicates that the unpaired electron is in an e_{1g}* orbital which is 65–75% metal-like in character.[529] Reaction of (**431b**) with O_2 generates the 18-electron (η^5-cyclohexadienyl) complex (**432**) and the superoxide (*see Superoxide*) radical anion ($O_2^{-}\cdot$). The complex (**431b**) thus acts as an excellent 'electron reservoir.' The Fe^I/Fe^{II} redox system can act as a catalyst for electrochemical reduction of nitrate to ammonia.[526] Complex

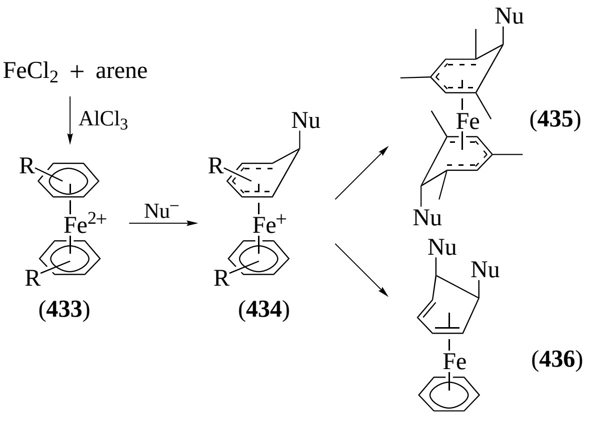


Scheme 108

(**432**) acts as reducing agent (aldehydes and ketones reduced to alcohols, and alkynes to alkenes), reacts with electrophiles (Ph_2PCl, Me_3SiCl, etc.) to allow modification of one of the arene methyl groups, and also can be peralkylated (KOH, RI).[528] Use of 1-(4-iodobutyl)ferrocene as an alkylating agent allows the construction of a heptanuclear complex cation that was prepared as part of a study to identify possible redox catalysts.[531]

8.3 Bis(η^6-arene)Iron Dications

The reaction of $FeCl_2$ or $FeCl_3$ with $AlCl_3$ in an arene solvent, at reflux, results in the formation of the corresponding bis(η^6-arene)iron dications (**433**) (Scheme 109).[4,493,532] These dications are susceptible to nucleophilic attack to afford the (η^6-arene)(η^5-cyclohexadienyl)iron cations (**434**). For the bis(mesitylene)iron dication, reaction with two equivalents of a nucleophile sequentially occurs on each of the arene rings to afford bis (η^5-cyclohexadienyl)iron complexes (**435**),[532] in accord with the prediction of the Davies–Green–Mingos rules (*see Davies–Green–Mingos Rules*) for nucleophilic addition.[533] More recently, it has been found that reaction of other cations (**434**) with a variety of nucleophiles, in THF



Scheme 109

solution, proceeds via attack at the cyclohexadienyl ligand to afford neutral (η^6-arene)(η^4-cyclohexadiene)iron complexes (**436**).[534] The regioselectivity of this second nucleophilic addition is dependent upon the steric demands of the ligands, the nature of the nucleophile, and the solvent.[535] This methodology may be used for the preparation of *cis*-1,2-disubstituted 2,5-cyclohexadienes.

BNCT = Boron neutron capture therapy; $BzNH_2$ = Benzylamine; 1- or N-BzIm = 1- or N-benzylimidazole; COSY = Homonuclear *J*-Correlated SpectroscopY (a two-dimensional NMR experiment); CuIM, NiIM = The Cu^{II} and Ni^{II} complexes of the Schiff base condensation product of 5-chloro-2-hydroxybenzophenone, 1,2-diaminobenzene, and imidazole-4-carbaldehyde; DCP, TDCPP, or $(2,6\text{-}Cl_2)_4TPP$ = Tetrakis(2,6-dichlorophenyl)porphyrin; DP or DPIX = deuteroporphyrin IX (see Figure 1); DPDME = Deuteroporphyrin IX dimethyl ester; EDRF = Endothelial-derived relaxing factor; ETIO = Etioporphyrin); EXSY = EXchange SpectroscopY (a two-dimensional NMR experiment that uses the same pulse sequence as NOESY); ImH = Imidazole; MNT^{2-} = *cis*-1,2-dicyano-1,2-ethylenedithiolate; MP or MPIX = Mesoporphyrin IX (see Figure 1); MP8-MP11 = Microperoxidase-8 to -11 (peptide hydrolysis fragments of horse heart cytochrome *c*); MPDME = Mesoporphyrin IX dimethyl ester; NOESY = Nuclear Overhauser and Exchange SpectroscopY (a two-dimensional NMR experiment); N-RIm = *N*-substituted imidazole; OAP = (2,3,7,8,12,13,17,18-octakis(diethylcarboxamide)porphyrin); OEAP = Octaethylazaporphyrin; OEB = Octaethylbiliverdin (see Scheme 3 below); OEC = Octaethylchlorin (see Figure 1); OECorr = Octaethylcorrole; OEiBC = Octaethylisobacteriochlorin (see Figure 1); OEOP = Octaethylverdoheme; OEP = Octaethylporphyrin (2,3,7,8,12,13,17,18-octaethylporphyrin); OEPO = (5-oxo)octaethylporphyrin or octaethylphlorin; OEPOH = (5-hydroxy)octaethylporphyrin; OETPP = Octaethyltetraphenylporphyrin (see Figure 1); OMTPP = Octamethyltetraphenylporphyrin; PP or PPIX = Protoporphyrin IX (see Figure 1); PPDME = Protoporphyrin IX dimethyl ester; Pyz = Pyrazine; RImH = Imidazole with an R substituent on one of the carbon atoms; RNC = Alkyl or aryl isocyanide (isonitrile); RNO = alkyl or aryl nitroso compound; RPy = Substituted pyridine; RTPP = *R*-phenyl substituted tetraphenylporphyrin; TC_6TPP = Tetra-β,β'-tetramethylenetetraphenyl-porphyrin; TMINP = Tetrakis(*o*-(methylisonicotinamidophenyl)porphyrin); T(*o*-M)PyP = Tetrakis(methyl-*o*-pyridinium)porphyrin; TMP = Tetramesitylporphyrin; T(*p*-M)PyP = Tetrakis (methyl-*p*-pyridinium)porphyrin; TMTMP = 2,7,12,17-tetramethyl-3,8,13,18-tetramesitylporphyrin; TPC = Tetra − phenylchlorin; TPCorr = Triphenylcorrole; T(*o*-Piv)PP, $T_{Piv}PP$, or $(o\text{-}Piv)_4TPP$ = Tetrakis(*o*-pivalamidophenyl)porphyrin (the $\alpha,\alpha,\alpha,\alpha$ atropisomer is called the ‘Picket Fence Porphyrin’); TPP = Tetraphenylporphyrin (5,10,15,20-tetraphenylporphyrin); $TPPBr_4$ = Tetraphenylporphyrin brominated on four β-pyrrole positions; $TPP(CN)_3$ and $TPP(CN)_4$ = Tetraphenylporphyrin with three or four β-pyrrole cyano groups, respectively; TPPS = Tetrakis(*m*-sulfophenyl)porphyrin (also called tetraphenylporphine sulfonate); TTMPP = Tetrakis(2,4,6-trimethoxyphenyl)porphyrin; TTP = tetratolylporphyrin; TTPPP = Tetrakis ((2,4,6-triphenyl)phenyl)porphyrin; $(X)_n(Y)_{4-n}TPP$ = Unsymmetrically phenyl substituted tetraphenylporphyrin, where *X* and *Y* are on different phenyl rings.

1 INTRODUCTION AND BACKGROUND

1.1 Occurrence and Roles of Natural Iron Porphyrins (Hemes) and Their Synthetic Analogs

Hemes and heme proteins (*see Polypeptide*; ***Iron: Heme Proteins & Dioxygen Transport & Storage***; ***Iron: Heme Proteins & Electron Transport***; ***Iron: Heme Proteins, Mono- & Dioxygenases***; ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***) are vital components of essentially every cell of nearly every living organism. They have such diverse roles in vital life processes as the transport and storage of dioxygen in higher animals (hemoglobin and myoglobin, respectively)[1] (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***); electron transport in the respiratory chains (*see Electron Transport Chains*) of organisms as diverse as *bacteria, archaea*, yeasts, plants and animals, and in photosynthetic cells from those of the simplest photosynthetic bacteria to those of higher plants (cytochromes *a, b, c, d, f, o*)[2–23] (*see* ***Iron: Heme Proteins & Electron Transport***; ***Photosynthesis***); synthesis, modification and/or degradation of fatty

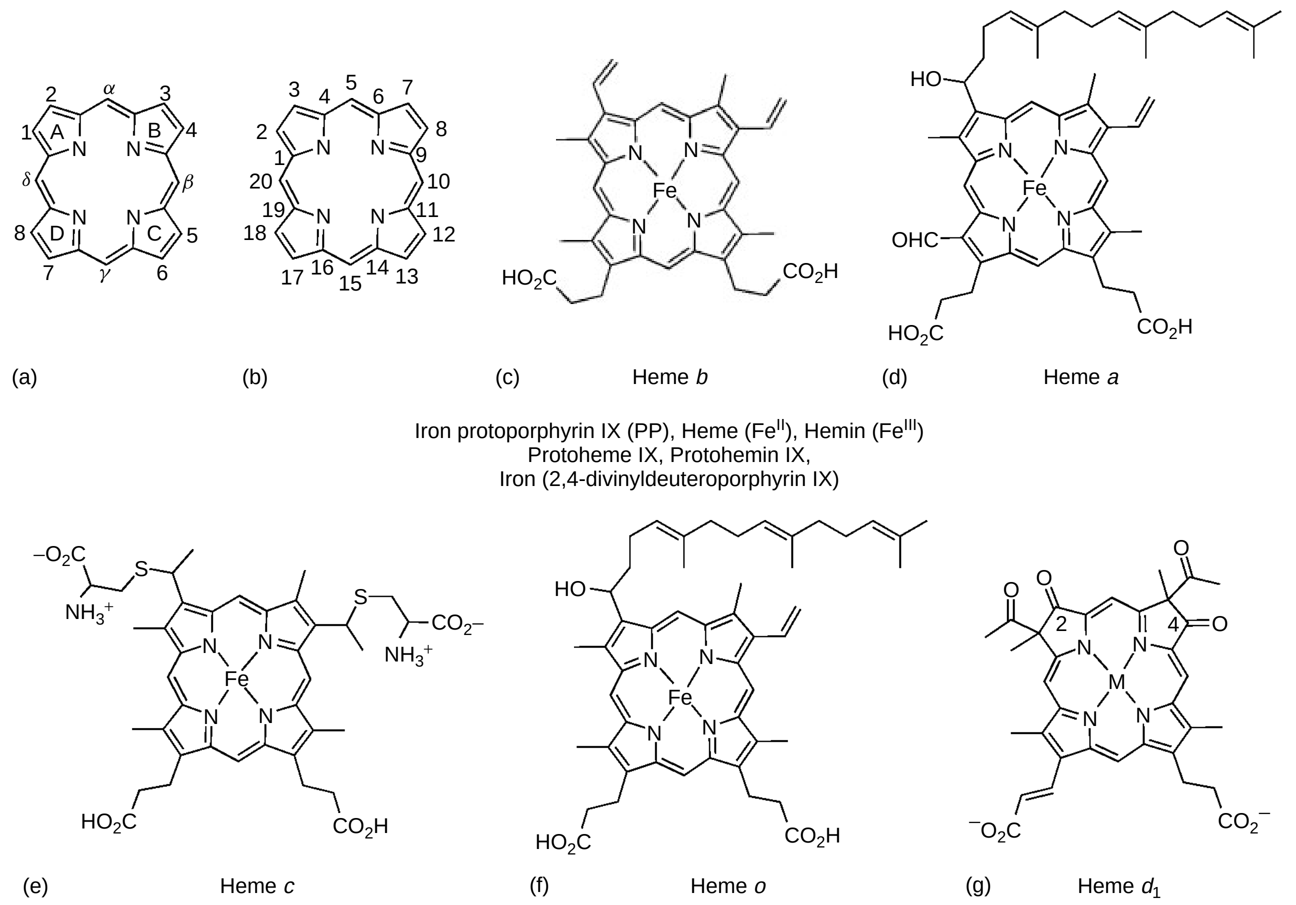

Figure 1 Structures of iron porphyrins, chlorins, and isobacteriochlorins and examples, with typical nomenclature. (a) Numbering system usually used for natural porphyrins and their derivatives. As will become apparent below, many natural porphyrins and their derivatives are named as 2,4-disubstituted deuteroporphyrin IX derivatives. (b) IUPAC numbering system for porphyrins. Synthetic porphyrins are named by *either* numbering scheme (a) or (b). (c)–(e) Common naturally occurring porphyrins found in heme proteins that are named *a–d* and *o* according to the relative positions of the α and β bands of the Fe^{II} form of the heme protein in the presence of excess pyridine (the so-called Pyridine Hemochrome spectrum). (h)–(j) Naturally occurring iron porphyrins. (k) The chlorin ring system. (l) The isobacteriochlorin ring system. (m) An example of an iron chlorin. (n and o) examples of iron isobacteriochlorins (Note also that heme d_1 (g) is the same oxidation level as d_1 an isobacteriochlorin). (p)–(r) Common synthetic porphyrins (note two naming systems). In this article, phenyl-substituted TPP derivatives are abbreviated as either (p-X)$_4$TPP or TpXPP, in line with the usage of the original authors. Common water soluble synthetic porphyrins include (s) and (t). Related macrocycles include (u)–(z)

acids, steroid and adrenal hormones, anesthetics, polycyclic aromatic hydrocarbons and other xenobiotics (cytochromes P450),[24–32] or in general insertion of one or both oxygen atoms of dioxygen into organic substrates (P450, secondary amine monooxygenase (SAMO), heme oxygenase (HO), prostaglandin H synthase (PGHS), indoleamine-2,3-oxygenase (IDO), and tryptophan-2,3-oxygenase (TDO)[32] (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***); breakdown of heme (HO),[32–34] activation and metabolism of hydrogen peroxide[24–26,35] (peroxidases,[26,35,36] myeloperoxidase, haloperoxidases,[14] lignin peroxidases,[37] catalases, etc.) (*see* ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***); metabolism of the oxides of nitrogen and sulfur (nitrite reductase,[38–40] sulfite reductase,[41,42] sulfite oxidase,[43,44] etc.); oxygen sensing proteins (FixL,[45–48] DosH[49]) and synthesis (nitric oxide synthase, NOS)[50–54] and transport[55–57] of the so-called endothelial-derived relaxing factor (EDRF), nitric oxide (NO), which has been shown to be an important biochemical effector of such diverse physiological processes as smooth muscle (including blood vessel) relaxation, platelet inhibition, neurotransmission, immune regulation, and penile erection[58] (*see* ***Nitrogen Monoxide (Nitric Oxide): Bioinorganic Chemistry***). Biologically important related molecules that involve modified hemes include the reduced hemes (iron chlorins, bacterio- and isobacteriochlorins, and sulfhemes)[41,59–68] (*see Siroheme*), as well as chlorophylls, pheophytins, and pheophorbides[69–73] vitamin B_{12},[69,74–81] Factor F430,[69,82,83] and some of the luciferins responsible for the diurnal cycles of many species of plants and animals.[84] Breakdown products of heme[33,34]

are harmful to newborn infants and alcoholics,[85] and intermediates in the synthesis of heme cause the genetic diseases called porphyrias.[86–88] Excessive heme breakdown can lead to the accumulation of bilirubin, which, when accumulated in the blood and tissues, leads to a condition called *hyperbilirubinemia* that is seen in neonatal jaundice in infants and the genetic disease *Crigler-Najjar Syndrome*.[89] Genetically modified forms of hemoglobin are responsible for sickle-cell anemia[90,91] and a number of methemoglobinemias.[92] Heme-NO complexes have been detected in cured meats,[93] and synthetic hemes or phthalocyanines can be used in bioremediation of pollutants.[94–99] Since porphyrinic pigments and their metal complexes are known to localize with high affinity in neoplastic tissues,[100–103] synthetically prepared or naturally occurring hemes are investigated with great interest in medical applications. For example, metalated porphyrins are studied as potential contrast agents in magnetic resonance imaging (MRI) techniques.[100,102–104]

(z) Iron texaphyrin

Figure 1 cont'd

Boronated porphyrins are investigated as agents forboron neutron capture therapy (BNCT),[104–106] whereas metalated and unmetalated porphyrins and other porphyrinic pigments have attracted widespread attention as promising photosensitizers in photodynamic therapy of oncological and non-oncological diseases.[107–122] Artemisinin, chloroquine, and various isonitriles derived from marine organisms form covalent adducts with protohemin and thus prevent the formation of hemozoan by the malaria-causing organism *Plasmodium falciparum*.[123–126] Water-soluble porphyrins and metalloporphyrins are reported to intercalate into DNA,[127–131] and cationic porphyrins have been shown to bind to potassium channel proteins with nanomolar affinities in a reversible fashion[132] to mimic peptide toxins excreted by scorpions, snakes, spiders, and other organisms[133,134] that partially block the electrical conductance of the channels. Metalloporphyrins have been investigated as highly conducting molecular materials,[135] polymers and dendrimers,[136–147] and for preparation of modified electrodes.[148–156] Considering the diverse applications listed above it is not surprising that the

isolation, characterization, and spectroscopic investigation of both naturally occurring and synthetic hemes have been active fields of research for many years.

In many cases, synthetic iron porphyrins have been investigated primarily as models of hemes in various proteins, but also as potentially useful magnetic materials, or as metal coordination complexes, since the porphyrin *Macrocycle* often confers upon the metal unique electronic, magnetic, and redox properties (*see Redox Properties & Processes*) and chemical reactivities that are interesting in their own right. The properties and chemical reactivities of iron porphyrins will be summarized in this article. Iron complexes of related macrocycles, including reduced hemes (chlorins, isobacteriochlorins, etc.),[59,61–67,157] *N*-alkyl- or *N*-arylporphyrins,[158,159] thiaporphyrins,[160–162] tetraazaporphyrins,[163] phthalocyanines,[164] and corroles[165] have also been investigated and, where appropriate, will be mentioned briefly.

Among the heme proteins, a variety of axial ligations, and oxidation and spin states of the central iron *Active Site* are stabilized by the particular protein environment created within the heme pocket of each of these proteins. Synthetic models of each of these have been prepared and investigated, as will be summarized below. The electronic states of the iron ion are particularly amenable to a wide variety of spectroscopic studies, including electronic (UV–visible–near IR),[166] vibrational (IR, Raman, and especially resonance Raman[167]), NMR,[168–175] EPR (or ESR)[176] (*see Electron Paramagnetic Resonance*), Mössbauer,[177] and MCD[178] spectroscopic techniques. In addition, magnetic susceptibility measurements[179] (*see* ***Magnetism of Transition Metal Ions***) and the investigations of the electrochemistry of heme proteins[180] and model hemes[181] (*see* ***Electrochemistry: Applications in Inorganic Chemistry***) have also been extremely useful in defining the electronic and oxidation states of these compounds. Three-dimensional structure determinations have been carried out for a wide variety of model hemes by single crystal X-ray crystallography,[182–185] and in selected cases by absorption spectroscopy (EXAFS, XANES).[186] In some cases, the arrangement of peripheral substituents has been determined by NMR spectroscopy.[174,175,187–192] Since detailed review of each of these techniques is beyond the scope of this article, the references given above are intended to provide the interested reader with extensive background information.

1.2 Structures and Electron Configurations of Iron Porphyrins

The general structures of iron porphyrins are shown in Figure 1, together with the structures of closely related ring systems, including iron chlorins and isobacteriochlorins, thiaporphyrins, tetraazaporphyrins, phthalocyanines, corroles, and texaphyrin. Examples of substituents present on commonly investigated natural and synthetic iron porphyrins are also included.

The possible coordination states of synthetic and natural iron porphyrins include 4-coordinate (no axial ligands), five-coordinate (one axial ligand), and six-coordinate (two axial ligands) geometries.[182,183] The number of axial ligands and their nature have dramatic influences on the Fe–N_{por} and Fe–axial ligand bond lengths,[182–185] spin states,[179,182–184] EPR g-values,[174,176,193,194] NMR chemical and isotropic shifts,[168,171,174,175,193,195] Mössbauer isomer shifts, quadrupole splittings and hyperfine coupling constants,[177,193,194,196] resonance Raman[167] and MCD[178,193] band positions and shapes, as well as reduction potentials[181] and reactivity towards reagents such as molecular oxygen, carbon monoxide,[197,198] unsaturated hydrocarbons,[24,26,27] and many other substances. The known oxidation states (*see Oxidation Number*) of iron porphyrins range from Fe^0 (d^8) to Fe^{IV} (d^4) and most recently also true Fe^V (d^3). Among these, the possible spin states include high-, intermediate-, and low-spin states (*see High-spin & Low-spin Compounds*) of Fe^{II} (d^6) and Fe^{III} (d^5), and high- and low-spin Fe^I (d^7) and Fe^{IV} (d^4). All of the possible spin states of these *d^n configuration* species have been observed except high-spin d^7, as summarized in Figure 2. It should be noted that the only diamagnetic (*see Diamagnetism*) member of this extensive series of possible oxidation and spin states is low-spin Fe^{II}; all other iron porphyrin complexes are paramagnetic (*see Paramagnetism*).

The valence electrons of iron porphyrins are almost invariably located in the 3d orbitals of the metal, except in the cases of π-cation radicals of Fe^{II} complexes of oxophlorins[199] and reduced hemes bonded to carbon monoxide, isocyanide or PF_3 ligands,[200] or NO,[201,202] and the π-cation radicals of Fe^{III}[203–211] and Fe^{IV}[210,212–219] porphyrins and corroles, where the 3d orbitals (*see d-Orbitals*) of the metal are very similar in energy to the HOMO of the porphyrin. In four-, five-, and six-coordinate metalloporphyrins the d orbitals consist of three general symmetry types (*see* ***Coordination & Organometallic Chemistry: Principles***): (1) the σ-symmetry orbitals that interact with the porphyrin nitrogens and with axial ligands (strictly speaking, in the idealized D_{4h} symmetry of four- and six-coordinate metalloporphyrins; these orbitals are of a_{1g} (d_{z^2}) and b_{1g} ($d_{x^2-y^2}$) symmetry, but in any case, they are engaged in σ-bonding interactions only, unless the iron is 5-coordinate and well out of the plane of the porphyrin[195,220]); (2) the d_π orbitals, d_{xz} and d_{yz}, which may engage in π-bonding with both filled and empty π-symmetry orbitals of the porphyrin ring as well as the axial ligands; and (3) the d_{xy} orbital, which is nonbonding, both in relation to the porphyrin ring if it is planar (see Section 6.3.2 below for the consequences of porphyrin ring nonplanarity), and also in relation to the axial ligands (*see* ***Ligand Field Theory & Spectra***). The splitting patterns of the five d orbitals (*see Crystal Field Theory*; *Splitting, Crystal Field & Molecular Orbital*) are generally expected to be those shown in Figure 2, although individual variations in the relative orbital energies have been observed.[174,175,195]

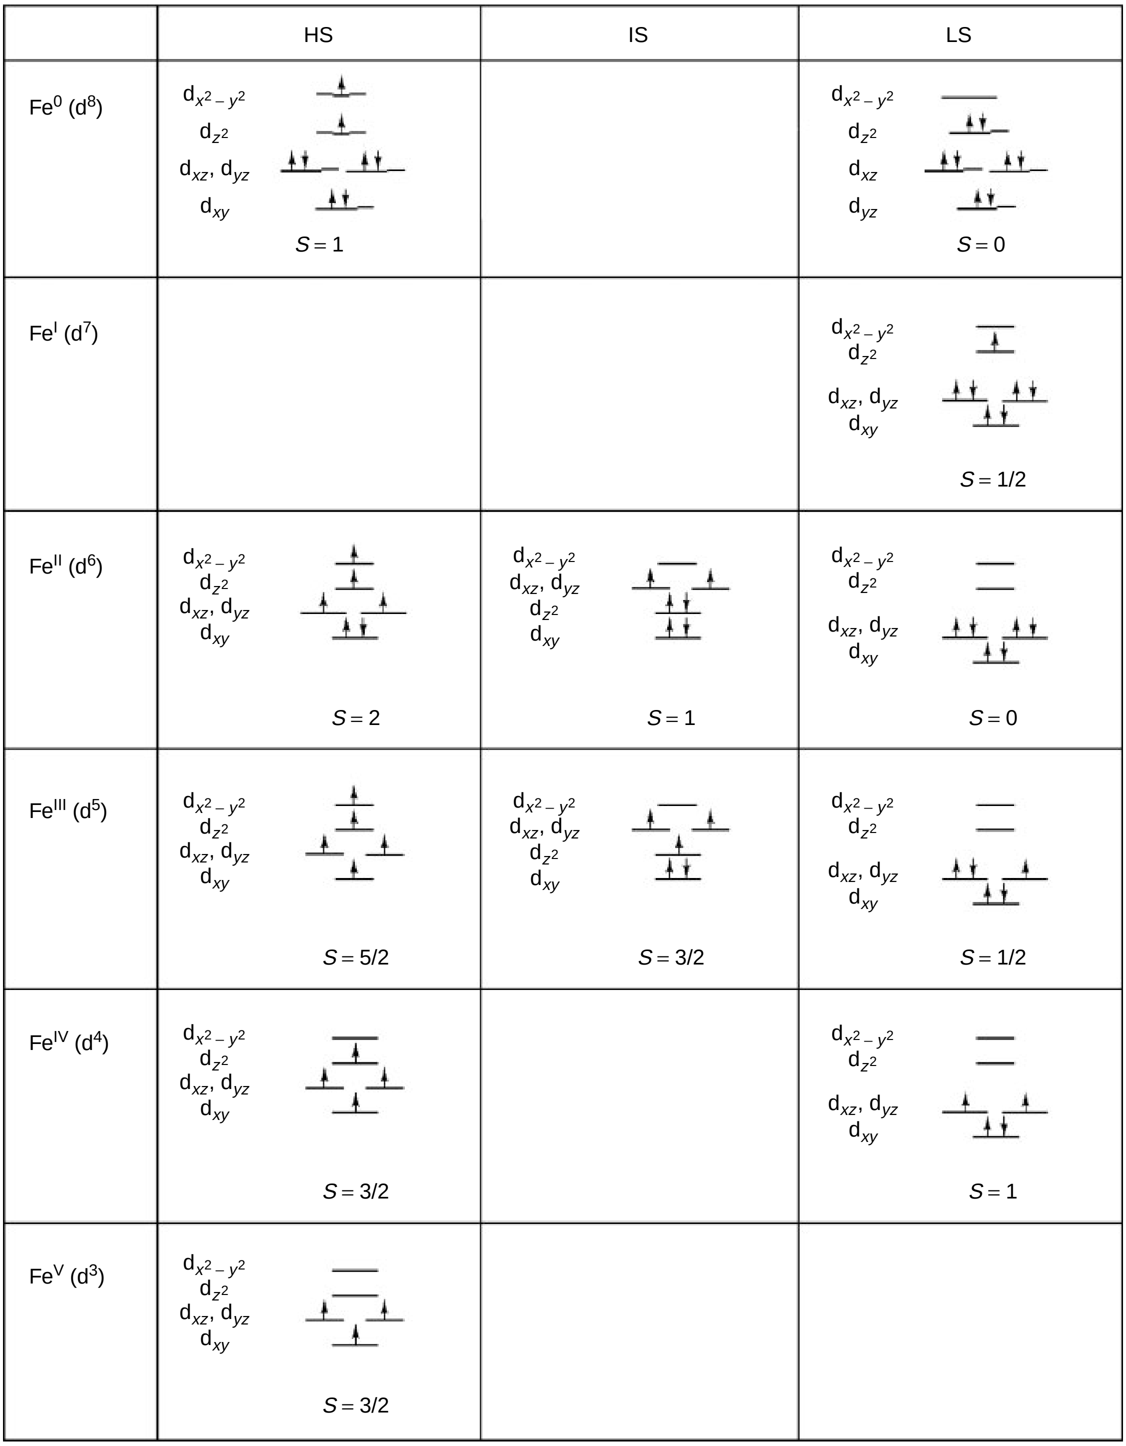

Figure 2 Possible oxidation and spin states of iron porphyrins and the d orbital configurations expected in each case. All of these states (excluding high-spin d^7, which is not included in the figure) have been observed for iron porphyrins, and are discussed in this article. In addition, the spin-admixed $S = 3/2,5/2$ state of Fe^{III} and the alternative orbital configuration for low-spin Fe^{III}, with d_{xy} higher in energy than d_{xz},d_{yz}, are also discussed

1.3 π Electron Configuration of the Porphyrin Ring

Both four- and six-coordinate metalloporphyrins have effective D_{4h} symmetry, if the effects of planar axial ligands, unsymmetrically placed porphyrin substituents, and distortions of the porphinato core (ruffling or saddling) are neglected. The bonding interactions between the metal atom and the porphyrin ligand are expected to be those shown

in Figure 3, where each porphyrin nitrogen supplies a σ-symmetry lone pair that points directly toward the metal ion either along the x, $-x$, y, or $-y$ axes, and a single π-symmetry p orbital that is perpendicular to the plane of the porphyrin ring. We will call this the p_z orbital of the bonding nitrogen.

Not only does the bonding nitrogen have an available π-symmetry p_z orbital, but so do each of the C_α, C_β, and C_{meso} carbons of the porphyrin skeleton. Researchers in the field[221–226] have developed more-or-less sophisticated molecular orbital treatments of the porphyrin ring and related macrocycles (*see* ***Molecular Orbital Theory***), and recent DFT calculations have been reported,[227] which will be mentioned in this article where appropriate. In the simplest of these treatments, π MOs are constructed based upon the symmetry properties of the idealized D_{4h} symmetry porphyrin ring. The 24 p_z orbitals of the porphine macrocycle are thus combined to produce 24 molecular orbitals (two a_{1u}, four a_{2u}, three b_{1u}, three b_{2u}, and six e_g sets), 13 of which are filled by the 26 p_z electrons of the 24 atoms of the porphyrin macrocycle. Although the theories differ in detail, all agree that the frontier and near-frontier orbitals (*see Frontier Orbitals*) are, in order of increasing energy, $3e(\pi) < 1a_{1u}(\pi) \sim 3a_{2u}(\pi) < 4e(\pi^*)$, using the notation of Longuet-Higgins *et al.*[221] The $3e(\pi)$, $1a_{1u}(\pi)$, and $3a_{2u}(\pi)$ orbitals are filled, while the $4e(\pi^*)$ orbitals are empty. All theories agree further that the $4e(\pi^*)$ set are the LUMO(s) of the porphyrin ring, while the HOMO(s) may be either $1a_{1u}(\pi)$, $3a_{2u}(\pi)$ of the porphyrin ring, or the d_{xy} or d_{xz},$d_{yz} = d_\pi$ orbitals of the metal, depending on the oxidation state of the metal, the porphyrin and degree of reduction of the macrocycle (chlorins and isobacteriochlorins), substituents and the axial ligand(s) present. The symmetry properties and electron distributions of the porphyrin π-symmetry frontier orbitals predicted from the simplest of these treatments are shown in Figure 4.

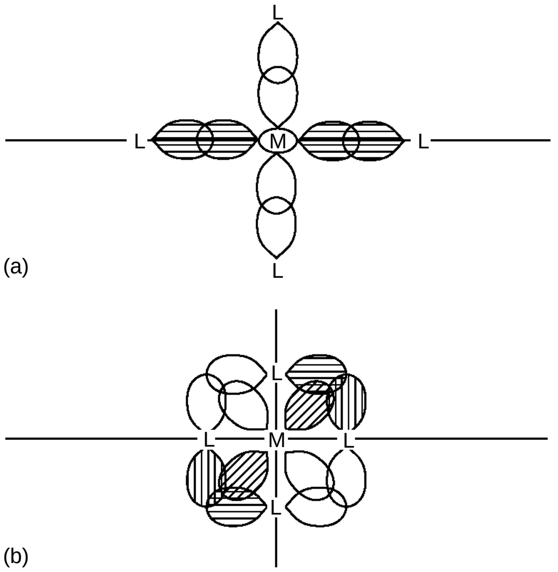

Figure 3 The symmetry-allowed interactions between metal d and porphyrin σ and π orbitals. (a) Interaction of the y-axis portion of the $d_{x^2-y^2}$ orbital with the σ-donor orbitals of two of the porphyrin nitrogens (porphyrin ring represented by the horizontal line) and the d_z^2 orbital interacting with the σ-donors of two axial ligands. (b) Interaction of one of the two d_π orbitals, d_{yz}, with the two porphyrin nitrogen p_π orbitals along the y-axis, and the ligand p_π orbitals of the two axial ligands. Note the nodal plane of this group of orbitals that passes through the axial ligand and metal centers and lies perpendicular to the plane of the figure. It is this nodal plane that ensures that only e-symmetry porphyrin π orbitals can be involved in π-bonding with the metal and π spin delocalization to or from the metal

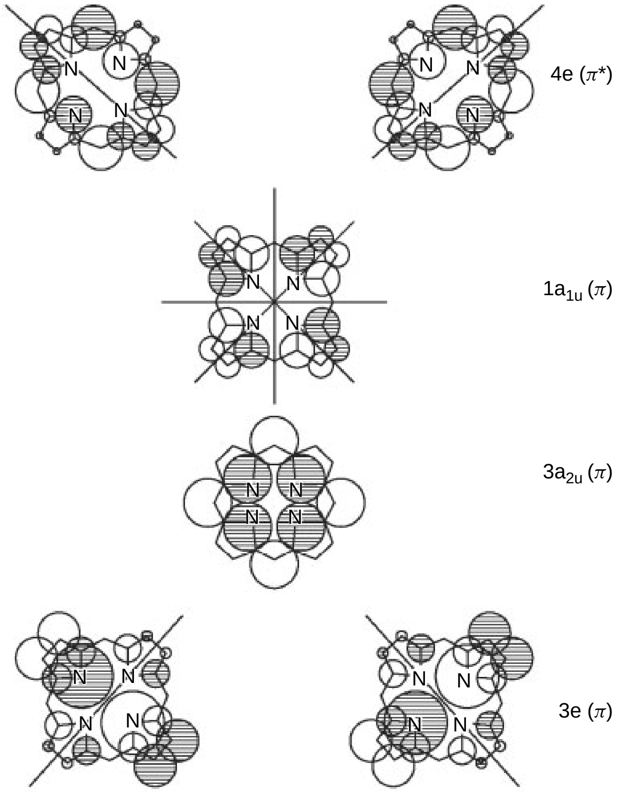

Figure 4 Nodal properties, relative energies, and electron density distributions in the frontier π orbitals of the porphyrin macrocycle.[221] The 3e(π), $3a_{2u}(\pi)$, and $1a_{1u}(\pi)$ orbitals are filled, and either the $3a_{2u}(\pi)$ or $1a_{1u}(\pi)$ is the HOMO of the porphyrin ring, while the 4e(π^*) orbitals are empty, and are thus the LUMOs of the porphyrin ring. Note that only the 3e(π) and 4e(π^*) orbitals have the proper symmetry (one nodal plane perpendicular to the plane of the porphyrin) for overlap with d_{xz} and d_{yz} (one for each), for planar metalloporphyrins

For electronic absorption spectra, excitations from $1a_{1u}(\pi)$ and $3a_{2u}(\pi)$ to $4e(\pi^*)$ give rise to the so-called α, β, and Soret bands (*see Soret Band*) in the visible spectra.[221–226] The electron configuration of π-cation radicals, $(PM)^{+\bullet}$ or $(P^{-\bullet})$ M, is typically either $(1a_{1u})^1$ or $(3a_{2u})^1$, since one or the other of these orbitals is typically the HOMO of the porphyrin π system.[228] Anion radicals, $(P^{3-\bullet})$ M, typically have the electron configuration $(4e)^1$, and dianions, (P^{4-})M, have the configuration $(4e)^2$.[228]

Although the $1a_{1u}(\pi)$ or $3a_{2u}(\pi)$ orbital is typically the HOMO of the porphyrin ring, neither of these orbitals has the proper symmetry to covalently overlap with the d_π orbitals of the metal if the porphyrin ring is planar. (However, if the porphyrin ring is ruffled, the $3a_{2u}(\pi)$ orbital can interact with the d_{xy} orbital, and if it is saddled it can interact with the $d_{x^2-y^2}$ orbital, as will be discussed in Section 6.3.2; if the porphyrin ring is planar but the metal is 5-coordinate and out of the plane of the porphyrin, then the $3a_{2u}(\pi)$ orbital can interact with the metal d_{z^2} orbital.[220]) Thus, only the $3e(\pi)$, which are lower in energy than either $1a_{1u}(\pi)$ or $3a_{2u}(\pi)$, and the $4e(\pi^*)$ orbitals, which are higher in energy than either $1a_{1u}(\pi)$ or $3a_{2u}(\pi)$ (all shown in Figure 4), have the proper symmetry for overlap with the metal d_π orbitals, while under special circumstances the $3a_{2u}(\pi)$ orbital can interact with metal orbitals, and can hence be involved in modification of the properties of the iron porphyrin through π bonding effects. Since the $3e(\pi)$ orbitals are filled, the type of overlap interaction that can occur between them and the metal d_π orbitals is P → Fe π bonding (*see π-Bond*). Similarly, since the $4e(\pi^*)$ orbitals of the porphyrin ring are empty, overlap of the metal d_π orbitals with the $4e(\pi^*)$ orbitals can occur via Fe → P π *Back-Bonding*. This Fe → P π back-bonding can potentially occur to varying degrees when the metal electron configuration is (d_{xz},d_{yz}).[1–3]

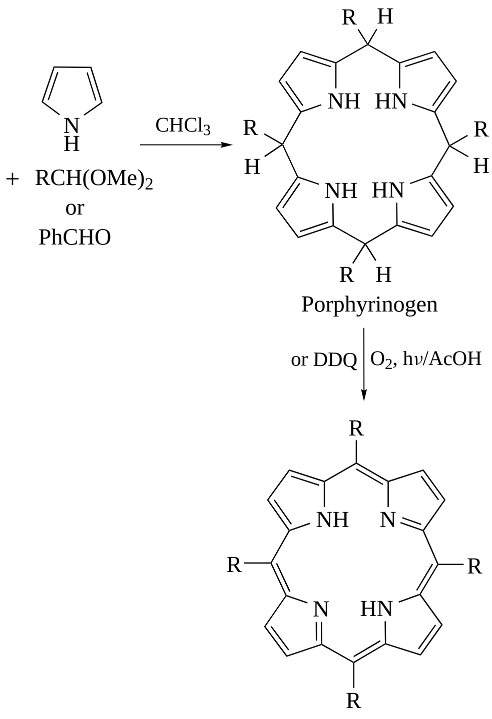
For dihydroporphyrins, also known as chlorins, the reduction of one pyrrole ring reduces the symmetry of the molecule, and thus removes the degeneracy of the $3e(\pi)$ and $4e(\pi^*)$ orbitals.[65,221–223] An important feature of this modification of the π orbitals of Figure 4 is that the former $1a_{1u}(\pi)$ orbital, which is denoted A_5 or $a_2(\pi)$ in the case of chlorins, has the proper symmetry at the nitrogens of the two rings adjacent to the reduced ring to allow overlap with one of the d_π orbitals. This has important consequences for the pattern of spin delocalization observed for both high- and low-spin Fe^{III} complexes of chlorins (ring system shown in Figure 1(m)),[65] and also for the reduction potentials of these complexes. Similar modifications of the electron density distribution and symmetry properties of the A,B-tetrahydroporphyrins (ring system shown in Figure 1(n)), better known as isobacteriochlorins, and the A,C-tetrahydroporphyrins, better known as bacteriochlorins, are also expected.

1.4 Synthesis of Metal Free Porphyrins

Because of the continued importance of porphyrin synthesis in biomedical, chemical, and industrial applications many new routes for synthesizing porphyrinic macrocycles have been developed and excellent overview articles have been published on the topic. To highlight the role that porphyrin synthesis plays, the entire volume 1 of the *Porphyrin Handbook* is devoted to the preparation of porphyrinic macrocycles. In this volume, Smith,[229,230] for example, describes strategies for synthesizing octaalkylporphryins by means of monopyrrole tetramerization, di- and tripyrrolic, and open-chain tetrapyrrolic intermediates, by degradation of natural pigments[229] or by means of cyclizations of a,c biladiene salts.[230] In the same volume, Lindsey[231] has reviewed the synthesis of *meso*-substituted porphyrins, Vicente the reactivity and functionalization of β-substituted porphyrins and chlorins,[232] Jaquinod[233] the functionalization of 5,10,15,20-tetra-substituded porphyrins, and Senge[234] the preparation of highly substituted porphyrins. In the following, the main points of some of the methods for synthesizing porphyrins are summarized.

Traditionally, both *meso*-aryl-substituted and β-pyrrole-substituted porphyrins, such as tetraphenylporphyrin (TPP) and octaethylporphyrin (OEP), respectively, as well as their hybrids, the dodecasubstituted porphyrins, such as octaalkyltetraphenylporphyrins and dodecaphenylporphyrins, have been synthesized by condensation of monopyrrolic moieties and the corresponding aromatic aldehydes. This synthetic pathway was described more than 60 years ago by Rothemund for the formation of TPP, which was prepared by reacting pyrrole and benzaldehyde in pyridine in a sealed bomb at 150 °C for 24 h.[235] Because of low product yields and harsh reaction conditions, only a few aromatic aldehydes were successfully used to synthesize the desired tetraphenylporphyrins. Thus, the initial reaction conditions for the synthesis of TPP have been modified. Adler *et al.*[236–240] obtained much higher yields by allowing benzaldehyde and pyrrole to reflux under *aerobic* conditions in propionic acid (141 °C) for about 30 min. By this method, a wider variety of porphyrins, including unsymmetrically substituted TPPs, have been obtained in yields of up to 20–30%. The preparation of the latter including mono-, di-, or trisubstituted tetraphenylporphyrins has been achieved by means of a modified Adler synthesis, the so-called 'mixed aldehyde approach'. Two different aromatic aldehydes and pyrrole are reacted in propionic or acetic acid to yield a mixture of porphyrins (*see Isomer, Types of*), which are separated by chromatographic techniques.[241–246]

One of the main drawbacks of the Adler method is the formation of large amounts of by-products. Since the separation of these tar-like products from the desired porphyrins by chromatographic techniques is tedious, expensive, and time-consuming, Lindsey[231,247,248] spearheaded the development of a new strategy for synthesizing tetraarylporphyrins by the condensation of dipyrromethanes. The two-step mechanism entails the acid-catalyzed condensation of pyrrole with the desired aromatic aldehyde to yield tetraphenylporphyrinogen, which is subsequently oxidized to the level of the porphyrin using mild oxidizing reagents, as shown in Scheme 1. Conditions for the one-pot, room temperature synthesis of *meso*-tetraphenylporphyrins,[249,250] and for the synthesis of substituted *meso*-tetraphenylporphyrins, such as tetramesitylporphyrin, using an automated microscale multireactor workstation[251] have been developed as well.



Scheme 1

A variation of this method that removes the water produced in the pyrrole/aldehyde or hydrated aldehyde condensation has been used to produce *meso*-tetrakis(perfluoroalkyl)porphyrins.[252,253] Lindsey's laboratory has also reported a rational synthesis of *meso*-substituted porphyrins bearing one nitrogen heterocyclic group[254] that can readily be used for preparing other mono-functionalized porphyrins, methods for minimizing scrambling in the synthesis of *trans*-porphyrins from dipyrromethanes and aldehydes,[255,256] and a rational synthesis of porphyrins bearing up to four different *meso* substituents.[257]

Van der Made *et al.*[258] and Kihn-Botulinski and Meunier[259] have discussed several factors crucial for the success of the Lindsey reaction and have optimized the conditions necessary to synthesize 'sterically hindered' porphyrins, such as tetramesitylporphyrin and tetrakis(2,6-dichlorophenyl)porphyrin. These compounds can be obtained in fairly high yields if all possible traces of water are removed during the reaction. Rocha-Gonsalves *et al.*[260] showed that porphyrinogens are very efficiently oxidized to porphyrins by nitrobenzene in the presence of acetic or propionic acid. The advantage of this method is that the formation of the porphyrinogen does not have to be maximized before the oxidizing agent is added. When the nitrobenzene/acetic acid or propionic acid oxidation is carried out as a 'one-pot' reaction, a variety of porphyrins have been obtained in crystalline form. The same laboratory has also published a one-step synthesis of dipyrromethanes in water, thereby providing convenient building blocks for the synthesis of a series of porphyrinic macrocycles.[261]

A rather different synthetic method has been developed by Bonar-Law, which involves the synthesis of porphyrins in aqueous micelles derived from sodium dodecylsulfate.[262] This is most appropriate for construction of porphyrins having particular hydrophobic multipoint recognition sites, such as those involving steroid dimers[262] or trans-disubstituted tetraarylporphyrins.[263]

Many investigators, including the authors, have used one or more of the synthetic approaches discussed above for the synthesis of symmetrically and unsymmetrically substituted tetraphenylporphyrins. These include porphyrins containing bulky substituents at one (or both) *ortho* position(s) of one (to four) phenyl ring(s), as well as sterically constrained porphyrins carrying potentially ligating tails. Excellent reviews of the preparation, structures, and reactions of porphyrins with appended peptides, chelated heme models, picket fence porphyrins, and capped and strapped porphyrins are given by Morgan and Dolphin[198] and Collman.[264,265] Since the first of these, many other sterically constrained porphyrins have been synthesized. They include the bis-picket fence porphyrin 5,10,15,20-tetrakis(2,6-dipivalamidophenyl)porphyrin,[266,267] octacarboxy-substituted porphyrins such as the 5,10,15,20-tetrakis(2,6-dicarboxyphenyl)-porphyrins,[268,269] 'picnic-basket' porphyrins,[270] 'arbor' porphyrins,[271] a steroid-capped porphyrin,[272] crown ether and A-frame capped porphyrins,[273] $\alpha,\alpha,\alpha,\alpha$-tetrakis(2-hydroxy-1-naphthyl)porphyrin, which complexes to quinones via multipoint hydrogen-bonding,[274] a picket-fence derivative that acts as a guest in a thermotropic nematic liquid crystalline host phase,[275] a phenol-pendant porphyrin as model of catalase,[276] a 2-hydroxy-5,10,15,20-tetraphenylporphyrin whose iron(III) complex makes a cyclic porphyrin trimer,[277] porphyrin-quinone conjugates for study of their ultrafast charge transfer reactions,[278–280] oxomolybdenum(V)-linked porphyrins,[281] porphyrins having two Kemp's triacid units to create a methane monoxygenase non-heme iron site contiguous with a porphyrin,[282–284] porphyrins having one hydrogen-bonding substituent within reach of an axial ligand,[285–287] porphyrins that self-assemble to form calixarene-porphyrin cages,[288] directly *meso-meso*-linked bis(triphenyl)porphyrins,[289] cofacial bisporphyrins[290–301] as models of the photosynthetic reaction center or the light-harvesting complexes, monoporphyrin, mono- or multi-accessory pigment complexes,[302,303] cyclic porphyrin trimers,[304] linear porphyrin dimers,[227,305–322] trimers,[311,321,322] to pentamers,[311,323] including those designed as molecular photonic wires,[324–329] molecular optoelectronic gates,[330–332] and 2,3- and 2,4-dioxoporphyrins as models for heme *d*.[333] Several routes to water-soluble tetraphenylporphyrins having 4-amino or alkylamino groups have been reported.[334–336]

Functionalization of 5,15-dibromo, 10,20-diphenylporphyrins and 2-bromotetraphenyl-porphyrins via metal-mediated cross-coupling methodology has led to a variety

of new porphyrins, including those having 2,2′-bipyridyl, vinyl, alkyl, or aryl groups bound to the position(s) originally carrying the bromine substituents.[337,338] As a special class of these reactions, the synthesis of phenylacetylene-linked porphyrins where the acetylene group is directly attached to the porphyrin core[321,322,339] and the related porphyrin-bridged donor-acceptor molecules having large molecular first hyperpolarizabilities[340–346] has been reported. The preparation of Suzuki porphyrins having pinacolborane functions as transmetalation reagents in Pd-catalyzed cross-coupling reactions[347] has provided an additional functionalization approach. Pd-catalyzed cross-coupling of porphyrins carrying aryl iodides to those carrying an aryl ethyne has also been reported.[348,349] Pyrrole-alkyne derivatives have been prepared from the pyrrole-brominated TPPs.[350,351] Mixed 4-substituted derivatives of tetraphenylporphyrin having three carboxy and one OH substituents[352] and other amphiphilic porphyrins that are *Membrane*-soluble[112,113,116,122,353–355] or *Membrane*-spanning[356] have been prepared. Tetraphenylporphyrins having p-carboxy and p-amino functionalities have been polymerized interfacially to produce chemically asymmetric membrane films.[357] Mercaptoporphyrins have also been polymerized to form ultrathin films of a porphyrin homopolymer based upon 5,10,15,20-tetrakis-(α-mercapto-p-tolyl)porphyrin,[358] and thiol-derivatized porphyrins for attachment to electroactive surfaces have been prepared and examined as means of information storage,[359–361] including those having a ferrocenyl moiety appended in several ways.[362] Various means of linking porphyrins to form arrays have been reviewed.[363] Preparation and investigation of the physical properties of cyclic tetra-,[364] hexa-,[365–367] hepta-porphyrin[368] and star-shaped multiporphyrin[325–327,369–372] or star-shaped tetra-[373] or octa-porphyrin, or monophthalocyanine[374] arrays have been described and reviewed.[375] As part of this work, methods of forming porphyrins in the presence of acid-labile metalloporphyrins that provide a new route to mixed-metal multiporphyrin arrays have been reported.[376]

Whereas a large number of model heme complexes are derived from the tetraphenylporphyrin moiety, another very important class of porphyrins bearing substituents only at the β-pyrrole carbon atoms, has been extensively investigated as models of heme proteins. One of the models most studied is octaethylporphyrin (OEP), which was originally synthesized from 2-dimethylaminomethyl-3,4-diethylpyrrole in an acid-catalyzed medium.[377,378] A similar approach is described by Ono *et al.*,[379,380] in which OEP, coproporphyrin or 2,7,12,17-tetraarylporphyrins are prepared in good yields from 2-carboxyethylpyrroles prepared from readily available nitroalkenes, or their equivalents, and aldehydes. A similar approach was used by Konishi *et al.*[381] for the synthesis of chiral strapped porphyrins, which were then resolved by chromatographic means to yield porphyrins with diasterotopic faces. It is also possible to condense 3,4-disubstituted pyrroles with formaldehyde in an acid-catalyzed medium to form octaalkylporphyrins.[382,383] A wide range of pyrroles are conveniently synthesized by reaction of tosylmethyl isocyanide (TosMIC) with a Michael acceptor.[384,385] When the reaction is carried out in the presence of two 3,4-disubstituted pyrroles, such as 3,4-diethylpyrrole and 3,4-bis(N,N-diethylcarboxamide)pyrrole, an isomer mixture containing OEP, the octakis(N,N-diethylcarboxamide)porphyrin, OAP,[383] and four unsymmetrically substituted porphyrins is obtained.[188] *Meso*-amino- and *meso*-amido-substituted OEP metal complexes can be prepared by treatment of the π-cation radical (for example, of Zn(II)) with amines or amides);[386] for primary amines, treatment with NaH to form the amide enhanced the reactivity. Liquid crystalline porphyrins, derived from octakis(β-hydroxyethyl)porphyrin, with long chain hydrocarbons attached at the alcohol functionalities, have also been prepared,[387] as have been porphyrin dimers based upon 5,8-ethanonaphtho-quinone bridging two pyrroles.[388]

Octaalkyltetraphenylporphyrins, which typically have a saddled geometry,[389] have been prepared by different routes.[229] For example, they have been synthesized by first preparing the dialkylpyrrole according to the methods of LeGoff and coworkers,[384,390] followed by reaction with benzaldehyde and oxidation with DDQ.[391] The cyclohexenyl-substituted octaalkyltetraphenylporphyrin, tetra-(β,β'-tetramethylene) tetraphenylporphyrin has been prepared by similar methods,[392,393] by first synthesizing the pyrrole, ethyl 3,4-butanopyrrole-2-carboxylate[394,395] from 1-nitrocyclohexane and ethyl isocyanoacetate in the presence of guanidine base,[396,397] followed by hydrolysis and decarboxylation to yield 3,4-tetramethylenepyrrole.[394] A water-soluble derivative of octaethyltetraphenylporphyrin, the octaacetic acid tetraphenylporphyrin, has also been prepared.[398] A 3,7,13,17-tetramethyl-5,15-diphenylporphyrin,[399] and tetraphenylporphyrins with graded degrees of β-ethyl substitution,[400] as well as octaalkyl-5,15-diphenylporphyrins[401,402] including one having an appended ferrocene derivative,[403] have also been synthesized. Other examples of sterically crowded porphyrins include 2,3,5,7,8,10,12,13,15,17,20-dodecaphenylporphyrin (DPP), which is synthesized according to a method similar to the one described by Lindsey.[247,248] Because of the steric crowding of the phenyl rings the porphyrin macrocycle is forced to adopt a nonplanar conformation in solution and in the solid state. The deviation from planarity is indicated by the red-shifted electronic absorption spectrum.[404] Additional examples include polyhalogenated tetraphenylporphyrins and their iron complexes that have been studied as potential catalysts (*see Catalysis*) for epoxidations and other reactions involving high-valent iron porphyrins.[405] Octafluoro- and octabromotetraphenylporphyrin derivatives have been prepared by the N-bromosuccinimide method described by Callot[406] and Traylor and Tsuchiya[405] or by its modification using CF_3CO_2H described by Battioni *et al.*[407] Another method for synthesizing bromo-substituted derivatives entails the bromination reaction of TPPCu followed by an acid demetalation reaction.[408] It should be noted that the analogous chloro-substituted products cannot be prepared as

described above. Facile chlorination is accomplished, when the corresponding porphyrins are reacted with Cl_2(g) in the presence of $FeCl_3$.[409] Mixed *β*-bromine, cyanide-substituted tetraphenylporphyrins have also been produced.[410]

Multi-ferrocenyl phthalocyanines having up to 16 ferrocene units per molecule have been built with oxyethylene linkers to create aliphatically linked ferrocene units,[411] and ethynyl bridges have been used to create ferrocenyl-linked tetrapyrroles of both phthalocyanine and porphyrin types with unsaturated links;[412] the porphyrins have two ferrocene units, which are placed on opposite *meso* positions. Both the aliphatically linked and the ethynyl-linked compounds were shown to exhibit no electrochemical communication between ferrocene units.[411,412]

Unsymmetrically substituted derivatives of protoporphyrin IX, such as vinylporphyrins, have been successfully synthesized according to the dipyrromethane method originally described by Johnson and Kay.[413,414] This general method has been modified[415] for the preparation of porphyrin-containing receptors for barbiturates as models of barbiturate-induced cytochromes P450.[416] Oxidative cyclization of open-chain tetrapyrrolic compounds, such as 1,19-dimethylbilenes-*b* and 1,19-dimethylbiladienes-*ac*,[417] and oxobilanes-*a* and oxobilanes-*b* (Figure 5), using copper(II) salts in refluxing solvents such as DMF or DMSO/pyridine, results in the formation of the corresponding porphyrins.[418–427] According to this method, in which dipyrrylmethanes were found to be important intermediates in constructing the open-chain tetrapyrrole, biologically relevant macrocycles, such as porphyrin *a* and chlorophylls c_1 and c_2, can be obtained.

Modification of protoporphyrin IX at the propionate positions has been used by Traylor and coworkers[428] and Casella *et al.*[429] to prepare porphyrin complexes with a covalently attached axial ligand or ligands. The latter workers

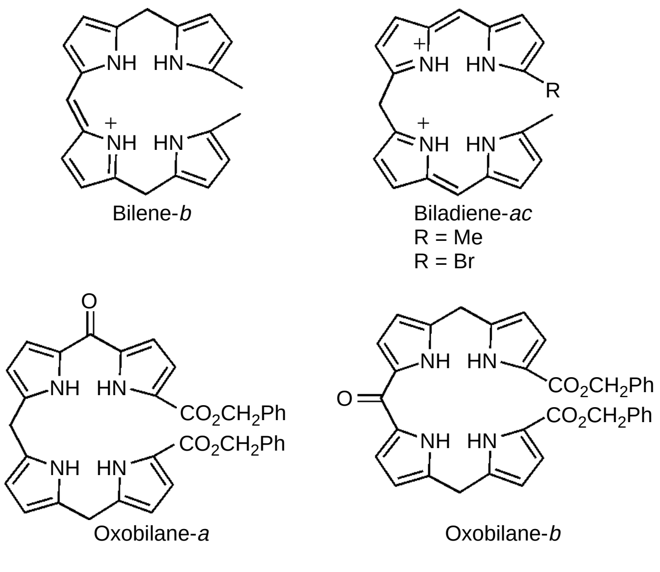


Figure 5 Open-chain tetrapyrroles used in porphyrin synthesis[422]

also bonded protohemin-6(7)-L-arginyl-L-alanine and –L-histidine methyl ester modified protohemins to apomyoglobin and investigated the reactivity of these complexes according to peroxidase-type oxidations.[430] Other very useful heme protein models are provided by the microperoxidases, MP8, MP9, MP10 and MP11, also called the heme octa- to undecapeptides, which use a similar approach, where the anchoring of the histidine axial ligand is retained and provided by the peptide chain and one additional axial position is available for various chemical reactions. These compounds, in which bovine cytochrome *c* is hydrolyzed with specific enzymes to leave only short fragments of polypeptide surrounding the Cys-XY-Cys-His sequence that provides the covalent attachment of the heme to the protein and one of the axial ligands can be prepared or purchased. Depending on the enzyme used, different numbers of amino acids are retained. For example, using pepsin and trypsin MP8 is obtained,[431–433] which consists of the fragment Cys-Ala-Gln-Cys-His-Thr-Val-Glu, amino acids 14–21 of the original horse heart cytochrome *c* protein. MP9, which also includes Lys-22, is a product of trypsin cleavage of horse heart cytochrome *c*.[434] MP10 can be made by trypsin-catalyzed peptide bond formation to the C-terminal end of MP9, where the residue added, at the original 23 position of cytochrome *c*, can be any desired amino acid.[435] Gray and coworkers have investigated Tyr-23, Met-23 and His-23 MP10 derivatives and reported that both Tyr-23 and His-23 bind to the Fe^{III} and Fe^{II} states to produce low-spin 6-coordinate heme centers, but that Met-23 does not bind to the iron ion in either oxidation state.[435] MP11 is the fragment that contains three additional N-terminal amino acids, Val-Glu-Lys, and is produced by pepsin cleavage of horse heart cytochrome *c*.[436] The N-terminal amino group is acylated to prevent aggregation.[432–434] Some of the microperoxidases are discussed further in the appropriate sections of this article.

Synthesis and characterization of other related macrocycles, including chlorins,[59,437–441] isobacteriochlorins,[157,441] bacteriochlorins,[441,442] mono- and dioxoporphyrins,[441,443–447] other more highly saturated hydroporphyrins,[441] *N*-alkyl- or *N*-arylporphyrins,[158,159] some of which are chiral,[448] porphodimethenes,[449,450] thiaporphyrins,[160,451–453] oxaporphyrins,[452,453] N-confused[452,454–456] and carbaporphyrins,[452,457] porphycenes[458–460] and corrphycenes,[461–464] tetraazaporphyrins,[163,465,466] phthalocyanines,[467,468] the ring-expanded sapphyrins,[455,469,470] texaphyrins[471,472] and others,[470] and the ring-contracted corroles[165,473–479] and corrolazines[480] have also been synthesized and are discussed in the indicated references.

1.5 Iron Insertion into Free-base Porphyrins

With a few exceptions, almost all metals and metalloids can be coordinated to the nitrogen atoms of the porphyrin macrocycle according to equation (1):

$$\text{P or H}_2 + \text{M}^{n+} \longrightarrow \text{P or M}^{(n-2)+} + 2\text{H}^+ \qquad (1)$$

For the insertion of the iron ion into the porphyrin a variety of general procedures have been described and reviewed.[481,482] In most cases, these methods lead to the formation of Fe^{III} complexes, which are then used to prepare Fe^{I}, Fe^{II}, Fe^{IV}, and Fe^{V} porphyrins. The most commonly employed methods for synthesizing Fe^{III} porphyrins are described below. The preparation of the Fe^{II} and Fe^{I} complexes from the iron(III) porphyrins by chemical or electrochemical means and the oxidized iron porphyrins (Fe^{III} π-cation radicals, Fe^{IV}, Fe^{IV} π-cation radicals, and Fe^{V}) by chemically or electrochemically oxidizing the iron(III) porphyrins is described in more detail in the sections on the corresponding iron porphyrins below. Whereas Fe^{III} porphyrins can be photochemically reduced to Fe^{II} porphyrins,[483] only a few examples of photooxidations of the iron center are known, which include laser photolysis of the co-condensation products of PFe^{II} at 15 K to produce $PFe^{IV} = O$.[484] Typical photochemical reactions of iron and other metalloporphyrins have been summarized by Suslick and Watson.[483]

1.5.1 Reaction of the Porphyrin with Iron(II) Sulfate in Acetic Acid[485]

According to this procedure, which uses mild metalation conditions and has no ill effects on most peripheral porphyrin substituents, the porphyrin is dissolved in a minimum amount of pyridine, diluted with glacial acetic acid, and reacted under an inert gas atmosphere at 90 °C with a freshly prepared saturated aqueous solution of iron(II) sulfate. The reaction mixture is cooled to room temperature while a stream of air is passed through the solution to oxidize Fe^{II} to Fe^{III}. Unreacted porphyrin is removed by column chromatography. This method has also been used with minor modifications for the insertion of ^{57}Fe into a number of porphyrins.[486,487]

1.5.2 Reaction of the Porphyrin with an Iron(II) Salt in Refluxing DMF[488–490]

The synthetic procedure for this method, which is a more rapid, but also a more harsh alternative, consists of simply reacting the porphyrin and a stoichiometric amount or a slight excess of an iron(II) salt, such as iron acetate, chloride, bromide, or carbonate, in refluxing DMF. The reaction is quantitative and the porphyrins are usually converted to the metal complex within a few minutes. However, we have found that considerably longer reflux times are required for insertion of iron into the tetrakis(2,6-disubstituted phenyl) porphyrins.[491,492] After cooling, water is added to the solution to crystallize the iron complex. For product isolation on a small scale it is, however, better to add chloroform or dichloromethane to the cooled DMF solution and then pour it through water, separate the organic layer, and then wash it repeatedly with equal volumes of water in a separatory funnel to remove remaining iron salts and DMF before evaporation to dryness.[493] If the reaction is carried out with $FeBr_2$ in 1,2-dimethoxyethane with small amounts of pyridine present, the conversion of the porphyrin to the iron complex is completed in about 4 h; the percent metalation in this solvent is only 50%.[494] If the above-mentioned isolation procedures or those described in method 1 and the methods to follow, are carried out in the presence of air, the iron(III) complex is formed. In the presence of water or hydroxide ion, most Fe^{III} porphyrins readily hydrolyze to form the μ-oxo dimers according to equation (2):

$$2PFe^{III}\text{–}OH \longrightarrow PFe^{III}\text{–}O\text{–}Fe^{III}P + H_2O \qquad (2)$$

To convert the dimer back to the monomeric form, dry gaseous HCl is typically bubbled through a solution (dry benzene, chloroform, or other nonprotic organic solvent) of the sample. Fe^{III} porphyrins containing acid-labile functionalities, including those having appended oxomolybdenum complexes,[281,495] cannot be treated this way, and hence the above-described isolation of the Fe^{III} porphyrin by extraction with water must be carried out using saturated aqueous NaCl, followed by drying over powdered NaCl instead.

1.5.3 Reaction of the Porphyrin in Chloroform with an Iron(II) Salt in Methanol/Chloroform[246,496]

Since working with high-boiling DMF is not always convenient, we have shown that iron ion insertion is easily achieved by reacting a chloroform solution containing the porphyrin with an excess of iron(II) salt, preferably anhydrous $FeBr_2$ or iron(II) acetate, dissolved in chloroform containing a minimum amount of methanol.[246,496] The solution is refluxed until no free-base porphyrin is detectable by UV–vis spectroscopy or TLC. Excess iron salt is removed by repeated washings with water,[246,496] as described above, and the solvent is evaporated under vacuum.

1.5.4 Reaction of the Porphyrin with Fe^{III} Salts[497]

It has also been shown that iron(III) ion can be directly inserted into the porphyrin ring by reacting it with $FeCl_3 \cdot 6H_2O$ in glacial acetic acid.[497] A trace amount of sodium acetate is added and the solution is allowed to reflux for 90 min. This method, however, is not suitable for protoporphyrin IX derivatives, which are susceptible to acid-catalyzed hydration of the vinyls to yield α-hydroxyethyl groups.

1.5.5 Reaction of the Porphyrin with Fe^{II} Acetylacetonate in High-boiling Solvents[498–500]

A less common method involves the reaction of the metal-free porphyrin with a metal(II) acetylacetonate in molten

phenol or in refluxing 1,2,4-trichlorobenzene.[498,499] In the case of reduced porphyrins (chlorins, isobacteriochlorins), where metal insertion is more facile, benzene, toluene, and chloroform can be used as refluxing solvents.[500]

1.5.6 *Reaction of the Dilithium Salt of the Porphyrin with Ferrous Chloride*[501]

In this method, which is appropriate for porphyrins having strongly electron-withdrawing substituents, such as β-tetrakis(trifluoromethyl)-*meso*-tetraphenylporphyrin, the porphyrin free base is reacted with lithium bis(trimethylsilyl)-amide in THF at room temperature under argon or nitrogen for 5 min, and then with a slightly less than stoichiometric amount of ferrous chloride under the inert gas atmosphere at 50 °C for two hours. Following solvent removal, the product is dissolved in CH_2Cl_2/petroleum ether (50/50 v/v) and chromatographed on a neutral alumina column. Solvent evaporation, followed by dissolution of the residue in CH_2Cl_2 and treatment with 6 M HCl, separation from the aqueous layer, drying over Na_2SO_4 and solvent evaporation yields the chloroiron(III) porphyrin complex.[501]

2 IRON(0) PORPHYRINS AND THEIR REACTIONS

As is described in more detail in subsequent sections, it is well established that iron(III) porphyrins can be reduced by photochemical, electrochemical, and radiochemical methods in organic or aqueous solutions to give Fe^{II} and Fe^{I} complexes.[502–510] Recently, it has also been shown that such reactions lead to the formation of complexes with the iron in the zero oxidation state. Such Fe^{0} porphyrins are, for example, formed electrochemically when Fe^{III} porphyrins ($[PFe^{III}]^{+}$) are reduced in three successive steps in DMF in the presence of a weak Brønsted acid as co-catalyst to yield the iron(II) porphyrin ($[PFe^{II}]$), the iron(I) porphyrin ($[PFe^{I}]^{-}$) and the iron(0) porphyrin ($[PFe^{0}]^{2-}$).[503–506] Iron(0) porphyrins are described to be effective and persistent molecular catalysts of H^{+} and CO_2 reduction to produce H_2 and CO, respectively.[503–506,508] The zero oxidation state complexes are stable in aprotic solvents, such as DMF or DMSO, on the timescale of slow scan cyclic voltammetry, thin-layer spectroelectrochemistry, and even longer periods when water and oxygen are carefully excluded.[506] Electrochemically generated Fe^{0} porphyrins undergo metal-centered reactions with alkyl and vicinal mono and dihalides,[506,509,511] and with CO_2[512] leading, for the vicinal dihalides and CO_2, to efficient catalysis of electrochemical reactions.[506] It is noteworthy that the Fe^{0} species can be electrochemically generated by reduction of iron(I) porphyrins. However, in the presence of axially coordinated CO this reduction does not take place. Axial CO binding to Fe^{I} yields iron(II) phlorin anion complexes, which may be converted back to iron(II) complexes upon anodic oxidation.[506] For CO_2, the reduction mechanism is suggested to involve a Fe(II)-CO_2 intermediate,[503] whereas the reduction of H^{+} is suggested to proceed via the formation of a an iron(II) hydride, which reacts with a second acid molecule with the evolution of H_2.[504] The finding that Fe^{0} porphyrins are good reductants of both H^{+} and CO_2 was corroborated by studies of Grodkowski *et al.*,[502] who showed that Fe^{I} porphyrins do not directly reduce H^{+} or CO_2, but that the Fe^{I} complexes undergo a disproportionation reaction to form PFe^{II} and $[PFe^{0}]^{2-}$ with the latter acting as reducing agent, in line with the results reported by Lexa and Savéant.[503–505,508–510,512–515]

3 IRON(I) PORPHYRINS AND THEIR REACTIONS

Although highly reduced iron porphyrins have been of interest because of the earlier belief that they might be involved in the catalytic cycles of certain redox proteins,[516–519] their importance for dioxygen activation,[520] and their synthetic value for preparing (σ-alkyl)porphyrin complexes,[513,514] only a few iron porphyrins, in which the metal atom is assigned the +1 oxidation state, have been synthesized and characterized. In these low-valent species, the porphyrin macrocycle is either derived from TPP, OEP, Etioporphyrin (ETIO),[521] 2,7,12,17-tetrabromo-5,10,15,20-tetraphenylporphyrin (Br_4TPP), 2,7,12-tricyano-5,10,15,20-tetraphenylporphyrin ($(CN)_3$TPP), 2,7,12,17-tetracyano-5,10,15,20-tetraphenylporphyrin ($(CN)_4$TPP),[516] dodecaporphyrins (DPP) with varying degrees of fluorination at the peripheral phenyl rings[522] (F_xDPP, with $x = 4$, 8, 12, 20, 28, or 36), or core-modified 5,10,15,20-tetraphenyl-21-oxaporphyrin (OTPP).[523] The TPP, OEP and DPP derivatives can be conveniently synthesized by means of chemical or electrochemical reduction. Both two-electron reduction of the corresponding iron(III) porphyrins by strong reducing reagents[182,518,519,524] or by cathodic electrolysis[515,516,520,525,526] yield the low-spin iron(I) complexes. The oxaporphyrin OTPPFe^{I} has been reported and prepared by two different routes, either by reduction of (OTPP)Fe^{II}Cl with $NaBH_4$ in THF or by the treatment of (OTPP)$Fe^{III}Cl_2$ with 2 equivalents of PhMgBr.[523] As described above, these iron(I) complexes can be further reduced electrochemically[503–505,507–510] or photochemically[502] to yield either ($P^{3-}\cdot$) Fe^{I} or PFe^{0} complexes.

A number of spectroscopic techniques and physical measurements have been used to unambiguously describe the electronic structures of the putative iron(I) complexes, and to determine whether the reduced species are best described as d^7 iron(I) porphyrins, $[PFe^{I}]^{-}$, with the spin of the unpaired electron residing in the d_{z^2} orbital, as porphyrin π anion radicals, or as intermediates between these two limiting cases.[518,522] This distinction is most easily achieved

by EPR spectroscopy as was first established by Bocian[516] and was shown recently for the DPP complexes[522] and by DFT calculations of g-tensors of low-spin TPP and OEP iron(I) porphyrins.[527] The Fe^{I} porphyrin complexes give rise to anisotropic signals with $g_\perp$ around 2.3 and $g_\parallel$ around 1.93, whereas the EPR spectra of iron(II) porphyrin π-anion radicals exhibit isotropic signals with g-values of 2.00. For the $DPPFe^{I}$ porphyrins, similar values were obtained ($g_\perp = 2.17$ and $g_\parallel = 1.96$).[522] For these complexes it is worth mentioning that the reduction of the non-fluorinated Fe^{II} complexes in benzonitrile leads to the formation of iron(I) porphyrins, whereas the fluorinated complexes, such as F_{20}DPPFe, produce iron(II) porphyrin π-anion radicals in the same solvent. By means of an intramolecular electron-transfer reaction, this complex is further reduced to the iron(I) species thereby highlighting the role of non-planar deformations. In pyridine, all DPPFe complexes are converted to porphyrin π-anion radicals upon electrochemical reduction to the Fe^{II} porphyrin independent of the degree of non-planarity of the complexes.[522] For the iron complexes of TPP, OEP, ETIO, the deuteroporphyrin IX dimethyl ester anion,[515] and for the phthalocyanine (Pc) analog,[528] NMR isotropic shifts,[521] EPR g-values ($g_\perp = 2.3$ and $g_\parallel = 1.93$ for $[TPPFe]^-$,[519,529] $g_\perp = 2.24$ and $g_\parallel = 1.92$ for $[OEPFe]^-$,[521] and $g_\perp = 2.119$ and $g_\parallel = 1.956$ for $[PcFe(Py)]^-$,[528] with $g_\perp > g_\parallel$ in each case), resonance Raman spectroscopy,[529,530] Mössbauer data,[518] and magnetic moments ranging from 2.3 to 5.0 μ_B[518,519,524] support the $[PFe^{I}]^-$ formulation of the complexes. A spin state of $S = 1/2$ is observed, with EPR parameters consistent with the unpaired electron residing in the d_{z^2} orbital,[519,521,528,529] by analogy with Co^{II} porphyrins.[531] Consistent with this electronic structure, five-coordinate complexes of $[PcFe]^-$ exhibit superhyperfine splitting from the N or P donor atom of the axial ligand.[528] The conclusions drawn from the spectroscopic data of four-coordinate porphyrin complexes are consistent with the molecular structure of the $[TPPFe]^-$ complex, which reveals a square planar geometry, with bond lengths fully consistent with the depopulation of the $d_{x^2-y^2}$ orbital.[518] DFT calculations of the g-values using a variational method for handling spin-orbit coupling and applying an average of configuration (AOC) of nearly degenerate states yielded what was considered reasonable comparison between calculated (2.51, 2.01) and experimental (2.3, 1.93) g-values for open-shell complexes,[532] although the difference between the calculated and experimental values seems to the authors to be unacceptably large, and the difference between $g_\parallel > 2$ and $g_\parallel < 2$ suggests that much improvement is still needed in these calculations.

However, based on UV–vis data[515,518,521,533,534] and other crystallographic studies,[535] the description of the reduced species as porphyrin π–anion radicals cannot be excluded in all cases. Electrochemical reduction of $(Br)_4$TPPFeCl, $(CN)_3$TPPFeCl, and $(CN)_4$TPPFeCl (the Br and CN substituents are on the β-pyrrole positions in these complexes)[516] results also in the formation of low-spin, singly reduced iron(II) complexes, with the spin of the unpaired electron residing either in a metal or porphyrin ring orbital.[516] Optical absorption, EPR, and resonance Raman studies of $[(Br)_4TPPFe]^-$, $[(CN)_3TPPFe]^-$, and $[(CN)_4TPPFe]^-$ indicate that the electron density in singly reduced iron(II) porphyrins can be systematically transferred between the metal ion and the porphyrin ring by altering the electron-withdrawing capability of the porphyrin ligand.[516] Complexes with more negative $[PFe^{II}]/[PFe^{I}]^-$ redox couple (-0.812 V) ($[TPPFe]^-$ and $[(Br)_4TPPFe]^-$) have the unpaired electron in the d_{z^2} orbital, but reduction results in the transfer of a significant amount of *paired* electron density to the macrocycle through π back-bonding. The ground state for the low-spin Fe^{I} porphyrin complexes are hence formulated as $^2A_{1g} = (d_{xy})^2(d_{xz},d_{yz})^4(d_{z^2})^1$. For $[(CN)_3TPPFe]^-$ and $[(CN)_4TPPFe]^-$, for which the redox couple is more positive (-0.539 V), the unpaired electron resides on the macrocycle, indicating a $[(P^{3-}\bullet)\ Fe^{II}]\ ^2E_g$ ground state for these complexes.[516]

The homolytic cleavage decomposition of n-butyliron(II) 5,10,15,20-tetraphenyl-21-oxaporphyrin creates an Fe(I) complex whose EPR spectrum (toluene-d_8) was interpreted as being consistent with a $(d_{xy})^2(d_{xz},d_{yz})^4(d_{z^2})^1(d_{x^2-y^2})^0$ electronic ground state ($g = 2.234, 2.032, 1.990$).[536] However, based on the shape of this EPR spectrum, which is very similar to those of Cu(II) tetragonal complexes, and the ^{1}H NMR spectral shifts, the authors suggest instead a $(d_{xy})^2(d_{xz},d_{yz})^4(d_{x^2-y^2})^1(d_{z^2})^0$ electron configuration. The ^{1}H NMR spectra, with large positive pyrrole-H shifts of 156.2, 129.5, and 76.3 ppm and furan-H shift of 161.4 ppm, is totally consistent with a low-spin d^7 electron configuration in which the unpaired electron is in the $d_{x^2-y^2}$ orbital.[536]

As already mentioned above, iron(I) porphyrins can undergo various reactions. They are of synthetic value for preparation of σ-alkyl iron porphyrins, which can be obtained by direct alkylation of the corresponding electrochemically generated iron(I) porphyrins with alkyl halides.[513,537] The highly reduced species can also be oxidized by molecular oxygen or hydrogen peroxide to yield the iron oxyporphyrin (oxophlorin), which is further oxidized to verdoheme by molecular oxygen,[538–540] as discussed in Section 6.1.5.

As potential models for the assimilatory nitrite reductases, electrochemical reduction of nitrosyliron(II) porphyrins (*see Nitrosyl Complexes*), PFeNO, yields first the Fe^{I}–NO complex, followed by two additional one-electron reductions. In the presence of phenols, the product of electrolysis is hydroxylamine.[541]

4 IRON(II) PORPHYRINS AND THEIR REACTIONS

Iron in the oxidation state +2 plays an important role in model heme and heme protein chemistry because of

dioxygen binding, activation, and transfer. Depending on the coordination and environment of the metal ion, iron porphyrins are either four-, five-, or six-coordinate, with intermediate spin states ($S = 1$) for the four-coordinate complexes, [PFe^{II}], high-spin ($S = 2$) states for the five- or six-coordinate complexes, [$PFe^{II}L$] or [$PFe^{II}L_2$], and low-spin ($S = 0$) states for the five- or six-coordinate complexes, [$PFe^{II}L$] and [$PFe^{II}L_2$]. Unlike iron(II) phthalocyanine, [$PcFe^{II}$], iron(II) porphyrins are typically very reactive toward dioxygen, not only in solution, but also in the solid state,[542] and thus have been extensively studied to elucidate, for example, the mechanisms of reversible dioxygen binding by hemoglobin (Hb) and myoglobin (Mb) (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***), and the modes of action of the P450 monooxygenases and other heme-containing oxygenases (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***).[32] The +2 oxidation state has also been identified for the ferrous and ferrous-CO forms of cytochrome P460, which belongs to the group of mono-heme cytochromes of ~18 kDa molecular weight. It is one of the monomers of the enzyme hydroxylamine oxidoreductase (HAO), which is a very complex homotrimer with a molecular weight of 64 kDa per monomer. Each monomer contains seven *c*-type hemes and a so-called P460 as the eighth heme.[543,544] Many of these proteins employ a five-coordinate iron center in their native deoxy state and are high-spin, $S = 2$ species. The sixth coordination site is vacant for binding of dioxygen or other small molecules, such as carbon monoxide, nitric oxide, or isocyanides and phosphines. Upon small molecule binding, either five- or six-coordinate iron porphyrin complexes may be formed, and, depending on the field strength of the coordinating ligand, a spin-state change occurs from the paramagnetic to the diamagnetic, low-spin ($S = 0$) state. Comprehensive overviews of the interactions of iron porphyrins with small ligands have been published. Momenteau and Reed[545] have summarized the chemistry of synthetic heme dioxygen complexes, covering the literature up to early 1993. To assess the factors that influence heme conformations, the late Momenteau also reviewed the literature on supramolecular control of structure and reactivity.[546] The binding and activation of nitric oxide by metalloporphyrins and hemes have been reviewed by Cheng and Richter-Addo,[547] and the solid state structures of metalloporphyrin NO_x compounds by Wyllie and Scheidt,[185] who also summarized the systematics of the stereochemistry of porphyrin and metalloporphyrin structures.[548] The mechanistic aspects of the reactions of nitric oxide with transition metal complexes have been discussed by Ford *et al.*,[549–551] the axial coordination chemistry of iron(II) by Sanders *et al.*,[552] and the binding of isocyanides and phosphines as axial ligands in heme proteins and iron porphyrin models by Simonneaux and Bondon.[553] We will begin our discussion of Fe^{II} porphyrins with the four-coordinate *Square Planar*, $S = 1$ state, then turn to the five-coordinate, $S = 2$ state, and finally to the six-coordinate, diamagnetic, $S = 0$ state.

Theoretical calculations of the energies of the electronic states of iron porphyrinates of coordination numbers 4, 5 and 6 have developed significantly in recent years. For example, the performance of density functional theory (DFT) calculations of the low-lying excited states of iron(II) porphyrinates using the B3LYP density functional in combination with ab initio effective core potentials (ECPs) that are derived from either Hartree-Fock or Dirac-Fock calculations was investigated.[554] Five low-lying spin states, $^1A_{1g}$, $^3A_{1g}$, $^3B_{2g}$, $^5A_{2g}$, and $^5B_{1g}$ and their properties were calculated. It was found that the effects of replacing the core electrons with ECPs are less significant than the choice of basis functions, and that ab initio ECPs can be combined with the B3LYP density functional theory to provide consistent and accurate results.[554] Other nonlocal DFT calculations using the 6-31G-(d) basis set for H, N, O, and the VTZ basis of Ahlrichs[555] have identified 8[556] or 10[557] low lying states ($^5A_{1g}$, ^5E_g, $^5B_{2g}$, $^3A_{2g}$, $^3B_{2g}$, $^3E_g(A)$, $^3E_g(B)$, $^1A_{1g}$). A relationship between the electronic state and the size of the porphyrin core was found, with the singlet and triplet states exhibiting the smaller, and the quintet states the larger, core sizes. From this it was concluded that for low-spin Fe^{II} porphyrins the metal-N_{por} bond lengths are determined mainly by the electronic state and the occupancy of the antibonding $d_{x^2-y^2}$ orbital,[556] and to a lesser extent by the nonbonding interactions between the axial-ligand atom and the porphyrin N atoms. The results of these calculations of particular model systems will be presented in the appropriate section below.

4.1 Four-coordinate Intermediate Spin ($S = 1$) Iron(II) Porphyrin Complexes

Structural Aspects. Four-coordinate iron(II) porphyrins are of intermediate spin state ($S = 1$) and are in general square planar, with the iron placed in the center of the porphyrin core. However, the porphyrin ring is not always planar, as is observed for the $OEPFe^{II}$ species. It can be ruffled as was found for $TPPFe^{II}$ or $OECFe^{II}$ derivatives,[548] or saddled as was reported for a second crystalline form of $TPPFe^{II}$.[558] All complexes are characterized by relatively short Fe-N_{por} bond lengths (1.95–1.97 Å), which are indicative of the depopulation of the $d_{x^2-y^2}$ orbital, as is required for the $S = 1$ spin state.

Synthesis. The [PFe^{II}] complexes are most conveniently prepared by reduction of the corresponding Fe^{III} porphyrins in the absence of potential axial ligands using either chromium(II) complexes, aqueous dithionite under vacuum,[559–561] sodium amalgam,[562,563] borohydride salts,[564] or zinc amalgam in aprotic organic solvents.[565–575] Using aqueous sodium dithionite or Zn/Hg an Fe(II) porphycene complex, namely the Fe(II) complex of 2,7,12,17-tetra-*n*-propylporphycene [($TprPc)Fe^{II}$] has also been synthesized by

the reduction of the respective Fe(III) complex.[576] Whereas superstructured or picket fence iron(II) porphyrins are often prepared by reduction with dithionite under vacuum,[559–561] an additional method of preparation involves the reaction of the four-coordinate porphyrin with anhydrous potassium carbonate and ferrous bromide under strictly anaerobic conditions.[577,578] Another strategy entails the demetalation of zinc(II) complexes with CF_3SO_3H followed by treatment with $FeBr_2$ in absolute ethanol.[579] Highly fluorinated [F_xTPPFe^{II}] complexes have been synthesized using mercury activated zinc powder in the reduction of the Fe^{III} species,[580,581] whereas the corresponding [Br_xTPPFe^{II}] complexes with $x = 0-8$ are generated by electroreduction of the high-spin Fe^{III} porphyrins.[582] This reaction also allowed the Fe^{I} and Fe^{I} π-cation radical to be electrochemically formed.[582] Other methods include the photoreduction of, for example, protoporphyrin dimethyl ester Fe^{III}, which in DMSO at 150 K leads to the formation of the unligated $S = 1$ Fe^{II} complex.[583] TMPFe^{II} complexes have been prepared by reduction of [TMPFe^{III}OH] solution in an aprotic solvent with ethanethiol or with a chloroform solution of zinc amalgam.[575] Ethanethiol has also been used to synthesize 4-coordinate perfluoroalkyltetraphenylporphyrinatoiron(II) complexes[584,585] or to synthesize TPPFe^{II} complexes[586] by reduction of the μ-oxo dimer $[FeTPP]_2O$ according to a method developed by Stolzenberg.[59] Two polymorphs of octaethyltetraazaporphyriniron(II) (α- and β-OETAPFe^{II}) have also been synthesized by reacting the unmetallated porphyrins with FeI_2 in THF/toluene with added 2,6-lutidine to give the air-sensitive unligated Fe(II) complexes.[587,588] These complexes have interesting magnetic properties, an extraordinarily large internal hyperfine field (62.4 T), and represent a rare case of true ferromagnetically ordered molecular solids.

Electronic Ground-state Configuration. While researchers agree that the ground state of four-coordinate Fe^{II} porphyrins is of intermediate spin, $S = 1$,[589] the electronic ground-state configuration remains controversial.[590] Among the ten low-lying possible ground states for four-coordinate iron(II) porphyrins ($^5A_{1g}$, ^5E_g, $^5B_{2g}$, $^3A_{2g}$, $^3B_{2g}$, ^3E_g(A), ^3E_g(B), $^1A_{1g}$, $^1B_{2g}$, and ^1E_g),[557] the one that is favored by most spectroscopic studies including magnetic, Mössbauer, NMR, and optical spectra of [TPPFe^{II}] and [OEPFe^{II}],[589] and DFT calculations,[556,590] is the $^3A_{2g}$ state arising from the electron configuration $(d_{xy})^2(d_{z^2})^2(d_{xz},d_{yz})^2$. However, the $^3A_{2g}$ assignment is not supported by the early literature. Resonance Raman data of [OEPFe^{II}] and Mössbauer and magnetic measurements of the Fe^{II} complex of octamethylbenzoporphine were in this literature interpreted in terms of the ^3E_g $(d_{xy})^2(d_{z^2})^1(d_{xz},d_{yz})^3$,[589,590] which does not rule out the $^3A_{2g}$ state, or the $^5B_{2g}$ states, respectively.[590] Whereas most workers have settled on the triplet $^3A_{2g}$ state, they differ in opinion on the details of the relative energies of the excited states. Susceptibility and magnetic anisotropy studies of single crystals of [TPPFe^{II}] at 4–300 K support the $^3A_{2g}$ ground state, but consider the ^3E and ^3B excited states as being close in energy (1425 and 2425 cm^{-1}, respectively) to the $^3A_2$ ground state.[544] Optical spectra have been explained in terms of the $^3A_{2g}$ ground state with the ^3E_g state being only 240 cm^{-1} higher in energy.[591] Mössbauer[592] and NMR[565–569,589] data pinpoint the $^3A_{2g}$ ground state as arising from the $(d_{xy})^2(d_{z^2})^2(d_{xz},d_{yz})^2$ configuration. Analyzing the isotropic shifts of the TPPFe^{II}, RTPPFe^{II}, and OEPFe^{II}, Goff and La Mar[565] found that with the exception of the pyrrole-H signals all other proton resonances are significantly shifted to lower shielding, which implies that at least a major portion of the isotropic shifts originates in the dipolar interaction. This is an expected result for four-coordinated Fe^{II} porphyrins, since they are highly magnetically anisotropic.[565] The negative pyrrole-H isotropic shifts indicate that electron spin is absent from the $d_{x^2-y^2}$ orbital and that the d_{xz} or d_{yz} orbital(s) are occupied by at least one unpaired electron.[168,174] These reflect extensive π spin delocalization via P $\rightarrow$ Fe π electron transfer, with no evidence for Fe $\rightarrow$ P π back-bonding, which requires unpaired spin in d_{xz} and d_{yz} thereby strongly supporting the $^3A_{2g}$ ground-state with the $(d_{xy})^2(d_{z^2})^2(d_{xz},d_{yz})^2$ electronic configuration.[565] In agreement with this configuration are most recent DFT calculations of TPP, OEP and octamethylbenzoporphyrin iron(II) complexes, and Fe porphine, which identified four-coordinate unligated complexes to have a $^3A_{2g}$ ground state.[556,590] These findings are also in agreement with McGarvey's theory[589] that was developed for interpreting NMR dipolar and contact shifts of four-coordinated Fe^{II} complexes. When applied to temperature studies of TPPFe^{II}, OEPFe^{II}, and OECFe^{II}, the $^3A_{2g}$ ground state is predicted for intermediate-spin Fe^{II} porphyrins with spin–orbit coupling to the ^3E_g state at energies of 600 cm^{-1} for [OECFe] and [OEPFe], and 1000 cm^{-1} for [TPPFe]. The theory also explains the temperature dependence of the dipolar shifts, but is less satisfactory in analyzing the contact shifts, particularly at the β-pyrrole positions, when the macrocycle is ruffled, as in the case of the chlorin complex.[548,589]

In contrast to the RTPPFe^{II} complexes, the ^{1}H NMR shifts of OEPFe^{II} and other naturally occurring porphyrin Fe(II) complexes have been found to be concentration dependent. The isotropic shifts for most resonances of functional groups close to the porphyrin ring are affected substantially by concentration changes with all signals broadened and shifted to lower frequency.[565,566] These spectral changes are reported to arise from intermolecular ring currents, dipolar shifts, and dipolar relaxation caused by aggregation, with the formation of face-to-face dimers favored at low concentrations and parallel stacking of the porphyrin planes at higher concentrations.[566]

The ^{1}H NMR spectra of the iron(II) porphycene complex of 2,7,12,17-tetra-*n*-propylporphycene [(TprPc)Fe^{II}], with an $S = 1$ ground state have also been reported.[576] The chemical shifts of all the proton resonances (pyrrole-H at −37.52 ppm; *meso*-H at 71.56 ppm, α-CH_2 at 27.47 ppm, β-CH_2 at 8.92 ppm, γ-CH_2 at 5.55 ppm) are consistent with a planar

unligated $S = 1$ iron(II) porphyrin. The complex is not very stable and upon exposure to dioxygen a (μ-peroxo)diiron(III) porphycene complex is formed.[576]

4.2 Six-coordinate Low-spin ($S = 0$) Iron(II) Porphyrin Complexes

4.2.1 Bis-ligand Complexes: Addition of Ligands to Four-coordinate Iron(II) Porphyrins

The four-coordinate square planar iron(II) porphyrins discussed above are not only of great value in heme protein model chemistry, but also in chemical applications, since they undergo a wealth of ligand addition reactions. For example it has been shown that $TPPFe^{II}$ complexes are active catalysts for important carbon transfer reactions in organic chemistry and are found to catalyze the stereoselective cyclopropanation of alkenes,[593] olefin formation from diazoalkanes,[593] and the efficient and selective olefination of aldehydes[594] and other carbonyl compounds.[595] The active species in these carbon transfer reactions are presumably iron porphyrin carbene complexes.[593–596] It was also found that ferrous hemin anchored to TiO_2 thin films reduce organic halides, which can pose serious health problems and are of considerable environmental concern because of their prevalence in groundwater.[597]

As already mentioned above, the $S = 1$ complexes undergo a wealth of ligand addition reactions to form in general either high-spin ($S = 2$) five- or six-coordinate complexes or five- or six-coordinate low-spin ($S = 0$) iron(II) complexes. However, it is important to recognize that it is synthetically not easy to control ligand addition to form selectively the five-coordinated species.[548] Very often six-coordinate species are unwanted by-products, which can be explained by the fact that the binding constant K_2 for the second ligand addition is in many cases more than 10 times, sometimes 15 times larger than the equilibrium constant K_1 for the binding of the first ligand.[548,552,598,599] Ligands that have been bonded to the square planar Fe(II) porphyrins in the solid and non-aqueous liquid state include anions[580,581,600] (acetate, bromide, chloride, cyanide, fluoride, hydroxide, imidazolate, isocyanide, mercaptide, methoxide, perchlorate, phenoxide), alkanes (*n*-heptane,[577,578] nitrosoalkanes[601]); amines (butyl-, benzyl-, and phenylethylamine),[602] carbon monosulfide (CS),[562] diazo compounds N≡N–C(Ph)R (R = –Ph, $–CO_2Et$, $–CO_2CH_2CH{=}CH_2$); nitrogen bases (imidazoles, pyridines, piperidines);[559–561,603–613] and small molecules (O_2, CO, CS, NO, RCN).[185,545,547,549,550,553] Each of these iron porphyrins is treated in their separate sections below.

4.2.2 Addition of Aromatic Nitrogen-donor Ligands

Because of their relevance in heme protein model chemistry, many studies have focused on the addition of nitrogen bases, such as hindered and non-hindered imidazoles or pyridines (*see* ***Ammonia & N-donor Ligands***), to four-coordinate PFe^{II} complexes to obtain a better understanding of the factors that affects the redox potentials and axial-ligand binding behavior of proteins such as the cytochromes *b*. In general, addition of imidazole or pyridine ligands to the four-coordinate complexes leads to the formation of the corresponding six-coordinate, diamagnetic, low-spin Fe^{II} complexes due to the large driving force for the binding of the second ligand.[548,552,575,599] Extensive investigations of the stepwise formation of the 1:1 and 2:1 axial-ligand complexes (see Section 6.3.6 and *see* ***Stability Constants & their Determination***) has shown that in the case of L = nonhindered imidazoles and pyridines, $K_1 < K_2$ (equations 3–7).[603–605]

$$PFe^{II} + L \rightleftharpoons PFe^{II}(L) \tag{3}$$

$$K_1 = \frac{[PFe^{II}(L)]}{[PFe^{II}][L]} \tag{4}$$

$$PFe^{II}(L) + L \rightleftharpoons PFe^{II}(L)_2 \tag{5}$$

$$K_2 = \frac{[PFe^{II}(L)_2]}{[PFe^{II}(L)][L]} \tag{6}$$

$$\beta_2 = K_1K_2 = \frac{[PFe^{II}L_2]}{[PFe^{II}][L]^2} \tag{7}$$

When the addition of the base is controlled, that is, when only one equivalent of base is added to one equivalent of PFe^{II}, typically only the four- and six-coordinate, and essentially none of the five-coordinate, species are detected; the five-coordinate complex usually disproportionates into the four- and six-coordinate iron(II) porphyrins. Only when L is a hindered ligand, such as a 2-substituted imidazole or pyridine, is K_1 sufficiently greater than K_2 that the five-coordinate complex is observed in solution. This has relevance for the stabilization of five-coordinate Fe^{II} porphyrins in solution, discussed in Sections 4.2 and 4.3.

Representative formation constants, K_1, K_2, and/or β_2, are summarized in Table 1, where it can be seen that the overall formation constants, β_2, are quite sensitive to solvent effects. For DMSO and DMF as solvents, it is known that the starting Fe^{II} porphyrin is six-coordinate[606,607] and high-spin.[491,599] The structure of the axial ligand and the magnitude of the equilibrium constants also have profound effects on the reactions observed. As mentioned above, ‘hindered’ ligands such as 2-methylimidazole and 1,2-dimethylimidazole tend to form only 1:1 complexes with Fe^{II} porphyrins, while they much more readily form 2:1 complexes with Fe^{III} porphyrins.[599,608] For example, for 2-MeImH addition to $TPPFe^{III}Cl$ in $CHCl_3$, $K_1 \le 16\ M^{-1}$ and $\beta_2 = 3.3 \times 10^3\ M^{-2}$, while for addition of the same ligand to $TPPFe^{II}$ in benzene, $K_1 = 2.4 \times 10^4\ M^{-1}$ and K_2 is too small to be measured.[604,609] The reasons for this behavior of Fe^{II} porphyrins is not entirely clear, although a number of possibilities have been considered.[610] $Fe–N_{ax}$ bond lengths (*see Bond Length*) of six-coordinate low-spin Fe^{II} and Fe^{III} porphyrins are very similar

(2.004–2.014 Å[611] and 1.964–1.977 Å,[612] respectively), with the Fe^{III}–N$_{ax}$ bond lengths being only very slightly shorter, and the Fe^{III}–N$_{ax}$ bond lengths of [TPPFe(2-MeImH)$_2$]$^+$ (2.015 Å[618]) being much longer than those of [TPPFe(ImH)$_2$]$^+$ (1.997 and 1.957 Å,[619] 1.964 or 1.977 Å, depending on ligand orientation[612]), and are almost identical in length to those of Fe^{II} porphyrin complexes with unhindered imidazoles, listed above. The possible effect of the low-spin d^6 electron configuration of the product is not of itself the reason, since the isoelectronic [TMPCo(2-MeImH)$_2$]$^+$ complex is stable and diamagnetic, with ligands in perpendicular planes at ambient temperatures,[620] and the Co–N$_{ax}$ bond lengths of the related complex, [TPPCo(ImH)$_2$]$^+$ (1.945 and 1.909 Å[613]), are only slightly shorter than those of [TPPFe(ImH)$_2$]ClO$_4$ quoted above. Thus, while it appears that axial bond lengths tend to decrease in the order $Fe^{II} > Fe^{III} > Co^{III}$, the existence of bis(2-MeImH) complexes of both Fe^{III} and Co^{III} makes it all the more curious that such complexes of Fe^{II} are relatively unstable. The reported log K_1, log K_2 and log β_2 values for 2-MeImH binding to TMPFe^{II} in toluene,[610] and those for the same ligand binding to TMPFe^{II}, (2,6-Cl$_2$)$_4$TPPFe^{II} and (2,6-Br$_2$)$_4$TPPFe^{II} in DMF,[491,599] reveals the need for further theoretical studies of these systems.

It should be noted that the crystal structures of all low-spin Fe^{II} model hemes investigated thus far, except for tetra-(*meso*-*n*-C$_3$H$_7$)porphyrinatoiron(II)-*bis*-pyridine[621] and [Br$_8$TFPPFe(Py)$_2$],[598] have been found to have their axial ligands lying over the *meso* positions ($\phi \sim 45°$) if those ligands are pyridines,[575,611] and at any angle, including over or near the porphyrin nitrogens ($\phi \sim 0$–$10°$), if the ligands are non-hindered imidazoles,[611] in parallel planes in both cases. Both π-donor and π-acceptor ligand complexes have these ligands in parallel planes,[575,611] which seems to be the preferred geometry for Fe^{II} porphyrinates that do not have bulky *meso*-substituents.[621] For cross-*trans*-linked iron(II) basket-handle porphyrin complexes, it is suggested that imidazoles or pyridines are bound in perpendicular planes, but no structures have been determined. In these cases the perpendicular orientation, if present, and the ruffling of the porphyrin core, are caused by the distortion due to short basket handles.[559] Unfortunately, no binding constants for the imidazoles or pyridines were reported. But it is mentioned that up to 1 M concentrations of the axial ligands were required to insure complete coordination, and the complexes showed particularly low affinity for pyridine.[559] With porphyrins having no such superstructures, there is evidence (Mössbauer[622] and NMR[188,620] spectroscopy) that only for the bis-(1,2-dimethylimidazole) complex of TMPFe^{II} at very low temperatures (200 to 4.2 K) can the axial ligands be stabilized in perpendicular planes. Hence, for complexes in which the axial ligands lie over the *meso* positions of the porphyrin ring, there appears to be an energy barrier to having the axial ligands in perpendicular planes *for Fe*^{II}, while Fe^{III} *prefers* having axial ligands in perpendicular planes if there is any steric interference between porphyrin substituents and axial ligands. It should be noted, however, that if there is no steric interference, Fe^{III} also prefers to have axial ligands in parallel planes. It has been hypothesized that the energy barrier in the case of Fe^{II} complexes might be because of the required ruffling of the porphyrin for the axial ligands to lie in perpendicular planes over the *meso* positions.[194] However, mammalian cytochromes c have very ruffled porphyrin rings with the histidine imidazole plane lying over the α,γ-*meso* positions,[623–625] yet ligand binding in the Fe^{II} state is very strong, stronger than in the Fe^{III} state, as evidenced by the positive reduction potentials of many cytochromes c.[626,627] Thus, theoretical investigations of the importance of ruffling in (de)stabilizing Fe^{II} heme centers are certainly needed.

Porphyrin substituents also have large effects on log β_2. In particular, the presence of *meso*-2,6-phenyl substituents greatly enhances the stability of the six-coordinate complexes, except when these substituents are methoxy groups.[491,599] In fact, for TMPFe^{II}, (2,6-Cl$_2$)$_4$TPPFe^{II}, and (2,6-Br$_2$)$_4$TPPFe^{II} in DMF, the bis-2-methylimidazole complexes are stable, with log $\beta_2 = 5.1$–5.8 (Table 1).[491,599] However, it should be noted that bis-axially coordinated TMPFe^{II}(2-MeImH)$_2$ is stable at ambient temperatures, but that 2-MeImH does not form complexes with TPPFe^{II}, (2,6-F$_2$)TMPFe^{II}, and 2,6 (2,6-(OCH$_3$)$_2$)TPPFe^{II}.[599] The increased stability of all TMPFe^{II} complexes over their TPP counterparts has been discussed by Traylor and coworkers,[610] and attributed to the perceived greater tendency of TMP to resist doming. However, in the absence of molecular structures of five-coordinate TMPFe^{II} complexes with nitrogen donor ligands it is not possible at present to verify this suggestion. Comparison of the values of log β_2 for tetraphenylporphyrin derivatives

in DMF reveals that there is both an electronic effect (2,6-$(OMe)_2 \ll 2,6\text{-}H_2 \ll 2,4,6\text{-}Me_3 \sim 2,6\text{-}Cl_2 \sim 2,6\text{-}Br_2$ for N-MeIm complexes) and a steric effect ($2,6\text{-}(OMe)_2 \ll 2,4,6\text{-}Me_3 < 2,6\text{-}Cl_2 < 2,6\text{-}Br_2$) involved, the latter evidenced by the 'levelling effect' of bis(substituted pyridine) complex formation constants for pyridines ranging in basicity from 4-NMe_2Py ($pK_a(PyH^+) = 9.7$) to 4-CNPy ($pK_a(PyH^+) = 1.1$) for each of the larger 2,6-phenyl substituents.[491,599] For axially N- and 2-methylimidazole, and pyridine ligated $FeTPP^{II}$ complexes with *ortho*-phenyl substituents of varying bulkiness, it was shown that the log β_2 values decrease in the order of Br > Cl > CH_3 > F > OCH_3 > H. This trend was described to be mainly due to the steric size of the substituent(s) rather than its electronegativity or the electron-donating/withdrawing characteristics of the substituent(s); it was found that the complexes with the sterically most bulky substituents have the largest equilibrium constants.[599]

One-side-hindered $TPPFe^{II}$ derivatives will in some cases bind two Lewis base axial ligands, especially if they are small and the porphyrin is a 'picket fence' type porphyrin, $(o\text{-Piv})_4TPP$ ($T_{Piv}PP$), or the larger 'cap' porphyrin, C_3cap (Table 1). The structure of one such complex, $[T_{Piv}PPFe(Im)(ImH)]^-$, has been reported,[628] but it was not possible to distinguish the neutral and anionic ligands crystallographically. Other *bis*-base sterically protected complexes were also studied. For example, the *bis*-base ligated pivalamido and the cross-trans-linked basket-handle iron(II) porphyrins mentioned above were studied by absorption and resonance Raman spectroscopy.[559,561] The visible absorption spectra of *bis N*-methylimidazole, 1,5-dicyclohexylimidazole, and pyridine coordinated complexes of atropisomers of Fe(II)-tetrakis(*o*-pivalamidophenyl)porphyrins [$\alpha\beta\alpha\beta$-$T_{Piv}PPFe^{II}$] revealed redshifts of the B and Q absorption bands by about 4–5 nm, and a shift by $+5\,cm^{-1}$ of the low frequency ν_8 resonance Raman mode, but no shifts of the skeletal high frequency modes. These data were interpreted in terms of the change in relative position of the axial imidazole rings from nearly parallel in the *bis-N*-methylimidazole complex to nearly perpendicular in the *bis*-dicyclohexylimidazole complex and the change from a planar to a saddled porphyrin ring structure.[559] Studies of the *bis*-imidazole and *bis* pyridine-ligated 'basket-handle' porphyrin complexes[561] complement these findings and allowed the spectroscopic properties of ruffled complexes to be characterized. As for the [$\alpha\beta\alpha\beta$-$T_{Piv}PPFe^{II}L_2$] complexes, a gradual red shift was observed for the Q and B bands, which was accompanied by both a downshift of the resonance Raman frequency ν_2 mode and an increased upshift of the ν_8 mode when the handles were shortened and/or when the steric hindrance of the axial ligands was increased. The spectroscopic data were attributed to the degree of ruffling in these complexes, which increases from *N*-methylimidazole to pyridine axial substitution, presumably due to steric interaction constraints between the axial-ligand rings, the porphyrin macrocycle, and the porphyrin handles.[561] The crystal structure of the *bis*-pyridine-ligated iron(II) complex of the highly brominated pentafluorophenyl TPP, $[(TFPPBr_8)(Py)_2]$ mentioned above[598] revealed a highly deformed porphyrin core, which had a twisted S_4 saddle-shape structure with an average Fe-N_{por} bond of 1.963 Å that is shorter than in other bis-pyridine-ligated iron(II) porphyrins.[548] The complex reacts very slowly with dioxygen, but is readily oxidized by *tert*-butyl hydroperoxide.

Bis-pyridine-coordinated low-spin iron(II) complexes of the octaethylporphyrin dianion (OEP^{2-}) were found to undergo interesting chemistry, which is discussed in greater detail in Section 6.1.5: Treatment of a series of *meso*-substituted $[OEPFe^{II}(Py)_2]$ complexes including [*meso*-NO_2-$OEPFe^{II}(Py)_2$], [*meso*-CN-$OEPFe^{II}(Py)_2$], [*meso*-HC(O)-$OEPFe^{II}(Py)_2$], [*meso*-Cl-$OEPFe^{II}(Py)_2$], [*meso*-OMe-$OEPFe^{II}(Py)_2$, [*meso*-Ph-$OEPFe^{II}(Py)_2$], and [*meso*-*n*-Bu-$OEPFe^{II}(Py)_2$] with hydrogen peroxide in pyridine–d_5 at low temperature under strict exclusion of dioxygen led to the formation of stable oxophlorin ($OEPOFe^{II}$) complexes, where OEPO is the monoanion of octaethyl-5-oxaporphyrin.[629] As revealed by ^1H NMR spectroscopy, the reaction produced a mixture of three oxygenation products, [*cis-meso*-R-$OEPOFe^{II}(Py)_2$], [*trans-meso*-R-$OEPOFe^{II}(Py)_2$], and $[OEPOFe^{II}(Py)_2]$. The isotropic shift patterns for these oxophlorins showed negatively-shifted *meso*-H resonances ranging from −41 ppm in the cis isomer of [*meso*-HC(O)-$OEPOFe^{II}(Py)_2$] to −152 ppm for the same isomer of [*meso*-OMe-$OEPOFe^{II}(Py)_2$], and positively- and negatively-shifted methylene signals. The methyl protons resonated in the spectral region of 0–5 ppm. For the *trans* isomers even greater variations in the *meso*-H shifts were observed. For [*meso*-HC(O)-$OEPOFe^{II}(Py)_2$] the single resonance of the *meso*-H is found at −17 ppm and for the [*meso*-OMe-$OEPOFe^{II}(Py)_2$] it is observed at −168 ppm. For all resonances non-Curie behavior was observed.[629] Further steps of oxidation can take place, leading to verdoheme and biliverdin, the breakdown products of heme. The topics of coupled oxidation of both Fe^{II} and Fe^{III} porphyrins, and the relationship of these reactions to those of the enzyme heme oxygenase, are discussed in more detail in Section 6.1.5 below.

4.2.3 *Photodissociation of Six-coordinate Low-spin Iron(II) Porphyrins, $PFeL_2$*

Not only has binding of imidazoles and pyridines to Fe^{II} protoporphyrin IX been studied,[615] as discussed in Section 4.1.2, but also photodissociation of axial ligands such as pyridines, imidazoles, or piperidines from six-coordinate, low-spin Fe^{II} porphyrins, in which the porphyrin is derived from protoporphyrin IX, or proto- or deuteroporphyrin IX dimethyl ester, has been investigated in nonaqueous solvents using picosecond transient absorption spectroscopy[630] (*see* ***Photochemistry of Transition Metal Complexes***). It has been shown that photodissociation leads to the formation of five-coordinate complexes, that is, only one ligand appears to be released upon excitation of the six-coordinate complex.[630]

Recombination rates range from 10^8 to $10^9\,M^{-1}\,s^{-1}$, with similar values obtained by nanosecond measurements, whereas photodissociation yields are low and range from 0.03–0.08. These low yields have been interpreted in terms of rapid relaxation of the photoexcited six-coordinate complex competing with ligand release.[630] Other five-coordinate complexes are also formed on picosecond photolysis; for example, a protoheme dimethyl ester bis(*t*-butyl isocyanide) in pure *t*-butyl isocyanide or in toluene. This photolysis results in the loss of one isocyanide ligand to produce an electronically excited five-coordinate complex, which decays to the ground state within 40 ps.[631] The recombination rate for the formation of the bis(isocyanide) complex is $2.5 \times 10^8\,M^{-1}\,s^{-1}$.[631] It has been further shown that when the photolyzed ligand is derived from other isocyanides or *N*-methylimidazole, a concentration-independent relaxation is observed, with a 40 to 95% return to the starting compound.[631,632] For CO, geminate recombination is only observed at high viscosity.[633]

4.2.4 Addition of Aliphatic Amine Ligands

Complexes with unprecedented structural data for the coordination of primary amines by iron(II) porphyrins are found in low-spin ($S = 0$), bis(primary amine)-ligated iron(II) porphyrins [Fe(TPP)$(RNH_2)_2$] with RNH_2 = 1-butylamine, benzylamine, and phenethylamine.[602] The complexes were prepared by reduction of the $TPPFe^{III}Cl$ with silver triflate followed by the addition of the amines in a nitrogen inert gas atmosphere, and were found to be structurally and spectroscopically similar to [Fe(TPP)$(Py)_2$] derivatives.[602] The Fe-N_{por} distances of the three complexes average 1.990(2) Å and the axial Fe-N_{amine} distances range from 2.028 Å in the [Fe(TPP)$(PhCH_2CH_2NH_2)_2$] complex to 2.043 Å in the [Fe(TPP)$(BzNH_2)_2$] complex. Consistent with an $S = 0$ iron(II) spin state, the zero-field Mössbauer spectra (5–300 K) show comparable isomer shifts (0.393(1)-0.493(1) mm/s) and quadrupole splittings (1.144(6)-1.204(3) mm/s. Molecular mechanics (MM) calculations with a force field parameterized for iron(II) porphyrin amine complexes show that stable conformations arise when the α-CH_2 and NH_2 protons of the coordinated ligands are staggered relative to the Fe-N_p bonds of the porphyrin core. The lowest energy conformations of the [Fe(TPP)$(RNH_2)_2$] complexes have the ligand α-carbons positioned directly over the Fe-N_p bonds of the porphyrin core.[602]

4.2.5 Addition of Phosphine Ligands

Trimethylphosphine and mixed phenyl, methyl phosphines readily bind to both Fe^{II} and Fe^{III} porphyrins to form low-spin complexes. The (p-OCH_3)$_4$TPP$Fe^{II}(PMe_3)_2$ and OEP$Fe^{II}(PMe_3)_2$ complexes have been characterized structurally,[634] as well as by ^{57}Fe NMR ($\delta_{Fe} = 7670$ and 7873 ppm, respectively)[487,634] and Mössbauer (for the OEP complex, $\delta = 0.36\,mm\,s^{-1}$, $\Delta E_Q = 0.35\,mm\,s^{-1}$)[635] spectroscopies. Mixed-ligand complexes of the types P$Fe^{II}(PMe_3)_2$, P$Fe^{II}(PMe_3)$(L), PFe^{II}(L)(L') and P$Fe^{II}(L)_2$ have also been investigated by the two spectroscopic techniques, and a correlation was found between the ^{57}Fe chemical shift, δ_{Fe}, and the Mössbauer quadrupole splitting, ΔE_Q.[635] This correlation helped to correct the unusual ^{57}Fe chemical shifts of the bis-pyrrolidine and bis-pyridine-d_5 complexes of TPPFe^{II} that were reported earlier.[636]

4.2.6 Binding of Anionic Ligands

Certain anionic ligands can also bind to iron(II) porphyrins to yield low-spin complexes. Mandon *et al.* showed that binding of imidazolate to a picket fence porphinatoiron(II) imidazole complex forms the corresponding ImH, Im^- low-spin complex ($S = 0$).[628] The low-spin nitrite complex has also been well characterized,[637] as discussed near the beginning of Section 4.3. Evidence for binding of Br^-, OAc^-, Cl^-, and F^- to TPPFe^{II} complexes has been obtained by spectroelectrochemical techniques. For binding of F^-, the $[TPPFeF]^-$ complex is formed, with a formation constant of approximately $600\,M^{-1}$.[600] For binding of Cl^- this constant, measured in DMF at 20 °C, is much smaller ($56\,M^{-1}$).[638] The formation constants for Cl^- complexes of a series of basket-handle porphyrins in DMF at 20 °C are much larger for amide linked handles (1.8×10^3 to $1.1 \times 10^2\,M^{-1}$)[638] and much smaller for ether-linked handles (3.6–$9.6 \times 10^{-2}\,M^{-1}$),[638] suggesting a 'local solvation effect' of the amide groups. It has also been shown that the addition of cyanide to the hydroxo complex of high-spin [(TMP)Fe^{III}OH] leads to the formation of the low-spin *bis*-cyanide ligated complex $[(TMP)Fe^{II}(CN)_2]^{2-}$. This complex has been crystallized with the cation *bis*-triphenylphospine nitrogen (PPN^+) acting as counterion. The average Fe-N_{por} bond is 2.003 Å, which is a typical value for $S = 0$ iron(II) complexes, and the Fe-CN bond length is 1.990 Å, slightly larger than that of the $[(TPP)Fe(CN)_2]$K complex.[639]

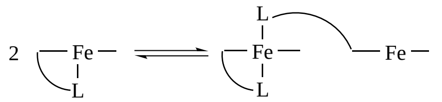
4.3 Five-coordinate $S = 2$ Iron(II) Porphyrin Complexes

Five-coordinate, high-spin Fe^{II} porphyrin complexes with imidazoles or pyridines as axial ligands are of specific interest, since they represent not only direct models of the oxygen transport and storage proteins deoxyhemoglobin and deoxymyoglobin (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***), but they are also excellent models of the reduced states of cytochromes P450 and chloroperoxidase, as well as peroxidases (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***; ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***). Axially imidazole coordinated iron(II) porphyrins may also serve as models for characterizing the active site of prostaglandin H synthase (PGHS) that is also known as cyclooygensae or COX, a member of the peroxidase

family. This enzyme has two isoforms (PGHS-1, PGHS-2), but consists in its ferrous state as a single species with histidine coordinating as the proximal axial ligand.[640]

Synthetic Aspects. Because of the much greater stability of many bis-ligated complexes of Fe^{II} porphyrins, discussed in Section 4.2, the synthesis of five-coordinate HS Fe^{II} complexes is challenging, and special methods must be used to prepare five-coordinate $PFe^{II}L$ complexes. The simplest method is the addition of sterically hindered bases, such as 2-substituted imidazoles or pyridines, to four-coordinate, nonhindered intermediate spin PFe^{II} complexes (see Section 4.1). The addition of one ligand decreases the binding constant for the second ligand without affecting the equilibrium constant of the binding of the first ligand.[548] This strategy was for example used to synthesize the [TPPFe(2-MeImH)] complex, which is produced by reacting $TPPFe^{II}$ with an excess of 2-methylimidazole.[548] In a similar fashion, other complexes are obtained, including complexes derived from synthetic and natural porphyrins. In these five-coordinate complexes the iron atom is displaced from the mean porphyrin plane by 0.3–0.6 Å,[641] which ensures that only a single sterically hindered base such as 2-methyl- or 1,2-dimethylimidazole coordinates to the metal ion. For many, but not all, porphyrinate iron(II) complexes, the energetics for bringing the Fe^{II} atom into the porphyrin plane to form a six-coordinate complex are quite unfavorable in the presence of these sterically bulky ligands as is evidenced by the fact that the binding constant for the second ligand addition is usually extremely small,[548,552,575,608,609] as is discussed above in Section 4.2.

The other approach that ensures five-coordination is to block one face of the porphyrin by the covalent attachment of an axial ligand, as was done for some of the models of deoxyhemoglobin and deoxymyoglobin, involving tailed picket fence porphyrins,[642] pocket porphyrins,[643] 'tailed basket-handle' porphyrins, or biphenyl-strapped porphyrins,[644] and other superstructured porphyrins.[645] These models are discussed in more detail under O_2/CO binding (Sections 4.5.1 and 4.5.2). NMR studies of the pocket porphyrin complexes, which form stable and reversible dioxygen adducts, revealed that these complexes remain predominantly five coordinate in the absence of gaseous ligands.[642,643,645] However, as the temperature is lowered to −25 °C, new sets of resonances between 10 and −10 ppm appear that are attributed to the disproportionation of the five-coordinate, high-spin Fe^{II} complex to yield one four-coordinate, intermediate-spin Fe^{II} complex and one diamagnetic, six-coordinate low-spin Fe^{II} complex by intermolecular sharing of axial ligands (equation 8).[642]



(8)

Other superstructured Fe(II) porphyrin complexes, in which the axial ligand is provided by 'straps, arms, or tethers' attached to the porphyrin macrocycle, have been prepared in many laboratories, including our laboratories. This strategy was also used to synthesize high-spin Fe^{II} complexes of peptide-sandwiched mesohemes, which were formed by attaching 13-residue peptides to the propionate groups of the mesoporphyrin IX iron(II) complex (MPIXFe) via amide linkages.[646] In these complexes, the imidazolyl ring of a histidine (His) residue in the peptide chain coordinates to the mesohemin iron.[646] The superstructured strategy was also employed to prepare synthetic analogs for the oxygen binding site in cytochrome c oxidase (*see* ***Cytochrome Oxidase***).

A third approach for synthesizing high-spin iron(II) porphyrins includes the binding of anions, such as imidazolate, thiolate, or acetate, to form complexes with an overall negative charge.[548]

Crystal Structures. Only a few crystal structures of high-spin Fe^{II} five-coordinate porphyrin complexes have been reported,[548,586] and these have been reviewed by Scheidt.[548] These include complexes of TPP, picket fence and hybrid porphyrins, and (*p*-chlorophenyl)porphyrin.[548] Because of the population of the $d_{x^2-y^2}$ orbital, these complexes are characterized by an expanded porphyrin core, long Fe-N_{por} bond lengths, and substantial displacement of the iron ion from the porphyrin core. Typical Fe–N_{ax} bond lengths are 2.13 Å (Fe 0.31 Å out of plane) in a *N*-methylimidazole complex[647] and 2.095 Å (Fe 0.40 Å out of plane) and 2.161 Å (Fe 0.42 Å out of plane) in the 2-MeImH complexes of the picket fence porphyrin[648] and an earlier $TPPFe^{II}$ structure,[641] respectively, but 2.127 Å (Fe 0.32 Å out of plane) in a more recent structure that is more highly ordered.[586] This structure demonstrates porphyrin core distortions and an asymmetry in the Fe–N_P bond distances, and emphasizes that high-spin iron(II) porphyrinate derivatives display substantial structural pliability with significant variations in iron atom displacements, porphyrin core hole size and axial and equatorial Fe–N bond lengths.[586] For the thiocarbonyl ligated complex [$OEPFe^{II}$(CS)], the average Fe–N bond length is 1.982 Å and the Fe–C(CS) bond distance is 1.662 Å with a fairly small 0.23 Å displacement of the iron ion from the mean plane of the porphyrin core.[649]

Typical geometries observed for anionic complexes relevant to biological systems include the 2-methylimidazolate (2.002 Å (Fe–N_{ax}), 0.65 Å out of the mean plane of the porphyrin core),[628] phenolate (1.937 Å, 0.56 Å out of plane),[650] thiolate (2.36–2.37 Å, 0.4–0.5 Å out of plane)[651,652] and acetate (2.03 Å, 0.64 Å out of plane)[653] complexes. Note that in cases where the picket fence porphyrin was used, the anionic ligand (imidazolate,[628] thiolate,[651,652,654] and acetate[653]) is on the same side of the porphyrin plane as the pivalamide 'pickets'.

Mössbauer Spectroscopy. Mössbauer spectra of high-spin Fe^{II} porphyrins are unique and vary greatly in their quadrupole splitting parameters ΔE_Q. With nitrogen bases such as 2-MeImH, quadrupole splittings $\Delta E_Q \sim 2.3–2.4\,mm\,s^{-1}$ and isomer shifts $\delta \sim 0.90–0.94\,mm\,s^{-1}$ are observed.[177,586,655] However, if anionic oxygen or nitrogen donors or chloride ion replaces the neutral base, then the Mössbauer spectrum changes characteristically. Extremely large quadrupole splittings are observed,[650,651,656,657] for example $\Delta E_Q = 3.51\,mm\,s^{-1}$ at 77 K for the imidazolate complex[628] or 4.01 or 4.25 $mm\,s^{-1}$ for anionic oxygen donors PhO^- or $MeCO_2^-$,[653] respectively.

Vibrational Spectroscopy. It was also shown that water can coordinate to the iron center to form an unusual monoaqua adduct of tetrakis [(*N*-*t*-butylcarbamoyl)phenyl]porphinato-iron(II).[658] The stabilization of this complex is ascribed to the formation of an internal hydrogen bond between the coordinated water molecule and one (or two) of the four carbamoyl carbonyl groups of the porphyrin. Resonance Raman spectra of the four-coordinate precursor complex show the ν_2 and ν_4 porphyrin modes at 1561 and 1362 cm^{-1}, indicating an increased degree of ruffling when compared to the picket fence analog TpivPPFe^{II} ($\nu_2 = 1566\,cm^{-1}$ and $\nu_4 = 1370\,cm^{-1}$). For the high-spin monoaqua five-coordinate complexes the skeletal porphyrin modes are observed at 1542 and 1346 cm^{-1}.[658] Depolarized resonance Raman bands sensitive to spin-, coordination-, and oxidation-state of iron porphyrins are observed at $\nu_{10} > 1600\,cm^{-1}$, while for iron chlorins the same band is strong and polarized, and is also observed in the IR spectrum. For iron isobacteriochlorins there is a strong polarized ν_{29}-equivalent band at $\approx 1400\,cm^{-1}$.[659] Recently resonance Raman spectroscopy was also used to study the iron out-of-plane mode in the proximal cavity mutant of deoxymyoglobin H93G.[660] In this mutant histidine is replaced by glycine to create a cavity for binding of numerous ligands, including, imidazoles (ImH, 1-, 2-, 4-MeIm, 1,2- and 1,4-Me_2Im, 2-ethyl-ImH, 4-CH_2OH-ImH, 4-BrImH, 4-Br-2-MeImH) and pyridines (3-FPy, 3-MePy, 3-BrPy, and 4-MePy). It was found that several RR modes in the low frequency region show axial-ligand dependencies. The largest effect was observed for the iron-ligand out-of-plane mode ranging from 180 cm^{-1} in the 4-BrImH and 2 Me-ImH mutants to 228 cm^{-1} in the 4-CH_2OH-ImH-ligated mutant, which in contrast to model hemes increased with the basicity of the axial ligand. Theoretical calculations revealed that this mode contained significant contributions from the Fe-ligand stretching and from the iron-heme doming.[660]

NMR Spectroscopy. The NMR spectra of five-coordinate complexes of iron(II) porphyrins are distinctive: the isotropic shifts of the pyrrole-H in the TPP complexes are positive, and those of the phenyl protons are negative, with typical isotropic shifts of 43.5 ppm for the pyrrole-H and −1.0 to −1.5 ppm for the *o*-, *m*-, and *p*-phenyl protons.[565] For five-coordinate OEPFe^{II} complexes, isotropic shifts of −7.0 ppm for the *meso*-H and +8.5 ppm for the pyrrole-α-CH_2 protons have been reported.[565] The *meso*-H protons in the natural porphyrins appear in the spectral region of 0 to +6 ppm.[565]

The isotropic shifts in these complexes, especially the shifts for the pyrrole-H and pyrrole α-CH_2 protons, serve as convenient probes for both oxidation and spin state of the metal ion.[168,565] The positive pyrrole-H and α-CH_2 isotropic shifts are indicative of primarily σ spin delocalization to the pyrrole positions. Such positive isotropic shifts at the β-pyrrole positions are characteristic of an unpaired electron in the $d_{x^2-y^2}$ orbital, leading to a ground-state assignment of $(d_{xy})^2(d_{xz},d_{yz})^2(d_{z^2})^1(d_{x^2-y^2})^1$ for the high-spin Fe^{II} ion.[218] Moderate π delocalization to the *meso* position is indicative of partially filled d_π orbitals, also consistent with the ground state proposed.[168,174]

The ^{1}H NMR spectrum of the high-spin Fe(II) complex of oxaporphyrin (OTPP)Fe^{II}Cl that is formed when the high-spin six-coordinate iron(III) complex (OTPP)Fe$^{III}Cl_2$ is reduced by means of moderate reducing agents, such as aqueous sodium dithionite or zinc amalgam, is characterized by unpaired electron spin density delocalization into both σ and filled and vacant π molecular orbitals.[536] This unpaired electron spin delocalization pattern explains that two of the pyrrole proton resonances are downfield shifted (39.3 and 29.5 ppm) and one is upfield shifted (−6.4 ppm), whereas the furan protons give rise to a downfield-shifted signal (33.2 ppm).[536] A similar upfield shift for one of the pyrrole resonances was also observed for iron(II) N-methylporphyrin (N-CH_3-TPP)FeCl and iron(II) 21-thiaporphyrin (STPP)FeCl.[523]

4.4 Six-coordinate $S = 2$ Fe(II) Porphyrin Complexes

Although high-spin iron(II) porphyrins are in general five-coordinate with large out-of-plane iron ion displacements, there are exceptions to this rule. In rare cases six-coordinate complexes are formed with the iron in the plane of the porphyrin macrocycle. Examples of such complexes include the bis (N-alkyl)porphyrin with two axial metallocycles reported by Battioni *et al.*,[661] the [TPPFe$^{II}(THF)_2$] complex described by Reed[662] and reexamined by Lecomte,[663] the THF adduct of [(F_8TPP)Fe$^{II}(THF)_2$] described by Karlin and Meyer,[664] and the *bis*-alcohol or aqua-coordinated adducts of *meso*-tetrakis(*o*-dichlorophenyl)-ß-octanitroporphyriniron(II).[579] [TPPFe$^{II}(THF)_2$] is an example of a high-spin complex that is six coordinate.[662] The iron is in the plane of the macrocycle. Magnetic susceptibility measurements ($\mu_{corr} = 5.5\,\mu_B$) and Mössbauer data ($\Delta E_Q = 2.65\,mm\,s^{-1}$ and $\delta = 0.95\,mm\,s^{-1}$ at 77 K; $\Delta E_Q = 2.42\,mm\,s^{-1}$ and $\delta = 0.89\,mm\,s^{-1}$ at 195 K, ΔE_Q of 2.76 $mm\,s^{-1}$ and an isomer shift $\delta = 0.98\,mm\,s^{-1}$ at 4.2 K) confirm the spin state ($S = 2$) of the complex. The quadrupole doublet exhibits narrow lines with ΔE_Q of 2.76 $mm\,s^{-1}$ and an isomer shift $\delta = 0.98\,mm\,s^{-1}$ at

4.2 K. Upon increasing the temperature the isomer shift decreases, consistent with expectations based on the second-order Doppler effect.[662,663] Electron density maps of the complex support the $^5E_{2g}$ ground state with an electronic configuration of $\{(d_{xy})^1(d_{xz},d_{yz})^3(d_{z^2})^1(d_{x^2-y^2})^1\}$.[663] Another high-spin, *bis*-ligated adduct of THF has also been characterized. The structure of $[(F_8TPP)Fe^{II}(THF)_2]$ is characterized by an average Fe–N_{por} bond distance of 2.07 Å with the ferrous iron in the plane of the porphyrin macrocycle. The ^1H NMR spectrum of the complex is that characteristic of a high-spin species. The pyrrole protons give rise to a single signal at 56.7 ppm, the *para*- and *meta*-phenyl protons give rise to the signals in the diamagnetic region at 8.38 and 7.15 ppm, respectively.[664] The electron-deficient *bis*-ethanol, *bis*-propanol, and *bis*-aqua-coordinated adducts of *meso*-tetrakis(*o*-dichlorophenyl)-ß-octanitroporphyriniron(II) complexes are air-stable and extraordinarily difficult to oxidize ($E_{1/2} = +1030$ mV).[579] Consistent with the $S = 2$ spin state are the Mössbauer data of the $(EtOH)_2$-coordinated complex with a quadrupole splitting of 2.136 mm s^{-1} and isomer shift of 0.921 mm s^{-1} at 77 K that decrease to $\Delta E_Q = 2.064$ mm s^{-1} and $\delta = 0.844$ mm s^{-1} at ambient temperature, and Fe–N bond distances of 2.088 Å and 2.095 Å that are slightly longer than those in the THF ligated complex. The porphyrin macrocycle is essentially planar, in contrast to the *bis*-aqua complex, which is ruffled at 100 K and has Fe–N_{por} (1.945 Å) and Fe–O (1.976 Å) bond distances that are atypically short for $S = 2$ Fe(II) porphyrin complexes. Several quintet ground-state configurations are theoretically possible for the electron-deficient complexes, $^5B_{2g}$, $^5A_{1g}$, $^5B_{1g}$, and $^5E_{2g}$. Whether they have the same ground state as the THF-ligated complex ($^5E_{2g}$) remains to be researched.[579]

4.5 Addition of Small Molecules to 5-Coordinate High-spin Iron(II) Porphyrins; Binding of O_2, CO, NO, HNO and Others to Heme Proteins and Their Models

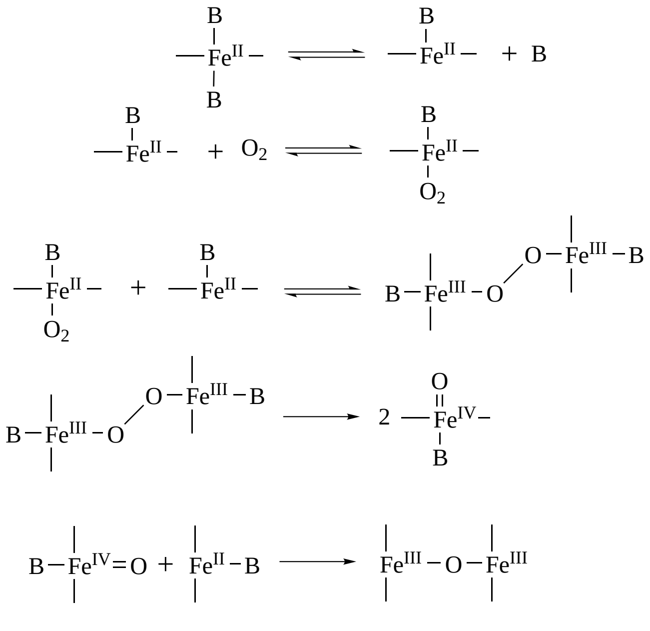
Six-coordinate, diamagnetic Fe^{II} porphyrins have been studied for a variety of reasons; the most relevant ones include the understanding of the mechanism of reversible dioxygen binding to hemoglobin (Hb) and myoglobin (Mb) (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***), dioxygen sensors (FixL,[45–48] DosH[49]) or oxidases including cytochrome *c* oxidase (*see* ***Cytochrome Oxidase***). These proteins employ a five-coordinate iron center in their native deoxy states and are high-spin, $S = 2$ species. The sixth coordination site is vacant for binding of dioxygen, carbon monoxide, or other small ligands, such as nitric oxide or isocyanides. Upon dioxygen binding, six-coordinate species are formed, which are diamagnetic and low-spin; that is the spin state changes from $S = 2$ Fe^{II} and $S = 1$ O_2 to $S = 0$ for the complex. Within the proteins, little oxidation occurs to form heme complexes with iron in its +3 oxidation state. As is discussed in the comprehensive review by Momenteau and Reed,[545] the FeO_2 moiety in hemoglobin and myoglobin has been the subject of many reviews and debates. For many years it was discussed whether an iron(II) dioxygen or an iron(III) superoxide formalism was the best description for the FeO_2 moiety. However, in recent years consensus seem to have developed that the best formalism to describe the polar $Fe^{\delta+}$–$O_2^{\delta-}$ bond is as iron(III) superoxo species with the understanding of the limitations of such a description.[545]

Whereas carbonmonoxymyoglobin, MbCO, has been shown to be a diamagnetic species, there has been controversy for some time as to whether oxymyoglobin and oxyhemoglobin indeed exist solely in their diamagnetic states.[665] The existence of a paramagnetic component in oxyhemoglobin has been supported by magnetic susceptibility investigations,[666] the temperature dependence of the Mössbauer quadrupole splitting,[667] and by single crystal Mössbauer studies.[668] $Hb(O_2)_4$ and MbO_2 have been discussed in terms of various possible spin-coupled systems: low-spin ($S = 1/2$) $Fe^{III}/O_2^{-}\cdot$, low-spin ($S = 0$) Fe^{II}/singlet O_2, or intermediate spin ($S = 1$) Fe^{II}/triplet O_2.[665] Theoretical studies performed on oxyhemoglobin predict a low-lying triplet state, which can be in thermal equilibrium with the singlet ground state.[669] To investigate whether the thermally populated paramagnetic state can be accommodated, Waleh and Loew have calculated the low-energy triplet states of HbCO and found that the energy of the lowest triplet state is too high to accommodate thermal population of the paramagnetic state.[670] However, it should be noted that the dioxygen complex is obtained when PFe^{III} is reacted with superoxide salts in weakly coordinating solvents (equation 9).[671,672] This suggests a facile valence tautomerism between the two species in equation (9), as discussed again in Section 6.1.

$$PFe^{III} + O_2^{-}\cdot \longrightarrow PFe^{II}O_2 \qquad (9)$$

To model the binding of dioxygen to heme proteins is a major task, since reversible oxygen binding without competing autoxidation is very difficult to accomplish in synthetic iron(II) porphyrins,[197,545,673] which are easily oxidized. Hence, proper care is needed in handling the compounds. Simple iron(II) porphyrins bind dioxygen reversibly only at low temperatures (−60 °C), whereas at room temperature, reaction with dioxygen in solution leads to autoxidation and μ-oxo Fe^{III}–O–Fe^{III} dimer formation, as already discussed earlier (Section 1.5). Scheme 2, adapted from the review article of Morgan and Dolphin,[198] highlights the process.

Another problem in mimicking the oxygen uptake by heme proteins is the preference of iron(II) for forming low-spin, six-coordinate Fe^{II} complexes. Nitrogen donor ligands such as pyridines and imidazoles normally coordinate readily to the iron to form complexes of the general type $PFe^{II}B_2$, as discussed above in Section 4.2. While formation of these six-coordinate Fe^{II} complexes impedes irreversible oxidation to the μ-oxo dimer, it also impedes formation of the



Scheme 2

desired dioxygen complex. Approaches for controlling the coordination of axial ligands in heme models, and for preventing the irreversible oxidation and subsequent formation of the μ-oxo dimers, include use of a hindered ligand, addition of excess ligand (in some cases), metal substitution, immobilization, covalent attachment of one ligand,[642,674,675] or steric blockage or protection of one or both coordination sites of the porphyrin. The approaches that have been developed for designing models that bind dioxygen reversibly are described in more detail elsewhere.[545,546] The wide variety of sterically protected systems include the following porphyrins: 'picket-fence[676,677]', 'picket pocket[676,678,679]', 'tailed picket fence[642]', 'capped[609,680–684]', 'cyclophane[685–687]', 'durene-capped[688]', 'crowned[689]', 'strapped[690–692]', biphenyl strapped,[644] 'gyroscope[693]', 'basket-handle[694,695]', picnic basket handle,[696] cross-trans-linked basket handle,[559] 'chiral '*ansa*' handle[697]', twin coronet,[698] and 'hybrid[647,655]' porphyrins, in which one or both faces of the porphyrin ring are protected by covalently attaching side chains to the macrocycle. (Examples of each of the above and several 'tailed', 'chelated' or 'pendant' hemes are shown in Figure 6). This approach ensures the formation of five-coordinate complexes by allowing the base to bind only to the open face. In addition, the steric blockage of at least one side helps to minimize or prevent μ-oxo dimer formation. Extensive coverage of such approaches is given by Morgan and Dolphin,[198] Momenteau and Reed,[545] and Momenteau.[546]

The mechanisms of binding of small ligands, such as O_2, CO, NO, and isocyanides (*see* ***Dioxygen & Related Ligands***) to model hemes and to heme proteins have been the subject of many investigations (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***). It has been suggested that ligand binding to heme proteins may be envisioned in terms of at least the following three steps: (1) diffusion up to and penetration of the ligand into the protein surface, (2) diffusion through the macromolecular structure to reach the sixth coordination site of the iron, and (3) covalent bond formation with concomitant orbital rearrangements and changes in the coordination geometry of the proximal ligand.[701] To assess the significance of such processes and to understand the factors that influence ligand binding in heme proteins, the following approaches have been undertaken: (1) measurement of the rates of rebinding of ligand molecules trapped within various parts of the protein after laser flash photolysis at low temperatures and high viscosities;[702] (2) structure determination of a variety of model heme complexes by X-ray crystallography;[183,548] (3) investigation of the ligand binding properties of five-coordinate ferrous porphyrins;[197,198,676,703–712] and (4) assessment of the influence of ligand size and stereochemistry on the rates and equilibrium constants for ligand binding to hemoglobin by using alkyl isocyanides as the sixth axial ligand.[545,713]

Reversible O_2 binding to synthetic iron(II) porphyrins was first reported by Wang.[714] Since then a variety of porphyrin complexes have been synthesized that reversibly bind dioxygen. In the following section we will address ligand binding to hemoglobin, myoglobin, and cytochrome P450 model complexes and focus on the literature that has not been covered by review articles on binding of O_2, CO, and other ligands to iron(II) porphyrins by Scheidt and Reed,[183] Traylor,[197] Morgan and Dolphin,[198] Collman,[676] Jones *et al.*,[703] Smith and James,[704] Bogatskii and Zhilina,[705] Collman *et al.*,[706,707] Jameson and Ibers,[708] David *et al.*,[709] Baldwin and Perlmutter,[710] Suslick and Reinert,[711] Momenteau and Reed,[545] and Momenteau.[546]

4.5.1 O_2/CO Binding to Models of Hemoglobin and Myoglobin

Investigations of the binding of dioxygen and carbon monoxide to iron(II) porphyrin complexes have provided valuable insights into the structure–function relationships of the dioxygen binding proteins hemoglobin and myoglobin, especially the concepts of cooperative ligand binding by hemoglobin and the factors that influence such binding (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***).[708,711] Large differences in the binding constants for dioxygen and carbon monoxide to hemoglobin have been observed. O_2 and CO affinities in heme proteins can vary over a wide range, and a 100- to 600-fold difference in the affinities of the R- and T-states of hemoglobin are observed,[712] with the T-state having lower affinity. For binding of O_2, typical values of $P_{1/2}$(human R-state Hb) $= 1.7 \times 10^{-1}$ mm and $P_{1/2}$(human T-state Hb) $\sim$26 mm Hg,[609,681,715,716] while those of $P_{1/2}$(CO) for human R- and T-state Hb have been found to be $\approx$1–4 $\times 10^{-3}$ mm and 1–2.8 $\times 10^{-1}$ mm, respectively,[609,681,715,716] where $P_{1/2}$ is the pressure of the

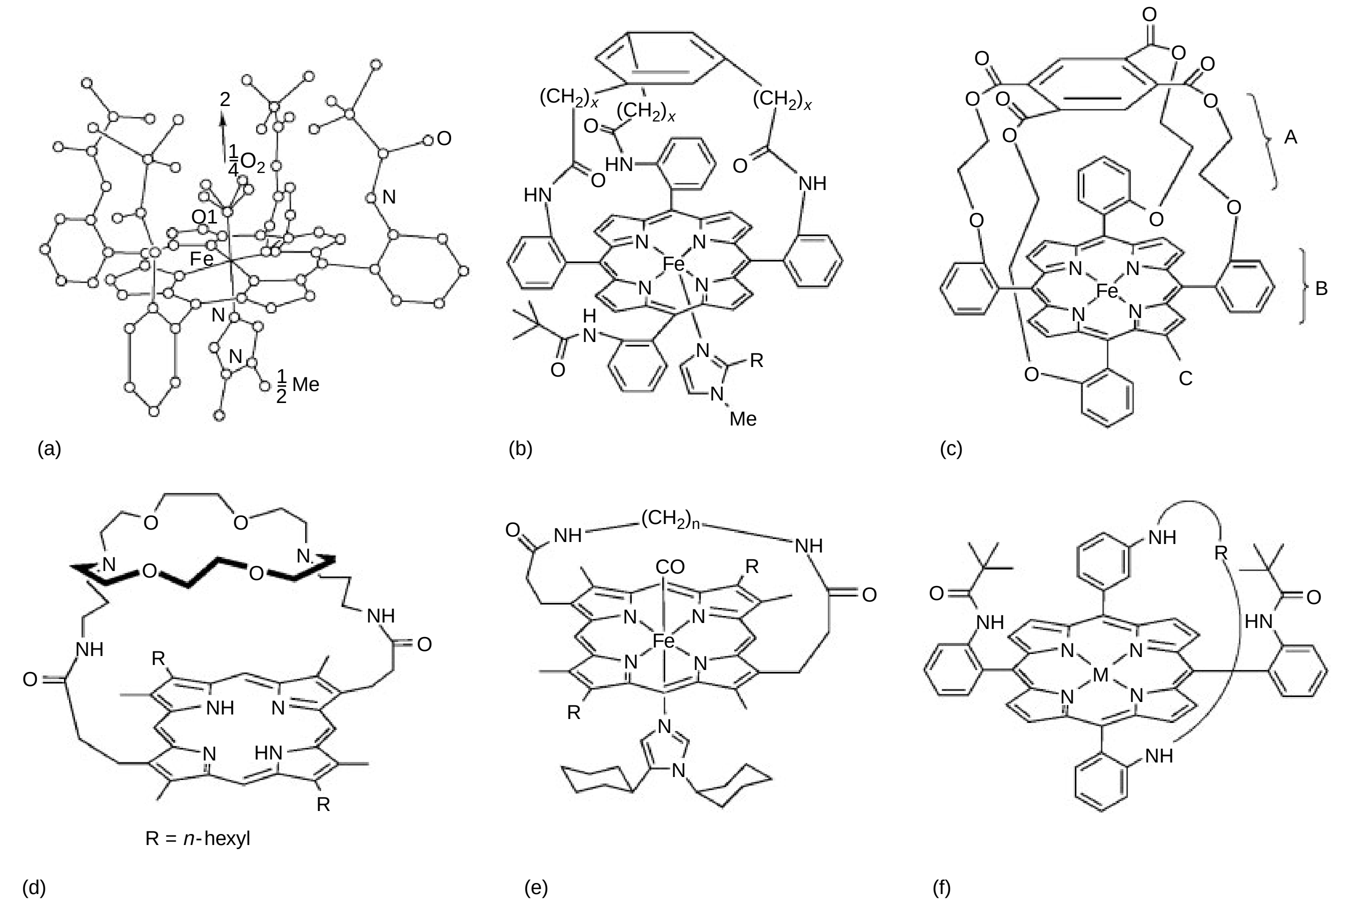


Figure 6 'Superstructured' and 'tailed' iron porphyrins used as models of myoglobin and hemoglobin for the investigation of dioxygen and CO binding to Fe^{II}. (a) The 'picket fence porphyrin' complexed to 2-methylimidazole and dioxygen[699] (b) The 'picket-pocket porphyrin[678]'; (c) 'capped' porphyrins, where the length of the attaching chain (A) (C_2Cap and C_3Cap) and nature of the aryl substituent (B) (phenyl, as in C_2Cap and C_3Cap or naphthyl as in NapC_2Cap) have been varied;[609,680,681] (d) 'crowned' porphyrin;[689] (e) 'cyclophane' porphyrins;[685–687] (f) 'hybrid' porphyrins;[586,647,648,650–655] (g) 'strapped' porphyrins;[691] (h) 'tailed picket fence' porphyrins;[642] (i) 'pendant base basket-handle' porphyrins;[700] and (j) 'chelated hemes'[674,675]

corresponding gas necessary to bind to one-half of all hemes in solution. ($P_{1/2}$ is the inverse of the binding constant for the gas, $P_{1/2} = 1/K_f$.). Additional values are given by Momenteau and Reed[545] and Collman.[717]

Equilibrium and Rate Constants. Under physiological conditions, hemoglobin reacts with O_2, CO, and NO to form oxyhemoglobin, Hb$(O_2)_4$, carbonmonoxyhemoglobin, Hb$(CO)_4$, and nitrosylhemoglobin, Hb$(NO)_4$. Comparison of the relative equilibrium constants, $K_{f,rel}$, for formation of the fully loaded complexes:[716,718]

$K_f(O_2)$	$K_f(CO)$	$K_f(NO)$
1.0	4×10^2	5×10^{15}

indicated that CO and NO complexes are much more stable than the O_2 complex. Similar trends are observed for other five-coordinate heme proteins containing iron(II). The reaction with O_2 is reversible, and the dissociation rate is rapid, whereas CO and NO dissociate much more slowly,[719] and typically laser flash photolysis is required to effect dissociation. The relative binding of O_2 and CO to Fe^{II} porphyrins and heme proteins is typically characterized in terms of the ratio $P_{1/2}(O_2)/P_{1/2}(CO)$. The ratio of $P_{1/2}(O_2)/P_{1/2}(CO)$, which is the same as $K_f(CO)/K_f(O_2)$, and is also referred to as the partition coefficient, in heme proteins ranges from 6000 for glycera Hb[720] to 0.075 in Ascaris Hb[721] (i.e. Ascaris Hb is the only heme protein that binds O_2 with greater affinity than CO), whereas those for model compounds range from ≈5 in polar environments to ≈50 000 in toluene or benzene.[686]

The differences in O_2/CO affinities have been the focus of many studies and debates[722] and were for years related to the proposed bent or tilted binding of CO to iron(II) heme proteins. This hypothesis was based on earlier, less well-resolved protein crystal structures, which were interpreted to show that the oxygen atom of the bound CO ligand deviates considerably

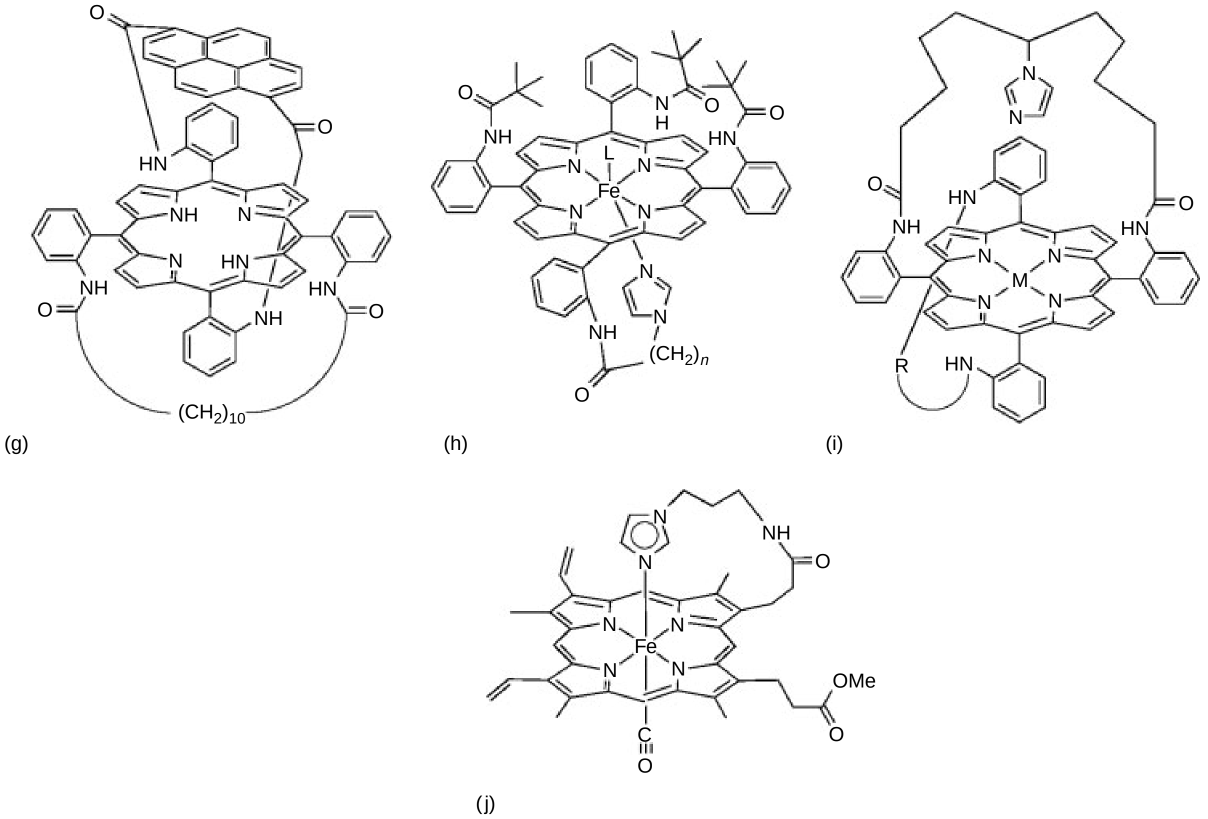

Figure 6 cont'd

from the normal to the heme plane.[723–730] This distortion was consequently attributed to nonbonding interactions of nearby distal protein residues with the CO ligand, which were believed to force the CO moiety to adopt the strained/bent or slanted geometry, whereas dioxygen does not experience such strains since it binds naturally in a bent fashion.[617,647,731–735] These steric interferences to ligation, referred to as distal steric effects, were hypothesized to decrease the affinity ratio of CO versus O_2,[692] resulting in discrimination between O_2 and CO binding. The knowledge of such factors that control O_2 or CO binding are believed to play an important role in preventing poisoning of O_2-carrying heme proteins by endogenously or exogenously produced CO.[530,709,733,734,736]

However, the idea of a bent CO adduct has come under increasing scrutiny over the past years.[737] More recent crystal structures of myoglobin do not show the large deviations from linearity that were reported earlier,[737] which is in agreement with most model heme crystal structures that also do not show large deviation from linearity, and with spectroscopic studies.[737] For example, a very recent crystal structure of myoglobin shows displacement of the O atom of the CO bond from linearity by only about 0.3 to 0.6 Å, as is also shown for most model heme complex structures. Thus, the Fe-CO unit seems to prefer a linear geometry to maximize Fe d_π – CO π^* back-bonding. For model hemes, the X-ray structures of various iron(II) porphyrins show that dioxygen adopts the end-on bent geometry,[648,699,736] as in the protein, with an average O–O separation of 1.22 Å and an Fe–O–O angle of 129°,[738] whereas carbon monoxide is shown to bind in a linear fashion to the metal.[641,739,740] Recent crystal structures of protected pocket and capped iron(II) porphyrin complexes demonstrate that the CO moiety is essentially linear. Fe-C-O angles around 178° are quite typical for CO-ligated complexes.[684] However, there is an example of a crystal structure of a sterically encumbered Fe^{II} porphyrin CO complex, [(β-PocPivP)Fe(1,2-Me_2Im)(CO)], which shows that the CO ligand does not necessarily adopt the linear geometry in model hemes.[741] In that structure the bound carbonyl ligand deviates slightly from linearity with the CO moiety being bent and tilted off the axis normal to the porphyrin plane, the Fe–C–O angle being 172.5°,[741] and the off-axis displacement for the C and O atoms are 0.18 and 0.38 Å, respectively. Nevertheless, it should be noted that no structure is available at present that models the large distortions of the Fe–CO unit that were predicted earlier for the proteins.[742,743]

The main distortions that can occur upon CO binding are distortion of the porphyrin ring, such as ruffling, and/or expansion of the porphyrin core, but no significant tilting or bending of the Fe-CO bond.[684] This finding is also supported by ^{13}C CP/MAS studies of heme protein models with axially

coordinated N-methylimidazole or 1,2-dimethylimidazole,[744] which showed that 1,2-MeIm coordination has no or little effect on the CO chemical shift and thus presumably the local CO geometry, and thus does not appear to result in a significant increase in bending of the Fe-CO unit. Similar conclusions were also drawn for [(OEP)Fe^{II}(CO)(N-MeIm)]. Solid state NMR spectroscopy coupled with DFT calculations revealed that the Fe-CO bond is close to linear.[745] Thus, at the current state of knowledge it can be at least assumed for myoglobin that the differences in O_2/CO ligand affinities are related to the polarity of the binding pocket and that H-bonding by the distal histidine ligand accounts for about 85% of the O_2/CO discrimination, whereas steric hindrance accounts for the remaining 15%.[737] It remains to be investigated whether this conclusion will also apply to other heme proteins.

Since the idea of the distal effect, that is, the steric interaction between bound CO and distal protein residues that result in a tilt or bend of the Fe-CO bond,[712,716,732,741,746] in altering the binding affinity of small ligands such as CO or O_2, has come under scrutiny,[737] other factors have been considered to explain the differences in O_2 and CO binding. These other factors that have been discussed at length elsewhere[545] include:

1. steric effects on the proximal axial ligand (axial-ligand strain),[732,747]
2. solvent effects,[748,749]
3. ligand stabilization through distal side effects,[750–755]
4. electronic effects associated with the porphyrin (*cis* effect),[609,756–764] and
5. electronic effects associated with the axial ligand (*trans* effect).[604,758,764–769]
6. hydrogen bonding[545]
7. polar interactions in the binding pocket.[744]

Among steric effects, two have been postulated to be of significance for heme proteins and their model complexes:[685] (1) heme deformation that moves the iron atom either toward (proximal push) or away from the incoming ligand (proximal pull) and (2) nonbonding groups that interfere with the approaching or bound ligand. It is believed that the proximal deformation of the heme macrocycle could preferentially stabilize either the five- or the six-coordinate state, resulting in decreased or increased ligand affinity.[685] The proximal pull effect is thought to be responsible for the R- to T-state change in hemoglobin.[685]

To evaluate the importance of the factors discussed above for the discrimination of CO and O_2 binding, a variety of five-coordinate model heme complexes have been synthesized.[198,369,545,546,645,648,653,686] Since addition of ligands such as imidazoles or pyridines to four-coordinate PFe^{II} complexes favors the formation of six-coordinate, diamagnetic complexes, as discussed in Section 4.1.2 (i.e. the open coordination site at the iron, essential to mimic reversible O_2 binding in model hemes, is blocked by the second ligand), it is often necessary to control the addition of ligand or use sterically bulky ligands.

Rate and equilibrium constants for O_2 and CO binding to Fe^{II} hemes have been measured in various solvents and at various temperatures. Dioxygen binding to Fe^{II} porphyrins can be studied at low temperatures by a variety of spectroscopic techniques,[545,708] where reactions that lead to irreversible autoxidation are suppressed. However, at higher temperatures (above ~0 °C) fast *Kinetic Methods*[570,631,633,675,710,770–774] must be employed to measure either the equilibria of dioxygen binding before oxidation takes place, or the kinetics of both O_2 and CO binding. The rates of O_2 and CO association, as well as O_2 dissociation, are conveniently measured by employing photochemical (*see Photochemistry*) techniques, namely nano-[775,776] or picosecond[630,653,685,687,692,701,748,774,777,778] laser flash photolysis techniques (*see* ***Photochemistry of Transition Metal Complexes***). The typical reaction scheme is shown in equation (10).

$$\text{B}{-}\text{Fe}^{II}{-}\text{CO} \underset{k_B^{CO}}{\overset{h\nu,\ k_B^{-CO}}{\rightleftharpoons}} \text{B}{-}\text{Fe}^{II}{-} \underset{-O_2,\ k_B^{-O_2}}{\overset{+O_2,\ k_B^{O_2}}{\rightleftharpoons}} \text{B}{-}\text{Fe}^{II}{-}O_2 \quad (10)$$

If the observed rate constant, k_{obs}, is defined as k_{return}, that for the return to the CO-ligated complex before O_2 is added, the kinetics are then described by equation (11):

$$\frac{1}{k_{return}} = \frac{1}{k_B^{O_2}} + \frac{K_B^{O_2}[O_2]}{k_B^{CO}[CO]} \quad (11)$$

and $k_B^{O_2}$ and $k_B^{-O_2}$ can be calculated from a plot of $1/k_{return}$ versus $[O_2]$.

Thermodynamic and kinetic data obtained by flash photolysis methods have indeed increased the understanding of O_2 and CO binding in heme proteins and have revealed that two factors, namely distal steric[197,198,686,687,706,708,711,779] and polarity effects,[197,545,686,694,709,711,749,780–785] appear to be important for the discrimination of O_2 and CO binding to simple Fe^{II} porphyrins. The '*ansa*' hanging basket porphyrin bridged by $-CH_2–C_6H_4–CH_2-$ appears to have the closest match of $P_{1/2}(O_2)/P_{1/2}(CO)$[779] to those reported for hemoglobins,[708,786] of models investigated thus far. The importance of the distal steric effect has been discussed by Tetreau *et al.*,[778] who showed for so-called 'hybrid' model complexes that increasing distal steric hindrance, by changing the length of the carbon chain, results in a reduction by a factor of 2500 of the affinity constant of CO, while dioxygen binding is reduced by less than a factor of 5. It was further shown that change in the carbon chain length affects only the CO association rate, whereas for O_2 binding, both association and dissociation rates are unchanged. Hence it was concluded that constraining the handle in such compounds results in increased sensitivity of both the rate and equilibrium constants upon changing the length of the distal chain.

To understand these effects, the profile of the energy barriers was also investigated. The compounds were found to react according to a double-energy barrier scheme, where the ligand must first overcome a free energy barrier due to steric hindrance on the distal side. This external barrier and the height of the top of the internal barrier are associated with bond formation and found to increase with encumbered hemes. Changes in $\Delta G^{\ddagger}$ are almost identical for CO and O_2 binding, confirming that steric discrimination against CO does not occur in the transition state.[785] Steric effects were also named as reasons for discriminating against CO binding in ether-linked capped systems.[683] It was shown that four-atom capped porphyrin systems discriminate against CO binding to an extent unknown in other models. Whereas the amide linked systems did not bind O_2 or CO even at very high partial pressures, the ether-linked systems had exceptionally high values of $P_{1/2}$(CO) (100 torr at 25 °C), which was ascribed to steric effects induced by the attachment of the benzene cap.[683] Tang and Dolphin,[682] however, showed for other capped complexes that the introduction of the amide functionality to the distal cage increases the O_2 affinity of these systems and suggested that hydrogen-bonding plays an important role in stabilizing O_2 binding and differentiating between O_2 and CO binding. Traylor[780] argued that the differentiation between O_2 and CO binding may be accomplished by solvent or local polarity effects, and not by steric effects, a conclusion that has been subject to some controversy, but seems to be generally accepted.[780,784,785] Studies performed for 3,5-pyridine-5,5-cyclophane heme[687] and other systems[780] confirmed that the differentiation of O_2 and CO binding, that is, the value of $P_{1/2}(O_2)/P_{1/2}$(CO), is strongly determined by polarity effects. Steric differentiation, observed in the association rates, was found to be controlled by the shape and size of the ligand, but not by the geometry of the bound state.[780]

In an earlier study, Stanford *et al.*[758] showed, by measuring the rates of CO binding to Fe^{II} porphyrins, that electronic control through π donor/acceptor interactions with the macrocycle is not an important consideration in controlling the reactivity of heme proteins toward O_2 and CO. Their study, however, confirmed that control through changes in the electronic properties of the metal-bound imidazole can have a large influence on the heme reactivity. Effects of electronic and steric changes in the equatorial plane of the porphyrin on the addition of axial ligands, such as oxygen and carbon monoxide, have also been examined by investigation of modified cap porphyrin complexes.[609] It was found that placing electron-withdrawing groups on the porphyrin ring, that is, transferring electron density away from the porphyrin macrocycle, stabilizes ligation by nitrogen bases, but destabilizes the dioxygen complex. Similar conclusions were reached earlier concerning the binding of nitrogen bases and dioxygen to cobalt(II) porphyrins.[766,787–792] It was further observed that the solvent effect on O_2 binding by the capped complexes is small, suggesting that the environment of the dioxygen bound inside the cap is protected from changes in solvent effects.[609]

Lopez and Kollman applied molecular dynamics and free energy perturbation computational techniques to simulate O_2 and CO binding to cyclophane, picket fence, and monochelated hemes.[793] These calculations showed that in 5,5-pyridinecyclophane heme and in the picket fence heme complex, O_2 binding is favored over CO binding, whereas in the monochelated heme and in 7,7-durenecyclophane heme, binding of CO is favored over O_2,[793] consistent with a distal steric effect playing an important role in discrimination.

The rates and equilibrium constants for dioxygen and carbon monoxide binding to model hemes have been reviewed by several authors, and selected kinetic and thermodynamic data for O_2 and CO binding are summarized in Table 2. Analysis of the data listed in Table 2 suggests that, in addition to distal steric and polarity effects, other factors need to be considered for the differentiation in O_2 and CO binding to Fe^{II} model complexes. These include other steric effects, such as proximal effects (i.e. it has been shown that the overall rates of ligand binding decrease if the fifth ligand is bulky and presents steric strain to the polar heme structure),[616,617,678] strain and blocking effects,[794] and effects such as molecular reorganization, solvation energy effects, solvent polarity, hydrogen-bonding, dipole–dipole interactions, intramolecular solvating of coordinated ligands, intrinsic affinity, and electron donation to the porphyrin or fifth ligand.[708,709,711,780,795–800] The suggestion that a combination of factors must be considered to understand O_2/CO binding is corroborated by studies of picnic basket porphyrin iron(II) complexes.[696] For these and those of other sterically encumbered picket fence, pocket, and basket-handle porphyrin complexes it was concluded that the dramatic variations in the observed O_2 affinities may be due to the combined effects of the electronic and structural nature of the porphyrin, solvation, and particularly the polarity of the dioxygen binding site and dipole–dipole or H-bonding interactions between bound dioxygen and protons of neighboring functional groups.

For a ferrous complex of hemiporphycene incorporated into the pocket of sperm whale apomyoglobin to form a functionally active Fe(II) myoglobin, it was shown that the system was able to bind O_2 and CO reversibly.[802] The O_2 affinity was 12-fold higher than that of the native myoglobin, while CO affinity was slightly lower, suggesting a decreased discrimination between O_2 and CO in the pocket. This functional anomaly was interpreted to reflect increased σ-bonding character in the Fe^{II}–O_2 bond. Similar observations were made by Hayashi *et al.* for 'blue myoglobin', reconstituted with an iron porphycene. The association rate of the ferrous rMb was 5 fold faster than that of the native protein.[803]

Although many interesting iron(II) porphyrin complexes have been synthesized that bind dioxygen reversibly, they are not suitable for achieving the cooperative O_2 binding profile of hemoglobin or myoglobin. However, entirely synthetic

O_2-carrying heme proteins have recently been synthesized by incorporating hydrophobic pivalamido porphyrin iron(II) complexes ($T_{Piv}PFe^{II}$(ImH) bearing a covalently linked axial imidazole into recombinant human serum albumin (HSA).[804–810] In these red-blood substitutes the iron(II) porphyrin is present as five-coordinate high-spin Fe(II) complexes that are non-covalently bonded to HSA. Up to an average of eight Fe^{II}P are bonded per HSA molecule with stepwise equilibrium constants ranging from 1.2×10^6 to 1.3×10^4.[809] These so-called human serum albumin-heme hybrids are remarkable, since they reversibly bind and release dioxygen under physiological conditions (pH = 7.4, 37 °C), thereby closely mimicking the behavior of Hb and Mb.[805–809] The red-colored solution is stable for up to three months at 4 °C and satisfies the physiological requirements for dioxygen infusion.[809] The dioxygen affinity $P_{1/2}(O_2)$ and O_2 transporting efficiency of HSA-Fe(II)P are 30 torr and 22%, respectively.[810] The kinetics of CO binding were suggested to occur in three phases (fast axial-ligand elimination, and slower recombination of the CO to the five-coordinate HS Fe^{II} ion). The rate constants ranged from $4.9 \times 10^6\,M^{-1}\,s^{-1}$ to $6.7 \times 10^5\,M^{-1}\,s^{-1}$.[804] In addition the oxygen binding and dissociation constants are extremely high in comparison to those of Hb.[810] However, the half-life of the dioxygen adduct with imidazole as axial ligand is short, 1 h at 37 °C[810] and 2 h under a 100% oxygen atmosphere.[804] The lifetime of the O_2 adduct, however, was lengthened by modifying the nature of the Fe^{II} porphyrin. When the substituents on the pickets were changed and histidine was coordinated as the axial ligand, the O_2 binding was significantly increased as was the lifetime of the O_2 adduct. Histidine coordination led to a lifetime of 25 h at 37 °C, which is 13 times longer than that of the unmodified T_{Piv}PPFe(Im) systems.[804] From these observations it was concluded that rather than chemical modifications of the pickets being responsible for the improved oxygen binding, axial histidine coordination, that is, the molecular environment of the coordination site, is a major factor in modulating O_2 binding affinities. Tsuchida's laboratory also showed that self-assembled lipid porphyrin bilayer vesicles can act as totally synthetic O_2 carriers under physiological conditions. These systems also bind dioxygen reversibly.[811]

Heme-ligand model systems, such as PFe^{II}BL with PFe^{II} = a picket fence porphyrin Fe(II) complex, B = methyl- or dimethylimidazole, and L = O_2 or CO, also proved useful for exploring the detailed kinetics of photodissociation-geminate recombination within the solvent cage.[679] It was shown that cage recombination efficiency in toluene after photolysis with 314 nm laser light is about 43%, when methylimidazole is used as base, but only 20% when dimethylimidazole is used. Geminate rebinding of CO was shown to be only 10% efficient. The addition of CO to deoxy heme proteins was shown to be a two-step process: diffusion of CO into the heme pocket and geminate recombination with the iron ion, which is typically the rate-determining step. The kinetics are complex, with a distribution of barriers centered around 2.5 kcal mol^{-1} in the case of the low-temperature reaction of photolyzed Mb-CO. Upon warming the distribution shifts to reach a value of 5 kcal mol^{-1} at temperature > 170 K.[812] DFT calculations were recently used to characterize the intrinsic barrier to the CO recombination reaction.[812] The ground state of deoxyheme was found to be a $^5A'$ state in C_s symmetry, with the excited $^5A''$, $^3A'$, and $^3A''$ lying 1–2 kcal mol^{-1} higher in energy, which revealed that the computed energies and geometries are in good agreement with experimental data.[812]

To lay the foundation for applying CO flash photolysis fast time-scale studies to cytochrome *c* model heme chemistry, flash photolysis studies were used to resolve the CO rebinding kinetics for the low-spin ($S = 0$) cytochrome *c* model heme [(F_8TPP)Fe^{II}(CO)(THF)] in both THF and cyclohexane. In CO-saturated THF, the conversion of [(F_8TPP)$Fe^{II}(THF)_2$] to [(F_8TPP)Fe^{II}(CO)(THF)] was monoexponential, with $k_{obs} = 1.6\,(\pm 0.2) \times 10^4\,s^{-1}$. Reduction in the concentration of CO by vigorous Ar purging gave a $k_{obs} = 10^3\,s^{-1}$ in cyclohexane.[664]

As mentioned above, only a few Fe^{II} porphyrins do not undergo reversible oxygenation. In addition to the sterically protected complexes, discussed above, the reaction of *N*-methylporphyrin with $FeCl_3$ in the presence of Fe^0 leads to the formation of the air-stable chloro(*N*-methylporphinato)iron(II).[158] $TPPFe^{II}$ synthesized by laser

photolysis of $TPPFe^{III}Cl$ in methanol reacts with dioxygen to give the $TPPFe^{II}O_2$ adduct, which dissociates to regenerate $[TPPFe^{III}]^+$ and form the O_2^- radical.[813] Due to the presence of the coordinatively restrictive *N*-methylporphyrin ligand the Fe^{II} oxidation state is stabilized in this complex. Oxidation and the well-established phenomenon of dimerization of Fe^{II} porphyrins can also be prevented if six-coordinate low-spin Fe^{II} porphyrins are produced and embedded in a micellar environment.[801]

UV-visible Spectra. Some synthetic diamagnetic Fe^{II} porphyrin complexes with various axial ligands have spectroscopic properties similar to the heme proteins. UV-visible spectra of the six-coordinate CO and O_2 complexes are characterized by three bands, the Soret band and the $Q(0,0) = \beta$ and $Q(1,0) = \alpha$ bands.[223] The CO complex of Traylor's chelated protoheme has Soret, β, and α bands at very similar wavelengths (420, 540, 569 nm) to those of carbonmonoxyhemoglobin (419, 540, 569 nm),[197] while the spectra of CO complexes of TPP-based models with imidazole ligands are slightly shifted and often do not have separate α and β bands, but rather a broad combined α,β band (Soret at 422–427 nm, α,β at 540–542 nm).[641,653,677,700,814] Myoglobin-CO derivatives typically have absorptions at around 420, 540 nm, and 570 nm.[815,816] Often there is a shoulder observed near 580 nm for both the models and the proteins.[700,814–816] For the CS complex of $TPPFe^{II}$(N-MeIm), the λ_{max} values are 425, 547, 583 nm,[817] and for the CSe complex they are nearly identical (426, 547, 583 nm).[818] For the corresponding O_2 complexes, again the chelated protoheme and oxyhemoglobin have similar λ_{max} values (414, 575, 543 nm and 415, 577, 541 nm, respectively),[197] while $TPPFe^{II}O_2$ derivatives with imidazole ligands have slightly shifted spectra (Soret at 425–429, α,β at 546–549 nm,[641,653,677,700] occasionally with a shoulder near 582 nm[700]). Hindered imidazoles as the 'proximal' base cause slight shifts of the λ_{max} values for both CO (424, 542 nm) and O_2 (421, 544 nm) complexes of TPP derivatives,[677] and for the CO complex of the chelated protoheme (420, 540, 569 nm).[769] Providing a 'congested' binding site for CO complexes, with strapped porphyrins, decreases the intensity of the Soret band and shifts the α,β band to lower wavelength, as in the series of $[(Piv)_2(C_n)TPPFe^{II}$(N-MeIm)(CO)] complexes having $n = 12$ (541 nm), 10 (537 nm), 9 (520 nm), and 8 (514 nm).[653] Similarly, the diamidopyrene strapped TPP derivative of Weiss and coworkers has the Soret maximum at 432 nm and the α,β band at 526 nm.[691] Much smaller shifts from the λ_{max} values quoted above are observed in the band maxima of the dioxygen complexes.[653,691] MCD spectra of five-coordinate high-spin and six-coordinate low-spin complexes of Fe^{II} porphyrin and chlorin models have been reported.[819]

Vibrational Spectra. The IR spectra of the hexa-coordinate carbonyl complexes of model hemes and the proteins show characteristic ν_{CO} stretching frequencies. Those of the α and β subunit CO moieties of carbonmonoxyhemoglobin are $\nu_{CO} = 1951$ and $1952\ cm^{-1}$,[764] while for TPP-derived model compounds, $\nu_{CO} = 1965\ cm^{-1}$ for $[(Piv)_4TPPFe^{II}$(N-MeIm)(CO)].[677] For the four $[(Piv)_2(C_n)TPPFe^{II}$(N-MeIm)(CO)] complexes mentioned above, the ν_{CO} band shifts $10\ cm^{-1}$ to lower frequency as the chain is shortened from 12 to 8 carbons ($1958 \rightarrow 1948\ cm^{-1}$),[653] but for the diamidopyrene strapped TPP derivative, $\nu_{CO} = 1980\ cm^{-1}$.[691] For the CS and CSe complexes of $TPPFe^{II}$(N-MeIm), $\nu_{CS} = 1278\ cm^{-1}$,[817] and $\nu_{CSe} = 1140\ cm^{-1}$.[818] For Fe^{II} $Hb(NO)_4$ and MbNO, $\nu_{NO} \sim 1623\ cm^{-1}$, and $\nu_{Fe–NO} \sim 551\ cm^{-1}$.[820] To find the FeCO bending fundamental, resonance Raman spectra in the range of $200–600\ cm^{-1}$ were acquired for CO-coordinated hemoglobin, and myoglobin, and also cytochromes *c* and P450. A new CO-isotope sensitive band near $365\ cm^{-1}$ was found for all proteins except MbCO where the band was found at $575\ cm^{-1}$. These results were interpreted to suggest that the $365\ cm^{-1}$ mode is due to the FeCO fundamental, whereas the $575\ cm^{-1}$ mode is a result of its combination with a porphyrin vibration and/or Fe-C deformation mode.[821] For ferrous chlorin complexes the Fe-C-O mode was found at around $500–530\ cm^{-1}$.[822] More recently, the Fe–NO stretching frequencies of Fe^{II}–NO and Fe^{III}–NO complexes have been reported. For $PFe^{II}NO$, $\nu_{Fe–NO} \sim 527\ cm^{-1}$; upon oxidation to $PFe^{III}NO$, $\nu_{Fe–NO}$ shifts to $602\ cm^{-1}$.[823] Addition of a pyridine or imidazole ligand to the sixth coordination site has very little effect on $\nu_{Fe–NO}$ for either oxidation state.[823] A detailed study of the vibrational spectra of a large number of PFeCO model hemes has appeared.[824]

Mössbauer Spectra. Debrunner has summarized the Mössbauer data of a variety of model heme complexes, including CO and O_2 complexes of pentacoordinate Fe^{II} porphyrins with nitrogen bases as fifth ligands. For [PFe(L)(CO)] complexes, values of $0.21\ mm\ s^{-1} < \delta Fe \leq 0.32\ mm\ s{-}1$ and $0 \leq \Delta E_Q \leq 0.94\ mm\ s^{-1}$, typical of diamagnetic FeII, are reported,[177] whereas for the dioxygen complexes $[PFe(L)(O_2)]$, although the isomer shift is also small ($0.23 \leq \delta_{Fe}(4.2\ K) \leq 0.32\ mm\ s^{-1}$), the quadrupole splitting is relatively large ($\Delta E_Q = (-2.23 \pm 0.15)\ mm\ s^{-1}$).[177] For some complexes, substantial temperature dependence of the quadrupole splitting has been observed. Some of these values agree well with those obtained for hemoglobin and myoglobin: for $Hb(O_2)_4$, $\delta_{Fe}(4.2\ K) = 0.27\ mm\ s^{-1}$, $\Delta E_Q = -2.25\ mm\ s^{-1}$; for $Hb(CO)_4$, $\delta_{Fe}(4.2\ K) = 0.26\ mm\ s^{-1}$, $\Delta E_Q = 0.36\ mm\ s^{-1}$;[825] for MbO_2, $\delta_{Fe}(4.2\ K) = 0.27\ mm\ s^{-1}$, $\Delta E_Q = -2.31\ mm\ s^{-1}$;[826] and for MbCO, $\delta_{Fe}(4.2\ K) = 0.27\ mm\ s^{-1}$, $\Delta E_Q = +0.35\ mm\ s^{-1}$.[827] Both the large size of the ΔE_Q of the dioxygen complexes and the temperature dependence of some of them have been considered incompatible with a low-spin d^6 ($S = 0$) ground state until 1991, when it was shown that the five-coordinate, low-spin, anionic complex $[(Piv)_4TPPFe^{II}(NO_2)]^-$ also has a large

quadrupole splitting ($\Delta E_Q = 2.28\,\text{mm s}^{-1}$, $\delta = 0.41\,\text{mm s}^{-1}$, neither with appreciable temperature dependence).[637] It thus appears that the large quadrupole splitting arises from a significant difference in the energies of the d_{xz} and d_{yz} orbitals due to the binding of the planar nitrite ion. It was concluded that 'the origin of the large ΔE_Q for the nitro- and oxyheme derivatives is the same, namely, a large rhombicity in the heme plane'.[637] For bis-ligated Fe^{II} porphyrins, $PFe^{II}LL'$, where L and L′ are either nitrogen or phosphorus donors, the following values of δ_{Fe} and ΔE_Q are characteristic: $0.33\,\text{mm s}^{-1} \leq \delta_{Fe}(4.2\,\text{K}) \leq 0.51\,\text{mm s}^{-1}$ and $0.5\,\text{mm s}^{-1} \leq \Delta E_Q \leq 1.5\,\text{mm s}^{-1}$.[177] The only exception to this is the case of $L = L' = 2-\text{MeImH}$ and 1,2-Me_2Im, where for $TMPFe^{II}$ the quadrupole splittings are 1.67 and $1.73\,\text{mm s}^{-1}$, respectively.[635] DFT calculations have shown that these values are only consistent with a highly ruffled porphyrinate core.[622]

^{13}C NMR Spectra. The ^{13}C resonance signal for the CO moiety has been observed at around 205 ppm for model complexes,[664,690] whereas for the proteins this resonance is slightly downfield shifted and observed at 206–207 ppm.[828] Providing steric encumbrance to the CO binding site using chiral '*ansa* handle' porphyrins with $-C_6H_4-$ or $-CH_2-C_6H_4-CH_2-$ bridging groups causes a shift to lower frequency (199.4 and 202.7 ppm, respectively).[829] The ^{57}Fe NMR shifts of a number of CO complexes of myoglobin[830,831] and model hemes[487,830,832–834] have been reported in a variety of solvents. The shifts (vs. external $Fe(CO)_5$) range from 8110 to 8219 ppm for the models and 8227 ppm for MbCO.[830,832] Three basket-handle porphyrin complexes of Fe^{II}(N-BuIm)(CO) show a decrease in the ^{57}Fe chemical shift from 8036 to 7728 to 7500 ppm as the basket-handle chain is shortened from twelve to ten to nine CH_2 units, probably due to bending of the Fe–CO bond,[834] discussed in greater detail above. For a series of superstuctured iron(II) complexes with ruffled porphyrin ring conformation, the ^{57}Fe signal was observed at around 8000 ppm.[835] An excellent correlation was found between the ^{57}Fe chemical shift and the degree of ruffling in these complexes. The correlation between the chemical shifts of ^{57}Fe and the *meso*-porphyrin ring carbons suggests that the two nuclear probes reflect similar types of electronic and structural perturbation, which are primarily due to porphyrin ruffling.[835] For comparison, the ^{57}Fe signal of a *bis*-pyridine-ligated $TMPFe^{II}$ complex was observed at 11 715 ppm and falls within its predicted range based on the correlation of the Fe chemical shifts with the Mössbauer quadrupole splittings.[635] Experimental measurements[836] and DFT calculations[836–839] of ^{57}Fe chemical shifts and Mössbauer quadrupole splittings in metalloporphyrins and heme proteins have been reported. DFT calculations of ^{17}O NMR chemical shifts and nuclear quadrupole coupling tensors of oxyheme model complexes have also been reported.[840]

4.5.2 O_2/CO Binding to Cytochrome P450 Model Complexes

Up to this point we have only discussed carbon monoxide and dioxygen binding to pentacoordinate Fe^{II} porphyrins that employ a nitrogen base, such as imidazole or pyridine, at the fifth coordination site, a feature important for understanding dioxygen transport and storage in hemoglobin and myoglobin. However, high-spin Fe^{II} complexes in which one of the axial coordination sites is occupied by a thiolate moiety are also capable of binding small ligands, such as carbon monoxide,[651,652,698,777,841–849] dioxygen,[651,846,849–852] and superoxide.[533] Pentacoordinate high-spin iron(II) thiolate complexes[777,841–853] and their ligand-binding properties (*see* ***S-donor Ligands***) have been investigated to obtain a better understanding of the structure–function relationships of cytochromes P450 (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***), especially to understand which factors control ligand binding in this family of enzymes. The diversity of reactions catalyzed by heme-thiolate proteins was recently reviewed by Mansuy.[854]

When CO is bound to cytochrome P450, the visible spectrum exhibits a typical hyperporphyrin spectrum with a very characteristic and unique feature: the Soret band is split, giving peaks at ∼380 and ∼450 nm (hence the name of this family of enzymes). The split Soret band is attributed to the presence of the thiolate ligand, with its strong σ and π donating capabilities.[845,855] To reproduce this feature, a variety of $PFe^{II}(RS^-)(CO)$ complexes have been synthesized. To force coordination of the thiolate ligand to the iron center and to prevent oxidation of the thiolate moiety to the disulfide, either a large excess of the thiolate has been used[856,857] or a tail has been attached covalently to one[846,847,858] or two[844,845,849,859] points on the porphyrin ring to successfully synthesize P450 models. Examples of such tailed complexes are shown in Figure 7.

Some of the carbon monoxide complexes of the P450 models have optical spectra that are very similar to those of the proteins; for example, the CO adduct of alkanethiolate complexes give typical hyperporphyrin spectra with absorption bands at 380 and 456 nm,[848] whereas a picket fence tetrafluorophenylthiolate complex gives rise to split Soret bands at 387 and 451 nm and a visible band at 559 nm.[651] The IR band associated with the carbonyl stretch is observed at $1956\,\text{cm}^{-1}$, and shifts to $1942\,\text{cm}^{-1}$ in the solid state.[651] Mössbauer data of $\Delta E_Q = 0.56\,\text{mm s}^{-1}$ at 4.2 K are also characteristic for the CO complex. The analogous O_2 adduct has $\Delta E_Q = 2.17\,\text{mm s}^{-1}$ at 4.2 K, very close to those reported for oxy $P450_{cam}$.[654] The IR frequencies of ν ($^{16}O_2$) at $1141\,\text{cm}^{-1}$ and ν ($^{18}O_2$) at $1075\,\text{cm}^{-1}$ indicate a bent end-on geometry for the Fe–O_2 moiety.[651,654] The structure of this dioxygen adduct of $[T_{Piv}PPFe^{II}(C_6HF_4S^-)]$ has also been reported, confirming the bent end-on geometry.[654] ^{13}C NMR spectroscopy is also a very valuable tool to investigate CO coordination in thiolate heme models. For example, the CO complex of a strapped porphyrin[844] has a ^{13}CO NMR

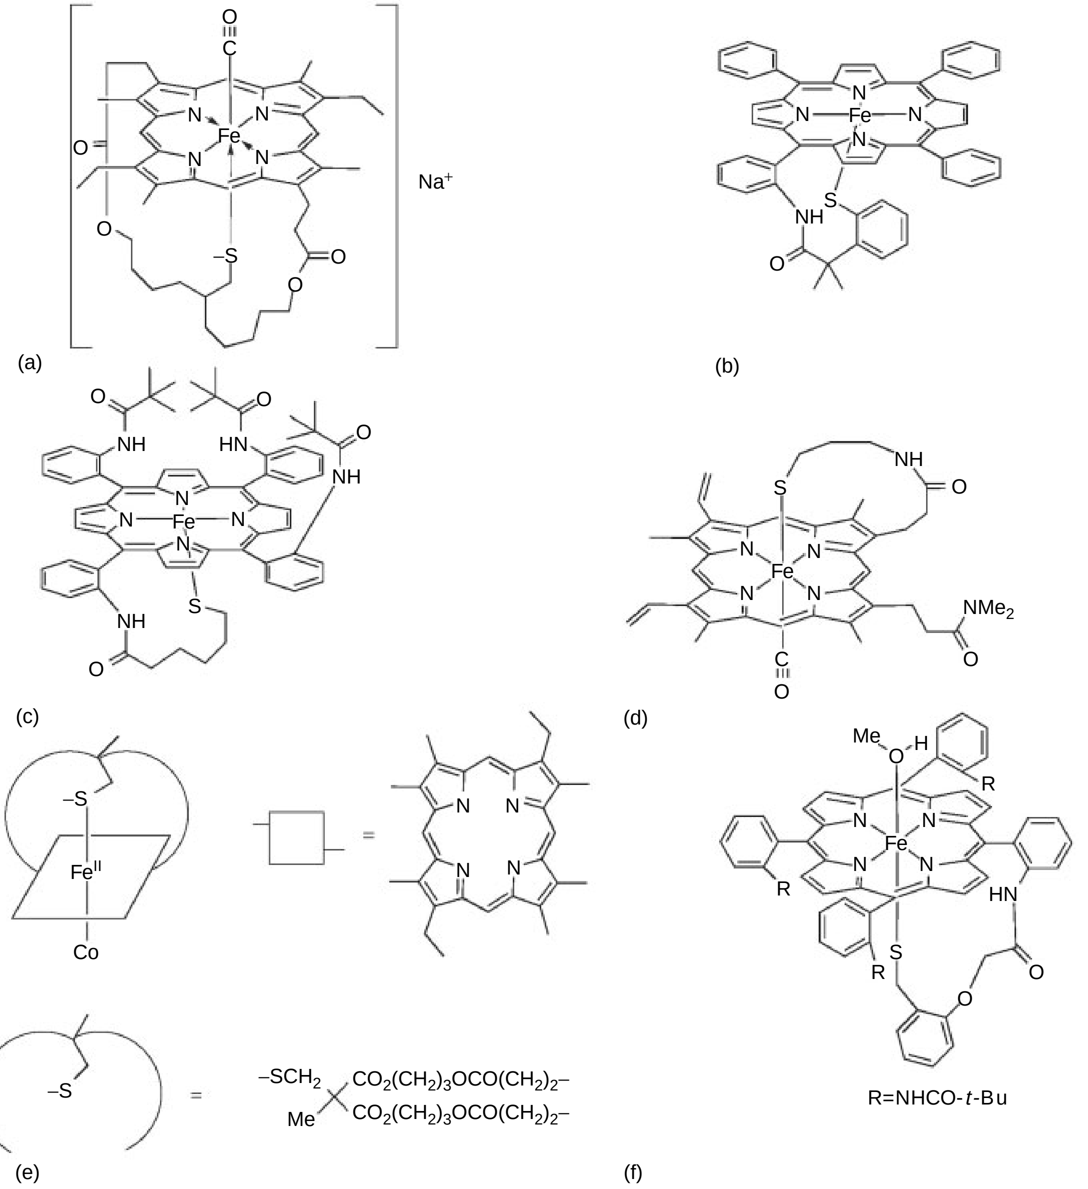

Figure 7 ‘Tailed’ iron porphyrins used as models of cytochrome P450. (a) model designed by Battersby and coworkers, attached at two points;[844] (b) TPP derivative with a pendant aryl thiol capable of bonding to the metal;[847] (c) a ‘picket fence’ derivative with a pendant alkyl thiol;[847] (d) a ‘chelated heme’ with a thiolate ligand;[858] (e) precursor of a model designed by Tatsuno *et al*., attached to the porphyrin at two points;[859] (f) another TPP derivative with a pendant aryl thiolate[846]

resonance frequency of 196.8 ppm, in good comparison to the natural $P450_{cam}$ ^{13}CO complex (200.3 ppm).[860]

Significant differences in the equilibrium constants for carbon monoxide binding to cytochromes P450 from bacterial, liver microsomal, and adrenal cortex microsomal sources, different isozymes of the liver microsomal proteins, and for substrate-free and substrate-bound enzymes, have been observed and have been related to similar factors that affect O_2 and CO binding in oxygen transport and storage heme proteins. The importance of the *cis* and *trans* effects, that is electronic effects associated with the porphyrin or the axial ligand, respectively, have been investigated by Gaul and Kassner.[777] CO affinities were also determined for *n*-butanethiolate Fe^{II} complexes. CO affinities follow the order diacetyldeuteroporphyrin > spirographisporphyrin > 2-acetyl-4*H*-DP > PP > MP, coproporphyrin > diacetyldeuteroporphyrin > dicyanodeuteroporphyrin, which corresponds to the order of decreasing porphyrin basicity. It was concluded that the direction and magnitude of the *cis* effects on CO binding is dependent on the *trans* axial-ligand basicity; the magnitude of the *Trans Effect* on CO binding appears to be related to the (*cis*) porphyrin basicity.[777] Using laser flash photolysis, the O_2

and CO association and dissociation rates of strapped and basket-handle thiolate-coordinated Fe(II) complexes have also been studied.[849] It was found that the increase in pK_a of the proximal ligand is accompanied by a decrease in O_2 and CO association rates, while the dissociation rates increase for CO, but decrease for O_2.

Since it has been shown that the structures of cytochromes P450 have at least one NH···S hydrogen bond at the active site,[861–866] the factors that affect the reduction potentials of the heme-thiolate center of these enzymes have been probed. P450 model complexes with single and double NH···S hydrogen bonds (provided by amides) at the thiolate site have been synthesized and characterized by X-ray crystallography, electrochemistry and infrared spectroscopy.[848,867,868] The reduction potentials of the Fe^{III}/Fe^{II} couples of these complexes show a positive shift of 0.10–0.33 V as compared to model complexes that do not have hydrogen bonds to the thiolate sulfur,[867] indicating greater ease in forming the reduced state that can bind dioxygen. However, there are complexes that have a NH···S hydrogen bond, which include one of the alkanethiolate complexes reported by Suzuki *et al*.[848] In this complex the hydrogen atom of the amide group is directed toward the thiolate sulfur atom to form a N–H···S hydrogen bond with a distance of 2.800 Å and an angle of 130.73°. The H-bond is described to shorten the Fe–S bond length, which is 2.18 Å. To confirm the shortening of the Fe–S bond, resonance Raman experiments were carried. The ν_{Fe-S} mode shifted to 394 cm^{-1} compared to the complex lacking the hydrogen bond. This result was interpreted as confirming that H-bonding induced Fe–S bond shortening, which was suggested to occur when the HOMO involves antibonding metal-S interaction. In support of the N–H···S hydrogen bond is the positive shift of the Fe^{III}/Fe^{II} redox couple by 0.1 V. Both the Fe–S and average Fe–N bond lengths (1.98 or 1.99 Å, depending on the nature of the thiolate ligand) are in good agreement with the structural data of P450$_{cam}$ and P450$_{terp}$.[848]

4.5.3 NO Binding to Iron(II) Porphyrins

Traylor and coworkers[869,870] showed that addition of NO to a carbonmonoxy chelated heme model complex leads to the formation of a five-coordinate PFe^{II}–NO complex. The same reaction occurs when NO is added to the *N*-methylimidazole–protoheme–CO complex at low base concentrations, that is CO is readily replaced by NO, with loss of the imidazole ligand. It has been suggested[869,870] that this loss of proximal ligand may have relevance to the EDRF (Endothelial-Derived Relaxing Factor) activity of nitric oxide in biological systems (*see* ***Nitrogen Monoxide (Nitric Oxide): Bioinorganic Chemistry***).[51,58] Since this report, NO binding to iron(II) porphyrins has become of great interest because of its physiological importance. As discussed earlier, NO plays key roles in many biological processes, and is involved in blood pressure control, vasodilation, and platelet aggregation, acts as neurotransmitter, and is able to kill intracellular parasites.[871,872] In 1992, NO was declared *molecule of the year*,[873] and in 1997 a journal (*Nitric Oxide: Biology and Chemistry*) was established with sole focus on NO chemistry and biology.[871] NO is important in processed nitrite-cured meats, since it is contained in the pentacoordinate nitrosylheme pigment that gives cured meat its color.[93] Nitric oxide is known to bind to many heme proteins, and thus it should not come as a surprise that five- and six-coordinate NO-ligated iron(II) porphyrins are extensively investigated to model the interactions of NO with these proteins. With three exceptions, all Fe(NO_x)-containing heme proteins contain a nitrosyl-bound iron porphyrin.[185,547] Some of the best known of the Fe^{II}-NO complexes include the nitrosyl adducts of hemoglobin and myoglobin, P450$_{nor}$, and cytochromes *c* and *c*′, to name only those proteins that are structurally characterized.[185] (see Section 6.3.4 for discussion of the Fe^{III}-NO models and proteins.) In recent years many reviews on NO model heme chemistry have been published. Ferrous nitrosyl hemes are covered by Scheidt and Wyllie,[185] Scheidt and Ellison,[874] and Scheidt[548] who addressed structural aspects of NO porphyrin chemistry; the laboratory of Ford, Laverman, and Lorkovic,[549,550] who summarized aspects of NO model chemistry, and Cheng and Richter-Addo,[547] who reviewed binding and activation of nitric oxide by metalloporphyrins and hemes. Because of the amount of information available, this section will highlight only certain structural and spectroscopic properties that pertain solely to ferrous NO porphyrins and that have received considerable attention as models of the heme proteins. Iron(III) NO systems are discussed in Section 6.3.4.

Both five and six-coordinate NO-ligated ferrous porphyrins are known, and in the Enemark and Feltham formalism[875] are described as $\{FeNO\}^7$, where the superscript 7 indicates the sum of the six d-electrons of the iron and the π^* electron of the NO ligand. Although all complexes are low-spin, they are paramagnetic because of the unpaired electron derived from the NO ligand.[876,877] These complexes are frequently synthesized by the reduction of the high-spin Fe^{III} porphyrins in an inert gas atmosphere followed by purging with purified NO gas. Techniques and pitfalls in working with NO are summarized in the review by Ford and Lorkovic.[550]

Structural Aspects. Five-coordinate Fe^{II} complexes that have been characterized by single crystal X-ray crystallography include the TPP complex, (TPP)FeNO,[878] the octabromopyrrole substituted TPP complex (Br_8TPP)FeNO, the tetrabromopyrrole substituted TPP complex (Br_4TPP)FeNO, the dichlorophenyl substituted TPP (2,6-Cl_2TPP)FeNO, the pivalamido TPP (T_{Piv}PP)FeNO, the octaethylporphyrin (OEP)FeNO, the ocatethyltetraazaporphyrin complex (OETAP)FeNO, the octaethylchlorin complex (oxo-OEC)FeNO,[185] and the deuteroporphyrin complex (DP) FeNO.[879] These Fe^{II} porphyrins and chlorins are characterized by Fe-N_{por} bond lengths typically observed in low-spin complexes, which range from 1.931 Å in the (OETAP)FeNO complex to 2.010 Å in the (OEP)FeNO complex.[185] The

NO ligand binds in a bent fashion with an Fe-N-O bond angle ranging from 138.9° in (2,6-Cl_2TPP)FeNO to 149.2° in (TPP)FeNO.[878] With this value, the angle lies between that for the strongly bent NO metal systems and the essentially linear complexes.[875] The nitrosyl ferrous proteins show a much larger range for this angle, which may be related to the lower resolutions of the heme protein crystal structures. As they become more refined, the angles may narrow. A summary of the NO geometry is given by Wyllie and Scheidt.[879] The iron is on average displaced by about 0.3 Å from the 24-atom porphyrin core and is tilted toward the NO ligand.[185,548,880] This tilt seems to be a general feature of five-coordinate ferrous-NO porphyrins and has been rationalized by DFT calculations in terms of three important interactions: σ-antibonding d_{z^2}(metal)$-\pi^*$(NO) interaction; d_{z^2}(metal)$-\pi^*$(NO) interaction; and d_{z^2}(metal)$-\pi$ (porphyrin) interaction.[881] The Fe–N_{NO} bond lengths show larger variations than the Fe–N_{por} distances and range from 1.691 Å in (Br_4TPP)FeNO to 1.74 Å in (T_{Piv}PP)FeNO, which reflects the difference in axial bonding and the loss of π interaction when transitioning from the linear to the bent geometry.[185,548]

The six-coordinate Fe^{II} complexes have very similar structural features to those of the five-coordinate complexes, indicating that the increase in coordination number does not affect the structural properties.[185,548,871] To date the structures of a number of complexes with imidazoles, piperidines, pyridines, or nitrites as second axial-ligand bonded to the iron have been solved. Most of these are TPP derivatives. These complexes include (TPP)Fe(NO)(N-MeIm),[185,882,883] (TPP)Fe(NO)(4-MePip),[185,871] (TPP)Fe(NO)(4-MePy),[871] (TPP)Fe(NO)(4-NMe_2Py),[871] (TPP)Fe(NO)(NO_2),[871] and [(T_{Piv}PP)Fe(NO)(NO_2)].[877] These six-coordinate Fe^{II} porphyrins are characterized by Fe–N_{por} bond lengths that are similar to those of the five-coordinate complexes and range from 1.988 Å in the (TPP)Fe(NO)(NO_2) complex to 2.008 Å in (TPP)Fe(NO)(N-MeIm).[185,871] The NO ligand binds in a bent fashion with an Fe-N-O bond angle that ranges from 137.4 Å in the (TPP)Fe(NO)(NO_2) complex to 143.7° in (TPP)Fe(NO)(4-MePip).[185,871] The largest displacement of the iron from the 24-atom porphyrin core is 0.11 Å, which is small compared to the 5-coordinate complexes. The Fe–N_{NO} bond lengths range from 1.72 Å in (TPP)Fe(NO)(4-MePip) to 1.84 Å in (TPP)Fe(NO)(NO_2).[871] An important feature in all complexes is the trans effect exhibited by the NO moiety, that is, the effect associated with the sixth ligand coordinating trans to NO. Related to the trans effect is the relatively long Fe-L bond,[185,548] which ranges from 2.463 Å in one of the two (TPP)Fe(NO)(4-MePip) forms to 2.060 Å in (TPP)Fe(NO)(NO_2).[871] The structural trans effect, which has been explained in terms of the partial population of the d_{z^2} orbital by an unpaired electron derived from the NO ligand,[185] has important implications. The binding constant of the sixth ligand is very low (estimated at $1-10\,M^{-1}$), thereby explaining why the formation of the of six-coordinate [PFe^{II}(NO)L] species is not favored.[185,869] The lengthening and weakening of the trans bond, which has been discussed recently by Scheidt's laboratory more thoroughly,[871] also has important physiological consequences. Bond breakage of the trans bond upon NO coordination is described as one of the means by which NO is believed to activate guanylate cyclase,[884] which then begins the process of vasodilation.

UV–vis Spectroscopy. The UV–vis spectra of five-coordinate ferrous nitrosyl complexes have been reported to reveal three bands with quite often a shoulder of the Soret band. The Soret band of tetraphenylporphyrin complexes is centered at around 405–412 nm, while that of the OEP complex is blue-shifted (TPPFeNO: 405 nm;[878] T_{piv}PPFeNO: 412 nm;[885] OEPFeNO: 387 nm[874]) and quite often has a shoulder at 475–477 nm (TPPFeNO: 475 nm; T_{Piv}PPFeNO: 476 nm; OEPFeNO: 480 nm). The β band is observed at 537–539 nm (TPPFeNO: 537 nm; T_{Piv}PPFeNO: 539 nm; OEPFeNO: 530 nm), whereas for TPP complexes the α band is found at 604–611 nm (TPPFeNO: 606 nm; OEPFeNO: 570 nm). For the six-coordinate complexes, the absorption band maxima of all bands are shifted to higher wavelength. For the representative example of [TPPFe(NO)(N-MeIm)] the following values were obtained: Soret band at 415 nm, shoulder at 460 nm, β band at 545 nm with a shoulder at 580 nm, α band at 643 nm,[883] while for [OEPFe(NO)(N-MeIm)] the same bands are found at 402, 480(sh), 535 and 565 nm.[874]

Vibrational Spectroscopy. For purposes of product identification, both the NO and the Fe-NO stretching frequencies are sensitive reporters on the nature of the bond between the iron(II) and the NO ligand, and reflect the bent geometry observed for the Fe-NO moiety in these complexes. The values for the NO stretching frequency are distinctively different in five- and six-coordinate complexes.[550,871] In five-coordinate complexes, the ν_{NO} band is observed in the narrow range of $1666\,cm^{-1}$ to $1673\,cm^{-1}$. Representative examples are: ν_{NO} (TPPFeNO) = $1670\,cm^{-1}$, ν_{NO}(OEPFeNO) = 1666, $1673\,cm^{-1}$, ν_{NO}((oxoOEC)FeNO)) = $1673\,cm^{-1}$, and ((T_{Piv}PP)FeN) = $1665\,cm^{-1}$).[550,871] The nitrosyl stretching frequency in six-coordinate ferrous NO complexes shifts by about $10-30\,cm^{-1}$ to lower frequency, which is associated with an increased electronic population of the π^* NO orbitals. The NO stretch is quite sensitive to the trans effect; ν_{NO} increases with decreasing interaction with the trans ligand. Representative examples of ν_{NO} values are found in [(TPP)Fe(NO)(NO_2)] – ν_{NO} $1625\,cm^{-1}$; [(TPP)Fe(NO)(N-MeIm)] – ν_{NO} $1628\,cm^{-1}$; [(TPP)Fe(NO)(4-MePip)] – ν_{NO} $1653-1656\,cm^{-1}$, and [(TPP)Fe(NO)(4-NMe_2Py)] – ν_{NO} $1653\,cm^{-1}$.[550,871] Whereas there is a distinctive difference in the nitrosyl stretching frequencies of five- and six-coordinate complexes, this difference is not reflected in the ν(Fe–N(NO)) stretching frequencies of penta- and

hexa-coordinated complexes. Resonance Raman bands associated with the ν(Fe–N(NO)) stretching frequency are in both types of complexes very similar in value. For the five-coordinate complex TPPFeNO, the ν(Fe–N(NO)) was observed at 525 cm^{-1},[886] whereas the corresponding band in the six-coordinate (TPP)Fe(NO)(Py) complex is found at 527 cm^{-1}.[887] Using Soret-excitation resonance Raman spectroscopy, it was also shown that the Fe^{II}–NO bond strength in six-coordinate complexes is not affected by steric or electronic properties of the sixth axial base ligand. However, solvent effects are found to be substantial.[887]

IR spectroscopy was also shown to provide an important tool for investigating the interactions of nitric oxide gas with thin layers of Fe^{II}(TPP).[888] The addition of NO to Fe^{II}(TPP) yields Fe(TPP)(NO) layers, which are inert to further reaction with excess NO. However, the nitrosyl-nitro complex, (TPP)Fe(NO)(NO_2), is readily formed when traces of dioxygen are added to the NO atmosphere. At high NO_2 concentrations in the NO/NO_2 mixture, the nitrato complex (TPP)Fe(NO_3) is also formed. Moderate shifts in the nitrosyl stretching frequency of (TPP)Fe(NO) were related to crystal packing effects, rather than to H-bonding of coordinated NO to protic contaminants. Removal of NO from layers containing (TPP)Fe(NO)(NO_2) led to the formation of Fe(TPP)(NO) and (TPP)Fe(NO_3).[888] Synchrotron far-IR spectroscopy has recently been used to investigate heme doming modes of model heme-CO complexes.[889]

A relatively new type of vibrational spectroscopy is that made available by synchrotron radiation at the Mössbauer γ-ray energy of ^{57}Fe (14.4 keV) or other probe nucleus, which is called Nuclear Resonance Vibrational Spectroscopy (NRVS) or Nuclear Inelastic Scattering (NIS).[890–899] This technique allows the measurement of the complete set of probe (iron for our interest) vibrational modes. Thus, all modes involving significant Fe motion will contribute to the measured spectrum. For hemes and heme proteins, these motions include heme doming, Fe–N_P symmetric and asymmetric stretches, Fe–N_{ax} and Fe–L stretches,[891,893,894,896–899] where L may be NO, CO or any number of other possible axial ligands. For TPPFeL complexes it has been found that there is significant mode coupling of the phenyl groups with the Fe-active modes, and DFT calculations are very helpful in understanding these couplings.[898,899] For (TPP)Fe(CO)(N-MeIm), it was possible to identify the iron-imidazole stretching mode for the first time, at 226 cm^{-1}.[898] For (TPP)Fe(CO)(N-MeIm)[898] and (TPP)Fe(NO),[899] quantitative comparison of calculated and measured Fe dynamics on an absolute scale reveals good overall agreement, suggesting that DFT calculations provide a reliable guide to the character of observed Fe vibrational modes. These include a series of modes involving Fe motion in the plane of the porphyrin, which are rarely identified using infrared and Raman spectroscopies, because these modes are generally weak in comparison to macrocycle vibrational modes. The NO binding geometry breaks the four-fold symmetry of the Fe environment, and the resulting frequency splittings of the in-plane modes predicted for (TPP)Fe(NO) agree with those observed. In contrast to expectations of a simple three-body model, mode energy remains localized on the FeNO fragment for only two modes, an N-O stretch and a mode with mixed Fe-NO stretch and FeNO bend character. Bending of the FeNO unit also contributes to several of the in-plane modes, but no primary FeNO bending mode is identified for (TPP)Fe(NO). Vibrations associated with hindered rotation of the NO and heme doming are predicted at low frequencies, where Fe motion perpendicular to the heme is identified experimentally at 73 and 128 cm^{-1}.[899] Identification of the latter two modes is a crucial first step toward quantifying the reactive energetics of Fe porphyrins and heme proteins.

EPR Spectroscopy. EPR spectroscopy provides insights into the electronic nature of the paramagnetic species, and allows determining whether ferrous nitrosyl $iron^{II}$ porphyrins are formed during a reaction, and to distinguish five- and six-coordinated Fe^{II} complexes. The EPR spectra of both types of Fe^{II} porphyrins have been studied and give rhombic EPR spectra owing to the π^* electron of the NO ligand[550,871,877,879–883,900] The spectra of five-coordinate Fe^{II} porphyrins show similar features in the solid and liquid state, and reveal hyperfine splittings that are consistent with the coupling to the nitrogen atom of the axially coordinated NO moiety.[877] EPR g-values for representative five-coordinate ferrous complexes are: TPPFeNO (toluene at 120 K): g_{max}2.102, a_{max}(^{14}N) 12.6 G, g_{mid}2.064, a_{mid}(^{14}N)17.2 G, g_{min}2.010, a_{min}(^{14}N)17.3 G;[876] (CH_2Cl_2 at 77 K): g_{max}2.098, g_{mid}2.031, g_{min}2.001;[879] and OEPFeNO (doped single crystal): g_{max}2.110, g_{mid}2.040, g_{min}2.012.[900] The EPR spectrum of the pigment contained in nitrite-cured red meat reveals similar features (g_{max}2.112, g_{mid}2.070, g_{min}2.009) that clearly can be attributed to a pentacoordinate nitrosyl heme present in the pigment.[93]

Depending on the nature of the sixth axial ligand, the spectra of six-coordinate Fe^{II} porphyrins reveal two different hyperfine splitting patterns. A nine-line hyperfine pattern arising from the interaction of the unpaired electron with both the nitrogen atom of NO and the N atom of the coordinating ligand was observed first for [(TPP)Fe(NO)(pip)][876] and more recently for [(TPP)Fe(NO)(N-MeIm)].[871] A less resolved three line pattern was obtained for [(T_{Piv}PP)Fe(NO)(NO_2)].[877] EPR g-values for representative six-coordinate complexes are: [(TPP)Fe(NO)(pip)] (toluene at 77 K): g_{max}2.08, g_{mid}2.04, g_{min}2.003;[871,876] [(TPP)Fe(NO)(N-MeIm)] (toluene at 77 K): g_{max}2.072, g_{mid}2.004, g_{min}1.966;[871] and [(TPP)Fe(NO)(4-NMePy)] (toluene at 77 K): g_{max}2.069, g_{mid}2.002, g_{min}1.973.[871] The hyperfine splitting patterns observed are consistent with the interpretation that the unpaired electron density in both five- and six-coordinated low-spin Fe^{II} complexes is localized in the d_{z^2} iron orbital. The three g-values reflect the non-axial symmetry of the complexes and the bent Fe-NO moiety. DFT calculation of the

g-tensors[901] of $\{FeNO\}^7$ complexes as a function of their structures have been reported.

Mössbauer Spectroscopy. Mössbauer spectroscopy has been used as a powerful technique to probe the electronic structure of the five- and six-coordinate ferrous nitrosyl porphyrins.[871,877] The isomer shifts of both types of complexes ($\delta \approx 0.35\,\mathrm{mm\,s^{-1}}$) are similar and show temperature dependences that are consistent with a second-order Doppler effect, but are slightly smaller than those of most other iron(II) porphyrin complexes ($\delta \approx 0.45\,\mathrm{mm\,s^{-1}}$).[871] Unlike the isomer shifts, the quadrupole splittings change upon coordination of a sixth ligand. As the environment changes from five- to six-coordination, the values of ΔE_Q decrease from, for example $1.22\,\mathrm{mm\,s^{-1}}$ in the pentacoordinate TPPFeNO complex to $0.75\,\mathrm{mm\,s^{-1}}$ in the corresponding 1-methylimidazole ligated porphyrin [(TPP)Fe(NO)(N-MeIm)] or $0.91\,\mathrm{mm\,s^{-1}}$ in the [(TPP)Fe(NO)(4-MePy)] complex.[871] To obtain reasonable spectral fits, rotation of the Mössbauer electric field gradients is required for the six-coordinate ferrous nitrosyl complexes, but not for the five-coordinate species. This result was interpreted as reflecting differing g-tensor orientations in five- and six-coordinate complexes.[871] DFT calculation of the Mössbauer parameters[902] of $\{FeNO\}^7$ complexes as a function of their structures have been reported.

X-ray Absorption Spectroscopy – EXAFS and XANES. To develop additional tools for characterizing electronic and structural properties of nitrosyl complexes, NO adducts of ferrous porphyrins and phthalocyanines were attached to the surface of high area carbon electrodes in an acidic aqueous solution and subjected to EXAFS and XANES investigations.[903,904] EXAFS spectra of a tetramethoxyphenyl substituted TPPFe complex were recorded in situ, that is, under potential control, in which the Fe^{II} center was constrained to reside in the center of the porphyrin macrocycle. Under these constraints, analysis of the iron K-edge data showed that the Fe-NO moiety is bent, which is in excellent agreement with single crystal X-ray data, as are the Fe-N_{por} and Fe-NO bond distances and angles.[903] The analysis of the Fe K-edge data of the nitrosyl complex of the phthalocyanine analog demonstrated that the geometry around the iron center is very similar to that of the better-characterized iron(II) porphyrin NO adducts. The Fe center in the phthalocyanine complex shows a five-coordinate square planar arrangement, with the axially coordinated NO forming an angle of about 40° with respect to the normal to the phthalocyanine plane.[904]

Mechanistic Aspects. To elucidate the controversial chemistry relating to the reactions of NO with (TPP)Fe(NO), a series of reactions were carried out in several laboratories, including that of Ford.[905] With highly pure NO the sole species, only observable at low temperature, was the diamagnetic *trans* dinitrosyl adduct $Fe(TPP)(NO)_2$.[906] This reaction was also observed for the more stable tetra-*m*-tolylporphyrinatoiron(II) complex, which reacted with NO at low temperature to form the *bis*-NO adduct $(TmTP)Fe(NO)_2$.[906] Wayland and Olson had originally detected the formation of this complex using (TPP)Fe(NO) by the disappearance of the EPR signal in the presence of high pressures of NO gas (400 torr).[876] Experimental evidence for the formation of the $TPPFe(NO)_2$, $(TmTP)Fe(NO)_2$ or also $(OEP)Fe(NO)_2$ complexes was obtained by IR spectroscopy.[907] Although the observation of a single NO stretching band in the IR spectrum of each complex first suggested a centrosymmetric D_{4h} or C_{2h} structure, DFT geometry optimizations and frequency calculations indicate that the trans-syn C_{2v} conformation should be more stable.[907] It should be noted that TPPFeNO does not react with NO to form $(TPP)Fe(NO_2)(NO)$ at room temperature in aprotic solvents,[908] but it readily reacts reversibly with N_2O_3 in the presence of excess NO to give the nitro nitrosyl complex $(TPP)Fe(NO_2)(NO)$.[905] This observation indicates that claims that Fe(TPP)(NO) promotes NO disproportionation to give $Fe(TPP)(NO_2)(NO)$[909] are most likely compromised by traces of air present in the nitric oxide sources.[905] $(TPP)Fe(NO_2)(NO)$ also undergoes reversible loss of NO to give the nitro species $(TPP)Fe(NO_2)$, which has been implicated as a powerful oxygen atom transfer agent in reactions with various substrates.[910]

The NO_2 complex can be synthesized from the 5-coordinate NO complex by controlled reaction of $(T_{Piv}PP)Fe(NO)$ with air in the presence of pyridine, and reconverted to the starting nitrosyl complex using triphenylphosphine as reductant.[911] In the presence of excess NO_2, $(TPP)Fe(NO_2)$ undergoes oxidation to the stable nitrato analog $(TPP)Fe(NO_3)$.[905] Owing to the reactivity of $(TPP)Fe(NO_2)$, flash photolysis and stopped-flow kinetics has been used to measure accurately the dissociation equilibria of $Fe(TPP)(NO_2)(NO)$ in toluene at 298 K.[905] Flash photolysis of $Fe(TPP)(NO_2)(NO)$ resulted in competitive NO_2 and NO dissociation to give Fe(TPP)(NO) and $Fe(TPP)(NO_2)$, respectively. The rate constant for the reaction of Fe(TPP)(NO) with N_2O_3 to generate $Fe(TPP)(NO_2)(NO)$ was determined to be $1.8 \times 10^6\,\mathrm{M^{-1}\,s^{-1}}$, and that for the NO reaction with $Fe(TPP)(NO_2)$ was similarly determined to be $4.2 \times 10^5\,\mathrm{M^{-1}\,s^{-1}}$.[905] Stopped-flow rapid dilution techniques were used to determine a rate constant of $2.6\,\mathrm{s^{-1}}$ for NO dissociation from $(TPP)Fe(NO_2)(NO)$. Rapid dilution experiments also demonstrated that $Fe(TPP)(NO_2)$ readily undergoes further oxidation to give $(TPP)Fe(NO_3)$.[905] Hoshino *et al*. also reported that TPP-Fe^{II}NO undergoes facile photodenitrosylation to give NO and TPPFe. The photodissociation yield was determined to be 0.55.[912] Laser flash photolysis in the presence of low concentrations of pyridine led to the formation of the five-coordinate complex TPPFe^{II}Py, which is in equilibrium with $(TPP)Fe^{II}(Py)_2$ and recombines with NO to reform TPPFe^{II}NO.[912] Analogously, it was also shown by laser-photolysis studies of nitrosyl protoporphyrin IX iron(II), that the (PPIX)Fe^{II}NO complex readily photodissociates NO to leave the (PPIX)Fe complex

in the micellar solution. The quantum yield was 0.15 for (PPIX)Fe^{II}(NO).[913] The (PPIX)Fe complex produced in the micelles recombines with NO to regenerate the parent nitrosyl porphyrin. The decay of (PPIX)Fe in the absence of excess NO follows second-order kinetics. In the presence of excess NO, the decay of (PPIX)Fe is pseudo-first-order.

As part of the work on model heme $\{FeNO\}^7$ complexes, mechanistic studies on the reversible binding of nitric oxide to metmyoglobin[914] and water soluble Fe^{II}, Co^{II} and Fe^{III} porphyrin complexes[915] in aqueous solution, ligand-promoted rapid NO or NO_2 dissociation from Fe^{II} porphyrins,[916] reductive nitrosylation of water-soluble iron porphyrins,[917,918] activation of nitrite ions to carry out O-atom transfer by Fe^{III} porphyrins,[910,919–921] demonstration of the role of scission of the proximal histidine-iron bond in the activation of soluble guanylyl cyclase through metalloporphyrin substitution studies,[922] reactions of peroxynitrite with iron porphyrins,[923,924] and the first observation of photoinduced nitrosyl linkage isomers of $\{FeNO\}^7$ heme complexes[925] have been reported.

Reactions of NO were also studied with the synthetic heme protein discussed earlier, namely the recombinant human serum albumin (rHSA) with eight incorporated $TPPFe^{II}$ derivatives bearing a covalently linked axial base, were also investigated.[926] The UV–vis absorption spectrum of the phosphate buffer solution at physiological pH showed absorption band maxima at 425 and 546 nm upon the addition of NO to form the nitrosyl species, which was also formed when the six-coordinate CO-adducts were reacted with NO gas. EPR spectroscopy revealed that the albumin-incorporated iron(II) porphyrin formed six-coordinate nitrosyl complexes. It was observed that the proximal imidazole moiety does not dissociate from the central iron when NO binds to the trans position. The NO-binding affinity $P1/2_{NO}$ was 1.7×10^{-6} torr at pH 7.3 and 298 K, significantly lower than that of the porphyrin complex itself, and was interpreted as arising from the decreased association rate constant (k_{on}(NO), $8.9 \times 10^8\,M^{-1}\,s^{-1}$–$1.5 \times 10^7\,M^{-1}\,s^{-1}$). Since NO-association is diffusion controlled, incorporation of the synthetic heme into the albumin matrix appears to restrict NO access to the central iron(II).[926]

4.5.4 *HNO Binding to Iron(II) Porphyrins*

The protonated 1-electron reduction product of NO, HNO, also known as nitroxyl, also binds to heme centers;[927] Farmer and coworkers have characterized the reaction of myoglobin(Fe^{II})-NO with Cr^{II} in the presence of H^+ to produce myoglobin(Fe^{II})–HNO and Cr^{III}:[928]

$$Mb(Fe^{II}) - NO + Cr^{II} + H^+ \longrightarrow Mb(Fe^{II}) - HNO + Cr^{III} \quad (12)$$

The same complex can also be produced by decomposition of Angeli's salt, $Na_2N_2O_3$, in neutral solution:[928]

$$N_2O_3^{2-} + H^+ \longrightarrow HNO + NO_2^- \quad (13)$$

$$HNO + Mb(Fe^{II}) \longrightarrow Mb(Fe^{II}) - HNO \quad (14)$$

The HNO adduct is characterized by a proton NMR resonance at 14.8 ppm that is due to the proton of coordinated HNO, a strictly diamagnetic species[927–929] (although it could also be thought of as a strongly antiferromagnetically-coupled Mb(Fe^{III})–($HNO^{-}\cdot$) electron configuration), and the solution structure of the Mb(Fe^{II})–HNO heme pocket has been determined by 2D NMR techniques.[929] HNO is an interesting small molecule, in that it is a singlet (spin-paired) species, while the ground state of its conjugate base, NO^-, is a triplet (isoelectronic with O_2).[930,931] Therefore, the deprotonation of HNO is spin forbidden, and the pK_a has been estimated as 11,[932,933] which is quite different from the earlier reported value of 4.7.[934] HNO reacts with itself to produce N_2O and H_2O, and is thought to be an intermediate in the enzymatic reduction of NO to N_2O, the reaction that is carried out by nitric oxide reductases (discussed in Section 6.1.4). An Fe-bound nitroxyl intermediate has been spectroscopically identified during turnover of $P450_{nor}$,[935,936] a fungal nitric oxide reductase (see also Section 6.1.4).

4.5.5 *Isocyanide Binding to Iron(II) Porphyrins*

Although isocyanides are not natural substrates, their interactions with heme proteins have been extensively investigated to obtain a better understanding of the importance of the distal steric effect.[716] Even though this effect has been addressed in a wide variety of studies, as discussed above, isocyanide binding has provided an understanding of the importance of the distal side steric effect.[709] Not unexpectedly, heme proteins generally bind alkyl and aryl isocyanides with reduced affinities as compared to simple model compounds.[428,685,687,703,713,937–940] A recent review has discussed in detail axial isocyanide and phosphine binding in heme proteins and model hemes.[553] Thus, in this section only certain aspects of isocyanide binding are highlighted.

Although isocyanide-ligated complexes are quite stable in de-gassed solutions, they react rapidly with traces of air. Thus, care must be taken when preparing such complexes.[553] Both mono- and *bis*-isocyanide ligated complexes are known, which most frequently are synthesized by the reduction of the corresponding Fe(III) porphyrins followed by the addition of excess alkyl or aryl isocyanide in the presence or absence of other potential ligands, including imidazoles or pyridines.[553] In this way, ferrous isocyanide complexes have been prepared from sterically unencumbered porphyrins (TPP, OEP, methylesters of 3,8 diacetyl deuteroporphyrin and protoporphyrin IX) and encumbered porphyrins (capped and anthracene porphyrins, as well as basket-handle porphyrins).[553]

Mono-axially coordinated species are most conveniently formed by the reaction of single face-hindered Fe(II) porphyrins with isocyanide in a non-coordinating solvent, such as toluene or benzene,[553] or when four-coordinate PFe^{II} are reacted under an inert atmosphere with nitrogen bases, such as imidazoles and pyridines in the presence of isocyanide.[745] This is consistent with equilibrium constant studies, which show that, for example, benzyl isocyanide binds more strongly to ferrous porphyrins than 1-methylimidazole, pyridine, or triphenylphosphine.[553] For isocyanide binding, correlations have been established among ligand basicity and binding affinity. But it should be noted that isocyanides bind Fe(II) ion more strongly than one would expect based on their ligand basicities.[553] It has been shown that addition of sterically bulky isocyanides, such as tosylmethyl isocyanide for example, affects only the ligand association rates, suggesting that steric effects are primarily manifested in the association and not the dissociation rates.[685]

Six-coordinate mono-isocyanide ligated ferrous complexes of TPP were investigated recently in the laboratory of Oldfield.[745] Both the pyridine and imidazole mixed isocyanide-ligated complexes $TPPFe^{II}(i PrNC)(N\text{-}MeIm)$ and $TPPFe^{II}(i PrNC)(Py)$ were prepared by reacting the reduced *bis*-pyridine and imidazole complexes with isopropylisocyanide (*i*PrNC). The crystal structure of $TPPFe^{II}(i PrNC)(N\text{-}MeIm)$ showed that the porphyrin ring was planar in the complex, but that the isocyanide moiety was considerably tilted. The average $Fe–N_{por}$ bond distance of 1.998 Å was consistent with the $S = 0$ spin state.[745] These features are consistent with an earlier crystal structure of $TPPFe^{II}((CH_3)_3CNC)_2$.[938] Solid state ^{13}C and ^{15}N NMR studies showed that the ^{13}C chemical shift of the isocyanide carbon ($\delta_{iso} = 151$ ppm) is about 18 ppm shielded from that in sperm whale Mb ($\delta_{iso} = 173.4$ ppm) and in adult human Hb ($\delta_{iso} = 173.3$ ppm). The chemical shifts and shift tensor were also calculated by DFT methods, which showed good agreement with the experimentally observed values.[745]

Bis-isocyanide-ligated ferrous porphyrins were synthesized by Le Plouzennec *et al*.[941] who showed that reaction of $TPPFe^{II}$ with two equivalents of *N*-benzoyl isocyanide results in the formation of the six-coordinate, low-spin bis(isocyanide) complex. The UV–visible bands are found at 428, 553, and 593 nm, and NMR shifts and Mössbauer quadrupole splittings are consistent with the hexacoordinate complex. If *N*-pivaloyl isocyanide is used, then both the mono and bis adducts are formed. The IR absorption band associated with the C≡N stretch of the mono adduct is observed at 1970 cm^{-1}, whereas the corresponding band in the bis adduct is shifted to higher frequency (2045 cm^{-1}). Reaction of the bis adduct with pyridine results in the replacement of one isocyanide ligand.[941] ^{57}Fe NMR shifts of Mb(RNC), where R = Et, *i*-Pr and *n*-Bu, range from 9223 to 9257 ppm versus external $Fe(CO)_5$,[942] and the model heme complex $TPPFe^{II}(PMe_3)(n\text{-}BuNC)$ in C_6D_6 has a shift of 8100 ppm versus external 90% $Fe(CO)_5$ in C_6D_6.[487]

4.5.6 Binding of Other Ligands to Iron(II) Porphyrins

Nitrosoalkanes as Ligands. Nitrosoalkane ligands are also capable of binding to Fe^{II} porphyrins with high affinities.[601] These complexes are conveniently obtained by reaction of the corresponding PFe^{II} complexes with the nitrosoalkane, RNO, or by reaction of the corresponding high-spin $PFe^{III}Cl$ complex with the hydroxylamino alkane, RNHOH, in the presence of excess ligand. It is found that hexacoordinate complexes are in fast exchange with the corresponding pentacoordinate PFe(RNO) complexes, and are low-spin species, with N=O stretching frequencies in the range 1400–1445 cm^{-1}.

Thiocarbonyl (CS) as Ligand. Both five- and six-coordinate low-spin iron complexes with a thiocarbonyl ligand have been structurally characterized.[548,562] An example of a five-coordinate low-spin thiocarbonyl ligated complex is exhibited by $[OEPFe^{II}(CS)]$. In this complex the average Fe–N bond length is 1.982 Å and the Fe–C(CS) bond distance is 1.662 Å with a fairly small displacement (0.23 Å) of the iron ion from the mean plane of the porphyrin core.[649] For low-spin Fe^{II} complexes, large quadrupole splittings (1.95 mm s^{-1} at 293 K, 1.93 mm s^{-1} at 4.2 K) have been observed for the thiocarbonyl ligated $OEPFe^{II}CS$ complex, which has an isomer shift (-0.03 mm s^{-1} at 293 K, +0.08 mm s^{-1} at 4.2 K) that is among the smallest reported for formally iron(II) porphyrins. This isomer shift is comparable to iron porphyrins with formal oxidation states of +3 and +4.[548,562] Six-coordinate complexes are also formed when the thiocarbonyl-ligated complex $OEPFe^{II}(CS)$ mentioned above is reacted with Py, N-MeIm, Pip, 4-CNPy, or 4-NMe_2Py.[562] The [OEPFe(CS)(Py)] and [OEPFe(CS)(N-MeIm)] complexes have been structurally characterized and have Fe–C bond distances ranging from 1.703 to 1.706 Å. These are significantly longer than those in the [OEPFe(CS)] complex and the $Fe–N_{por}$ bond lengths range from 2.112 to 2.155 Å.

Carbenes as Ligands. As mentioned above, $TPPFe^{II}$ complexes have been reported to be active catalysts in carbon transfer reactions, in which the active species are assumed to be iron porphy-rin carbene complexes.[593–596] Since carbene complexes are typically synthesized as models of cytochrome P450 enzymes, they are discussed in the corresponding section on P450 models, Section 8.2.

5 IRON(II) MACROCYCLE π-CATION RADICALS AND THEIR VALENCE TAUTOMERISM WITH IRON(III) MACROCYCLES

Although there has not yet been a report of the preparation and full characterization of a bona fide Fe^{II} porphyrin π-cation radical, the $[OETPPFe(4\text{-}CNPy)_2]ClO_4$ complex has

overall spin state $S = 3/2$, but with very large and negative phenyl-H shift differences, $\delta_m - \delta_p$ and $\delta_m - \delta_o$, may indicate the presence of negative spin density at the *meso*-carbons.**[195,943]** Careful analysis of the pyrrole-CH_2 shifts also shows that they are much larger**[943]** than expected for either of the proposed**[944]** electronic configurations of intermediate spin Fe^{III}, $S = 3/2$, but rather indicate that the $d_{x^2-y^2}$ orbital of iron is at least partially occupied.**[943]** Thus, the combination of negative phenyl-H shift differences and the larger-than-expected pyrrole-CH_2 shifts indicates at least partial electron transfer from the porphyrin to the metal, yielding an electron configuration of $(d_{xy})^2(d_{xz},d_{yz})^2(d_{z^2})^1(d_{x^2-y^2})^{(1-x)}$ for the iron, and $(OETPP)^{(2-x)-}$ for the porphyrinate ring.**[943]** Thus, this is at least one possible example of a Fe^{II} porphyrin π-cation radical.

In addition, there have been several reports of reduced porphyrin or oxophlorin π-cation radicals of Fe^{II}.**[199–202]** Since it has been suggested that Fe^{III} isobacteriochlorin π-cation radicals are viable species for at least two reaction states of the hemoprotein subunit of *E. coli* sulfite reductase**[945]** and assimilatory nitrite reductases from several organisms,**[38]** and at least one state of the heme d_1 (chlorin) center of the dissimilatory nitrite reductases from several microorganisms,**[38]** the investigation of the one-electron reduced states of these proposed intermediates has also been undertaken.

The one-electron electrochemical oxidation of $(MAC)Fe^{II}$ NO complexes, where MAC are the porphyrin, chlorin, and isobacteriochlorin macrocycles, has been reported.**[201]** In all three cases the oxidations are reversible: $E_{1/2} = 0.63$ (OEP), 0.48 (OEC), and 0.22 V (OEiBC) in butyronitrile.**[201]** Controlled potential electrolysis in vacuo of each of these complexes yielded species whose optical spectra correspond to those of $[(OEP^{2-})Fe^{III}(NO)]ClO_4$, but in the cases of the reduced macrocycles the spectra were indicative of the valence isomer, $[(OEC^{-}\bullet)\ Fe^{II}(NO)]ClO_4$, the π-cation radical of the OEC macrocycle, and $[(OEiBC^{-}\bullet)Fe^{II}(NO)]ClO_4$, the π-cation radical of the OEiBC macrocycle. The typical $[Fe^{II}NO]$ EPR spectrum of each complex disappeared upon oxidation as a result of the production of even-electron species in each case. The presence of the NO ligand in each case was confirmed by re-reduction to yield the original $[Fe^{II}NO]$ optical and EPR spectra. The IR spectra of the oxidized compounds also confirmed the presence of NO: $\nu_{NO} = 1830$ (OEP), 1705 (OEC), and 1680 (OEiBC) cm^{-1}.**[201]**

Chemical oxidation of iron(II) nitrosyl complexes of deuterium-substituted octaethylchlorin and octaethylisobacteriochlorin with silver hexafluoroantimonate ($AgSbF_6$) in dichloromethane has been reported.**[202]** Although no EPR spectra are observed, electron spin relaxation due to the unpaired electron on the NO moiety allows these radical species to have well-resolved hyperfine-shifted ^2H NMR spectra. The pattern of isotropic shifts observed in each case is characteristic of an $a_2(\pi)$ -type unpaired electron (the analog of the $1a_{1u}$ (π) orbital of the porphyrin ring, Figure 4), having large spin density at the α-C positions of the reduced pyrrole rings of the macrocycles.**[202]** From the temperature dependence of the NMR spectra it appears that the two unpaired electrons are weakly antiferromagnetically coupled, with $J \sim -46\,cm^{-1}$, and about 35% triplet content at 296 K. Addition of ligands (L) such as imidazole, pyridine, THF, and acetonitrile at low temperatures appears to change the electron configuration to $[Fe^{III}NO]$ in both cases, as evidenced by changes in the optical spectra, and upon warming to room temperature the optical spectra convert to those of $OECFe^{III}L_2^+$ and $OE\mathit{i}BCFe^{III}L_2^+$, respectively. Thus for the reduced hemes there appears to be a facile valence tautomerism (equation 15):**[202]**

$$\underset{\text{A}}{\overset{\text{NO}}{-\mathrm{Fe^{II}}-\!\overset{+}{\cdot}}} \longleftrightarrow \underset{\text{B}}{\overset{\text{NO}^+}{-\mathrm{Fe^{II}}-}} \longleftrightarrow \underset{\text{C}}{\overset{\text{NO}}{-\mathrm{Fe^{III}}-}} \qquad (15)$$

For five-coordinate complexes, A is the electron configuration, while for six-coordinate complexes the electron configuration could be represented by either B or C, but in the presence of Lewis bases, NO is labile, suggesting the configuration shown in C.**[202]** (Interestingly, the binding constants of NO to the Fe^{III} state of hemoglobins and myoglobins are of the order of 10^3–$10^5\ M^{-1}$ and the kinetics of NO dissociation are fast,**[946]** while the binding constants for NO to the Fe^{II} state of the same proteins are in the order of $10^{11}\ M^{-1}$ and the kinetics of NO dissociation are very slow.**[947]** This lability of NO from Fe^{III} heme proteins may be used as a means of delivery of this biological effector from the saliva of a blood-sucking insect from the Amazon basin (*Rhodnius prolixus*) to the blood stream of its victim.**[55–57]**)

Deprotonation of *meso*-hydroxyoctaethylporphyrinato-iron(III) $(OEPOH)Fe^{III}$, discussed in Section 6.1.5 below, and simultaneous coordination of two pyridine ligands in pyridine-d_5, produces a species whose optical and NMR spectra suggested that it should be characterized as an Fe^{II} oxophlorin π-cation radical.**[948]** This would be another example of valence tautomerism, that is of $(OEPO^-)Fe^{III}(Py)_2 \rightleftharpoons (OEPO^{+}\bullet)\ Fe^{II}(Py)_2$. The NMR spectra of the complex are characterized by large π delocalization to the *meso* positions and relatively small σ delocalization to all but one of the β-pyrrole positions, suggesting that the electron has been removed from the $b_2(\pi)$ orbital, the analog of the $3a_{2u}(\pi)$ orbital of the porphyrin ring (Figure 4). The curvature observed in the temperature dependence of the NMR spectra suggests that the $a_2(\pi)$ orbital (the analog of the $1a_{1u}(\pi)$ orbital of the porphyrin ring (Figure 4)) is nearly degenerate with the $b_2(\pi)$ orbital and that these two π orbitals are populated to different extents as the temperature is changed.**[948]** However, the EPR spectra of the bis-pyridine and – imidazole complexes showed that the unpaired electron was located on the iron, rather than on the macrocycle, and thus the complexes contain Fe^{III}–$OEPO^{2-}$ rather than Fe^{II}–$OEPO^{-}\bullet$; the g-values change from 2.64, 2.20, 1.64 (N-MeIm)**[199,948]** to 2.20, 2.20, 1.90 (4-AcPy)**[948]** in a manner consistent with a change in

electronic ground state of the low-spin Fe^{III} complexes from $(d_{xy})^2(d_{xz},d_{yz})^3$ to $(d_{xz},d_{yz})^4(d_{xy})^1$ as the basicity of the axial ligands is lowered.[948] However, when 2,6-xylylisocyanide ligands are bound to FeOEPO, a true free radical EPR signal is observed, indicating that with π-acceptor axial ligands the Fe^{II}–$OEPO^{-}\cdot$ electron configuration is stabilized.[199] It was also found that the bis-N-MeIm complex, although low-spin at 4.2 K, becomes high-spin ($S = 5/2$) or spin-admixed ($S = 3/2–5/2$) Fe^{III} at ambient temperatures, as shown by a study of the temperature dependence of the magnetic susceptibility and the Fe–N_{ax} bond lengths determined by X-ray crystallography.[199]

The reversible reaction of chloroiron(III) octaethylisobacteriochlorin (or the Br^-, NCS^-, or PhS^- analog) with π-acid ligands such as carbon monoxide, t-butyl isocyanide or PF_3 in toluene solution produces EPR spectra at 77 K that are indicative of a π-cation radical (equation 16):[200]

$$(\text{OE}i\text{BC}^{2-})\text{Fe}^{\text{III}}\text{X} + \text{L} \rightleftharpoons (\text{OE}i\text{BC}^{-}\cdot)\text{Fe}^{\text{II}}(\text{L})\text{X} \qquad (16)$$

In contrast to the iron(III) isobacteriochlorins, iron(III) porphyrins do not react with CO.[200]

6 IRON(III) PORPHYRINS AND THEIR REACTIONS

Since the porphyrin ring neutralizes only two of the positive charges of the metal, Fe^{III} porphyrins must have an associated counterion. This counterion may be directly bound to the metal, as in five-coordinate high-, intermediate-, and low-spin Fe^{III} porphyrins, or may exist as a separate species that forms an ion-pair with the iron porphyrin complex, as in all six-coordinate complexes of Fe^{III} porphyrins with neutral ligands. We will survey the structures, properties, and reactions of Fe^{III} porphyrins of each of the possible spin states.

6.1 High-spin ($S = 5/2$) Iron(III) Porphyrins

6.1.1 Five-coordinate, Monomeric High-spin Iron(III) Complexes

These complexes have the metal significantly (≈0.5 Å) out of the plane, as is evidenced by the 3D structures of five-coordinate porphyrin complexes determined by X-ray crystallography[182,183] and the existence of two o-H and m-H NMR resonances for TPP derivatives and two α-CH_2 resonances for OEP, OETPP and *meso*-alkyl porphyrin complexes.[174,175] In addition to halides as counterions,[174,182,183] a number of other monomeric, five-coordinate, high-spin Fe^{III} porphyrins have been reported, including those having $X^- = OH^-$,[949–951] OR^-,[215,952–956] RS^-,[956–959] OO^{2-},[960,961] OOR^-,[215] N_3^-,[962,963] NCS^-,[964,965] $C{\equiv}CR^-$,[966] RCO_2^-,[967] NO_3^-,[968] $OTeF_5^-$,[447] SO_4^{2-},[968,969] HSO_4^-,[969,970] RSO_3^-,[968,969] RSO_2^-,[971] WS_4^{2-},[972] 2-methylimidazole,[962] (triazolate)$^-$,[973] (tetrazolate)$^-$,[973] and the microperoxidases, MP8[432] and MP11,[974] at pH 7.0, where the imidazole ring of histidine serves as the ligand. Of these, the NO_3^- complex is known to have the anion binding in a bidentate fashion to Fe^{III} in the solid state,[968] and both it and the RSO_3^- complexes are believed to behave as bidentate anions in solution.[968] However, a recent structure of $TC_6TPPFcONO_2$ shows the nitrate ion to be monodentate, and NMR data are consistent with monodentate coordination of this anion in solution.[975] The electron configuration of high-spin Fe^{III} ($S = 5/2$) gives rise to a ^6A ground state, with relatively large splittings of the zero-field Kramers' doublets, ±1/2, ±3/2, ±5/2.[976] In addition to the halides,[976] zero-field splitting constants, D, have been estimated for some of these anions: $OTeF_5^-$ appears to be similar to Cl^-,[977] $N_3^- < Cl^- \sim N_4C(Me)^- < N_4C(Ph)^-$.[973] For the complexes [TPPFeX] having anions $X^- = NCS^-$, Cl^-, Br^-, and I^-, $D = 5.1$, 6.0, 12.5, and 13.5 cm^{-1}, respectively,[964,965] and for OH^- in TMPFeOH, $D = 8.9\ cm^{-1}$.[951]

At 300 K the ^1H NMR spectra of 5-coordinate high-spin Fe^{III} porphyrinates have β-pyrrole–H resonances (of TPP-type porphyrins) at 82 ppm for the chloride and hydroxide complexes (and for a series of 2-substituted TPPFeCl complexes, the 3-H ranges from 33.4 to 104 ppm, with the other six pyrrole-H resonances giving a spread from 89 to 71 ppm[978]) and +82–70 ppm or so for other anionic complexes, and the pyrrole-H of the very domed and ruffled tetramethylchiroporphyriniron(III) chloride resonate between 80 and 100 ppm,[979] while the pyrrole CH_2 or CH_3 ^1H resonances (of OEP-type or natural porphyrins) occur at about 40–50 ppm for α-CH_2 and +50–80 ppm for α-CH_3 at 298 K.[168,174,175] A unique feature of the ^1H NMR spectra of 5-coordinate high-spin Fe^{III} complexes of OEP-type or natural porphyrins is that the *meso*-H resonances occur at about −57 ppm at 294 K for the 5-coordinate chloride complex,[168,174,175] yet at +42 ppm at 294 K for the 6-coordinate high-spin bis-DMSO complex discussed in Section 6.1.2. The reason for the very negative chemical shifts of the *meso*-H resonances of 5-coordinate high-spin Fe^{III} porphyrinates was earlier explained as being indicative of the involvement of the $4e(\pi)$ orbitals (Figure 4) in Fe → porphyrin π spin delocalization,[168,174] but no adequate explanation was provided for the approximately 100 ppm shift of the *meso*-H resonances upon change of coordination number from 5 to 6.[175] Recently, however, the chemical shifts of the *meso*-H resonances of 5-coordinate high-spin Fe^{III} porphyrinates have been explained via DFT calculations, which show the importance of the d_{z^2} orbital of high-spin Fe^{III} in allowing spin delocalization by porphyrin → Fe π spin delocalization via the filled $3a_{2u}(\pi)$ orbital (Figure 4), which is made possible by the strongly out-of-plane position of the iron(III) when it is 5-coordinate.[220] For symmetry reasons, this mechanism of spin delocalization is not available to 6-coordinate high-spin

Fe^{III} porphyrinates,[220] and hence the *meso*-H resonances of these complexes are shifted into the positive chemical shift region. The positive shifts of the *meso*-H resonances of 6-coordinate high-spin Fe^{III} porphyrinates are thus undoubtedly characteristic of σ spin delocalization, largely from the $d_{x^2-y^2}$ unpaired electron, and there is probably thus little, if any, spin delocalization to the $4e(\pi)$ orbitals of the porphyrin ring in any high-spin Fe^{III} porphyrinates or reduced hemes.

Five-coordinate Fe^{III} complexes of tetra-(*meso*-heptafluoro-*n*-propyl)porphyrin have pyrrole-H peaks at 101.5 and 86.4 ppm as a result of S_4-distortion of the porphyrin ring, probably a ruffling distortion, since the structure of the bis-pyridine Fe^{II} complex is highly ruffled.[621] Five-coordinate Fe^{III} complexes of reduced porphyrins have also been reported: ^{1}H NMR spectra of high-spin Fe^{III} complexes of *trans*-octaethylchlorin (OEC) ($X^- = Cl^-$, $OTeF_5^-$, NCS^-) and tetraphenylchlorin (TPC) ($X^- = Cl^-$, $OTeF_5^-$) have been compared to those of the corresponding OEP and TPP complexes.[980] The pattern of spin delocalization to the *meso* positions is most consistent with that expected for the filled orbital, A_5, which is derived from the $a_{1u}(\pi)$ orbital of the porphyrin.[980] More recently, the resonances of OECFeCl and TPCFeCl have been assigned by saturation transfer from the low-spin complexes.[981,982] The protons on the *meso* positions on either side of the reduced pyrrole ring are those that exchange more rapidly with deuterium under acid conditions,[983] and these *meso* positions are thus most electron-rich. Five-coordinate HS Fe^{III} complexes of both *trans,trans,trans* (*ttt*) and *trans,cis,trans* (*tct*) octaethylisobacteriochlorin, OE*i*BC, have also been investigated by NMR spectroscopy[983] and by electrochemistry.[984]

Particularly notable among the five-coordinate, monomeric, high-spin Fe^{III} complexes is the hydroxo complex, because of the difficulty of preventing its well-known hydrolysis to form the μ-oxo dimer (equation 17), which was discussed earlier (Section 4.3, Scheme 2):

$$2[\mathrm{PFeOH}] \rightleftharpoons [\mathrm{PFeOFeP}] + \mathrm{H_2O} \qquad (17)$$

This problem was solved by using tetraphenylporphyrin ligands having *o,o′*-substituents on the phenyl rings, such as Me (TMP),[247,248] OMe ([2,4,6-$(OMe)_3]_4$TPP),[973] or halogens (F or Cl),[950] very bulky *m,m′*-substituents such as *t*-butyl,[949] or by use of superstructured porphyrins such as ‘basket-handle[985]’, ‘picket fence[986]’, or related water-soluble ‘picket fence’ derivatives[987] (see Section 4.3). $Fe^{III}TPPS_4$, the tetrasulfonate of TPP, was shown to aggregate on cationic reversed micelles as a function of pH, in part probably due to formation of μ-oxo dimers.[988] $Fe^{III}TPPS_4$ also has been found to bind to cyclodextrins, which reduces the rotational correlation time of the porphyrin and thereby increases the magnetic relaxation efficiency of the complex and also inhibits dimer formation, making it a better water relaxation agent for MRI purposes.[989]

The reaction of superoxide, $O_2^{-}\bullet$, with TPPFeCl in nonaqueous solvents generates $TPPFe^{II}$ and O_2 in strongly coordinating solvents (pyridine, DMSO),[671,672] and $TPPFe^{II}O_2$ in weakly coordinating solvents (DMF).[672] The formation of the dioxygen complex of an Fe^{II} porphyrin in this way is strong evidence for the valence tautomerism of this complex (equation 18):

$$[\mathrm{PFe^{II}O_2}] \rightleftharpoons [\mathrm{PFe^{III}O_2}^{-}\cdot] \qquad (18)$$

Reaction of superoxide with water-soluble Fe^{III} porphyrins results in dismutation of superoxide to O_2 and H_2O_2 (equation 19)[990] (*see* ***Oxygen: Inorganic Chemistry***):

$$\mathrm{HO_2}\bullet + \mathrm{O_2}^{-}\bullet + \mathrm{H_2O} \longrightarrow \mathrm{O_2} + \mathrm{H_2O_2} + \mathrm{OH^-} \qquad (19)$$

The peroxo complex $[TPPFeO_2]^-$ was prepared from $[TPPFe^{II}]$ and superoxide,[672,960] and is another example of the facile, reversible redox reaction that takes place between Fe^{II} and dioxygen and its redox-active reduced derivatives, superoxide and peroxide. The OEP and TPP complexes can also be prepared by treatment of PFeCl with 2 mols of superoxide in acetonitrile.[961] The NMR spectrum is clearly diagnostic of a high-spin Fe^{III} porphyrin.[960] However, the crystal structure of the Mn^{III} analog, $[TPPMn^{III}O_2^-]$, shows that the peroxide ion is bound in a symmetrical, η^2 fashion.[991] By analogy, the Fe^{III} complex is believed to have the same structure.[961] The Fe^{III} complex has been shown to be very nucleophilic in its reactions with olefins.[992,993] More recent work related to the peroxo intermediates of cytochromes P450,[32] peroxidases,[32] and heme oxygenase[994] indicates that if a strong-field nitrogen- or sulfur-donor ligand is bound to the iron, the structure is that of an unsymmetrical Fe-O-O unit[995,996] whose further reaction depends upon which oxygen atom is protonated, as discussed in Section 9 below. Based upon its reactivity, the hydroperoxo complex of heme oxygenase is believed to be electrophilic.[33]

Formation and spectroscopic properties of peroxoiron(III) chlorin complexes of tetraphenylchlorin (TPC), tetramesitylchlorin (TMC) and octaethylchlorin (OEC) have also been reported and shown to be high-spin Fe(III) complexes with EPR g-values of 8.5–8.8, 4.2 and 2.0.[997] These complexes have red-shifted Soret and α,β visible bands and an O–O stretching frequency of 806 cm^{-1}, the latter implying that the peroxo ligand is bound in an η^2 fashion.[997] The ^{1}H and ^{2}H NMR spectra of these complexes are also consistent with their formulation as HS Fe^{III} complexes, with pyrrole-H or – D shifts of 66, 61, and 57 ppm and pyrroline-H or – D shifts of 7 and -50 ppm at 293 K, as compared to those of the chloroiron(III) complex (87, 79, 69 ppm and -6 ppm, respectively);[997] for $[OECFeO_2]^-$ the *meso*-H or – D signals are found at −29 and −54 ppm and the pyrroline-H or – D are found at 29 and −38 ppm at 273 K in these 5-coordinate complexes.[997] Alkylperoxo complexes, $PFe^{III}OO$-*t*-Bu, formed from PFe^{II} and *t*-BuOOH, have been studied at very low temperatures

(−70 °C)[215,998] to prevent thermal decomposition to $PFe^{IV}O$ and t-BuO· (equations 20 and 21):

$$[TMPFe^{II}] + t\text{-Bu-OOH} \longrightarrow [TMPFe^{III}\text{-OO-}t\text{-Bu}] + \text{side products} \quad (20)$$

$$[TMPFe^{III}\text{-OO-}t\text{-Bu}] \longrightarrow [TMPFe^{IV}{=}O] + t\text{-BuO}\cdot \quad (21)$$

(followed by further reactions). Decomposition is catalyzed by bases, such as N-methylimidazole.[215] The chemical properties and reactions of the $(Fe^{IV} = O)^{2+}$ unit will be discussed in Section 8.

While both 5-coordinate alkylperoxide and methoxide complexes of $TPPFe^{III}$ are high-spin, the combination of a methoxide and an alkylperoxide ligand, or two of either one, creates low-spin Fe^{III} complexes,[999–1002] as is discussed further in Section 6.3.1.

Model hemes coordinated to phenoxides and aryl thiolates have been investigated as models of catalase and hemoglobins M (which have tyrosine substituted for either the proximal or distal histidine)[952,956] and cytochromes P450 (which have the thiolate of cysteine coordinated to Fe^{III}).[533,956]

6.1.2 Six-coordinate, Monomeric High-spin Iron(III) Porphyrin Complexes

In the presence of ligands of medium coordinative ability, with weakly binding counterions, Fe^{III} porphyrins form high-spin, six-coordinate complexes. Such is the case of [TPPFeI] in 1:3 mixed $CDCl_3/CD_2Cl_2$ solutions with added DMSO.[1003] Varying the concentrations of both [TPPFeI] and DMSO confirmed that the stoichiometry of the complex was 2 DMSO:1 Fe^{III}. The crystal structure of $[TPPFe(tetramethylene\ sulfoxide)_2]ClO_4$ shows that the porphyrin core is expanded, with $Fe–N_P = 2.045$ Å, and long $Fe–O_{sulfoxide}$ bonds (2.069, 2.087 Å).[1004] The phosphine oxide complex was also prepared and characterized.[1004] The crystal structure of $[TPPFe(phenylphosphinic\ methyl\ ester)_2]ClO_4$ has also been reported, and shows similar porphyrin core expansion ($Fe–N_P = 2.034$, 2.038 Å) and long $Fe–O_{PO}$ bonds (2.102 Å).[1005] Several naturally occurring iron(III) chlorins have been investigated by ^1H NMR spectroscopy, including the bis(DMSO) complex of the stable green sulfhemin prosthetic group extracted from sulfmyoglobin[64,65] and that of (pyropheophorbide a)iron(III).[1006,1007] The positive NMR ^1H chemical shifts of the *meso*-H suggest six-coordinate, bis(DMSO) complexes in each case. The shift patterns observed are consistent with those observed earlier for complexes of $OECFe^{III}$.[980] A similar positive *meso*-H chemical shift is also observed for the corresponding OEP complex.[175]

DMF also appears to coordinate to [TPPFeI] to form six-coordinate complexes,[1003,1008] and the structures and magnetic susceptibilities of two bis(ethanol) complexes of $TPPFe^{III}$ salts[1009] and one $OEPFe^{III}$ salt[1010] have been reported. The structure of $[TPPFe(H_2O)_2]ClO_4$ has also been reported;[1011] the $Fe–N_P$ bond distances are 2.041 Å and the Fe–O(aqua) bond distances are quite long, at 2.097 Å, with the metal in the plane of the porphyrin ring. A different type of six-coordinate high-spin Fe^{III} porphyrin complex is produced if [TPPFeF] is reacted with hydrated tetrabutylammonium fluoride ($Bu_4NF{\cdot}3H_2O$) in dichloromethane:[1012] The bis-fluoride anionic complex $[TPPFeF_2]^-$ is stable ($K_f = 4 \times 10^3\ M^{-1}$ at 25 °C). Lack of splitting of the ^1H NMR signals of o- and m-phenyl protons of $[TPPFeF_2]^-$ supports the assumption of diaxial fluoride coordination with the metal in the plane of the porphyrin.[217,1012] In aqueous solution at high pH, water-soluble iron(III) porphyrins such as tetrakis(o-methylpyridinium)porphyrin, $T(o\text{-MPy})PFe^{III}$, bind two hydroxide ions and give rise to a characteristic $\nu_{HO–Fe–OH}$ resonance Raman band at 447 cm^{-1}.[1013]

The high-spin dichloroiron(III) complex of 5,10,15,20-tetraphenyl-21-oxaporphyrin has been prepared and characterized.[536] Its ^1H NMR spectra show pyrrole-H shifts of 86.2, 67.9, and 66.3, highly characteristic of the pyrrole-H shifts of high-spin Fe^{III} porphyrins, and furan-H shift of 47.7 ppm. The Fe–Cl bonds (2.302 Å) are much longer than that of TPPFeCl,[1014] as might be expected for a dichloride complex of Fe^{III}.

Six-coordinate complexes of several Fe^{III} porphyrins, having one pyridine and one isothiocyanate ligand, have been reported.[1015,1016] Interestingly, the pyridine/N-bound thiocyanate anion combination appears to lie close to the $S = 1/2 \rightleftharpoons 5/2$ spin crossover point for the $TPPFe^{III}$ complex and, depending on the crystal lattice, exists as either a low-spin[1015] or a thermal equilibrium between a low-spin and a high-spin complex,[1016] while the $OEPFe^{III}$ complex is high-spin at all temperatures.[1015]

Finally, an unusual six-coordinate, mononuclear Fe^{III} complex is formed in the solid state by *meso*-$\alpha,\alpha,\alpha,\alpha$-tetrakis($o$-nicotinamidophenyl)porphyrinatoiron(III) chloride, which consists of polymeric chains in which the Fe atom of one molecule is coordinated to a pyridine nitrogen of the nicotinamide unit of a second molecule. The chloride ion occupies the sixth coordination site, inside the ‘pocket’ of the four nicotinamide groups. Magnetic susceptibility, EPR, and Mössbauer data on solid samples indicated a mixture of high-spin monomer (70%) and high-spin Heisenberg chain (30%), with $D = 10\ cm^{-1}$, $E = 2.25\ cm^{-1}$, and $J = -5\ cm^{-1}$ contributions from spin crossover.[986] The solution behavior of the complex resembles that of other monomeric five-coordinate Fe^{III} porphyrins.

6.1.3 Bridged Dimeric Complexes of High-spin Iron(III) Porphyrins and Chlorins

A number of the properties of μ-oxo dimers of Fe^{III} porphyrins, formed by hydrolysis of the hydroxo complex (equation 17)[1017] or by reaction of molecular oxygen with Fe^{II} porphyrins (see below), have been investigated, including ^1H and ^{13}C NMR, IR and Raman, and Mössbauer spectra, magnetic susceptibilities, and crystal and molecular structures.

The structure of [$(TPPFe)_2O$] was reported by Hoard.[1018] Structures of two crystalline forms of [$(OEPFe)_2O$] have been solved and in this case show nearly eclipsed porphyrin ring orientation.[1019] The eight Fe–N_P bond distances have average values of 2.077 and 2.080 Å, the average Fe–O bond lengths are 1.756 and 1.755 Å, and the average displacement of the iron(III) from the mean porphinato plane are 0.50 and 0.54 Å, respectively, in the triclinic and monoclinic forms.[1019] The linear PFe–O–FeP units are antiferromagnetically coupled dimers of high-spin Fe^{III}. Attempts to measure the coupling constant, $-2J$, from the temperature dependence of the magnetic susceptibility or NMR isotropic shifts have yielded a range of values.[168,183] Magnetic susceptibility results for [$(TPPFe)_2O$] in the solid state give $-2J = 271\,cm^{-1}$,[1020] while values of $258\,cm^{-1}$ and $312\,cm^{-1}$ have been obtained from ^1H[1021] and ^{13}C[179] NMR results, respectively. Calculation of $-2J$ from the temperature dependence of the NMR spectra of these complexes is complicated by the possibility of dipolar, ZFS, and contact contributions to the isotropic shifts.[168] In any case, the isotropic shifts of the protons of these PFe–O–FeP dimers are significantly different from those of the high-spin Fe^{III} monomers,[168] with all resonances occurring between 7 and 14 ppm at 320 K. Similar NMR spectra are observed for the reduced porphyrin analog [$(TPCFe)_2O$], with the addition of two signals from the two types of protons in the pyrroline ring.[1021] The tetraphenylchlorin complex has a similar derived value of $-2J$ ($265\,cm^{-1}$).

As mentioned in Section 1.5.2, the μ-oxo dimers PFeOFeP are readily cleaved by dry HCl in nonaqueous solvents (equation 22):

$$\text{PFe–O–FeP} + 2\text{HCl} \longrightarrow 2\text{PFeCl} + \text{H}_2\text{O} \quad (22)$$

In nonaqueous solvents, such treatment with dry hydrohalic acids is the only way to cleave the μ-oxo dimer nonoxidatively. However, the μ-oxo dimers of water-soluble porphyrins are readily cleaved by Lewis bases such as hydroxide, imidazole, histidine, and pyridine.[1022–1024] Both the equilibria[1022] and kinetics[1023] of such reactions have been reported. In addition, μ-oxo dimers of water-insoluble Fe^{III} porphyrins in dichloromethane can be oxidatively cleaved to yield $PFe^{III}F_2^-$ and (probably) an Fe^{IV} species.[1025] Studies of the picosecond decay of the excited state of $(TPPFe)_2O$ in benzene following a 532- or 355-nm 25-ps pulse suggest that the intermediate state is a photodissociated pair, $(TPP^-\cdot)Fe^{II} + TPPFe^{III} - (O^-\cdot)$, and a small amount of disproportionation reaction products, $TPPFe^{II} + TPPFe^{IV} = O$.[1026]

It has been shown that the μ-oxo dimer $(OEPFe)_2O$ can be monoprotonated to yield the μ-hydroxo species [$(OEPFe)_2OH$]ClO_4, via a mixed-phase reaction.[1027] The formulation of the complex has been confirmed by an X-ray diffraction study, which reveals a single bridging group and a single perchlorate counterion per dimer unit. The Fe–O(H)–Fe bond, with an angle of 146.2°, is considerably bent from the linear Fe–O–Fe geometry typically observed for μ-oxo dimers of Fe^{III} porphyrins,[1027] while the Mn(III) analog is nearly linear.[1028] The UV–vis spectrum of [$(OEPFe)_2OH$]ClO_4 shows a large blue shift (Soret band at 362 nm) compared to $(OEPFe)_2O$ (389 nm); the Mössbauer parameters are typical of high-spin Fe^{III}. Consistent with the magnetic susceptibility, which shows strong antiferromagnetic coupling, no EPR spectrum is observed.[1027]

Iron(III) porphycenes readily form μ-oxo dimers, and a complex having tetra-CF_3 etioporphycene was investigated by X-ray crystallography, electrochemistry and solution reactivity.[1029] The structure displays a severe saddled distortion of the porphycene framework as a result of the steric and electronic effects of the CF_3 substituents. The oxidation and reduction potentials for the μ-oxo dimer are significantly more positive compared to those observed for non-CF_3-containing iron porphycenes.[1030] Further study of the redox chemistry of μ-oxo dimers of iron(III) porphycenes shows that oxidation states of these dimers can range from -4 to $+4$.[1031,1032] The μ-oxo dimer is readily converted into the monomeric ferrous complex in pyridine-d_5 through autoreduction for one day.[1029]

A series of mixed metal μ-oxo dimers of the type PFe–O–CrP′ have been prepared from PFe^{II} and $P'Cr^{IV} = O$.[1033] Their ^1H NMR spectra are characterized by resonances due to the PFe^{III} in the positions found for the symmetrical PFe–O–FeP dimer, and a resonance at 38 ppm that is due to the pyrrole-H of the chromium porphyrin unit. The temperature dependence of the magnetic susceptibility of the mixed-metal dimer leads to its formulation as antiferromagnetically coupled Fe^{III} ($S = 5/2$) and Cr^{III} ($S = 3/2$), yielding $S' = 1$, with $-2J \sim 260{-}300\,cm^{-1}$ and D_{Fe} and g_{Fe} ranging from $3.8{-}4.9\,cm^{-1}$ and 1.98–2.05, respectively, assuming $D_{Cr} \sim -1\,cm^{-1}$.[1033] Similar mixed-metal dinuclear μ-oxo dimers can be synthesized in which the iron complex is the phthalocyanine, $PcFe^{III}$.[1033]

The μ-peroxo dimer intermediate, C, in the oxidation of four-coordinate Fe^{II} porphyrins to the PFe–O–FeP μ-oxo dimer via equations (23A–C) (cf. Scheme 2) of tetrakis(m-tolyl)porphinatoiron(III), has been detected by NMR spectroscopy at low temperatures.[1034] The μ-peroxo complex has a larger isotropic shift (16 vs. 13 ppm for the μ-oxo dimer at −50 °C) for the pyrrole-H at all temperatures, and has an antiferromagnetic coupling constant, $-2J$, that is about 30% smaller than that for the μ-oxo dimer, E; the magnetic moment decreases from $2.6\,\mu_B$ at −50 °C to about $2.2\,\mu_B$ at −80 °C, both consistent with weaker antiferromagnetic coupling in the μ-peroxo complex.[1034]

$$\underset{A}{PFe^{II}} + O_2 \longrightarrow \underset{B}{PFeO_2}$$

$$PFeO_2 + PFe^{II} \longrightarrow \underset{C}{PFe^{III}\text{–OO–}Fe^{III}P} \longrightarrow \underset{D}{2PFe^{IV}O} \quad (23)$$

$$C \downarrow$$

$$PFe^{IV}O + PFe^{II} \longrightarrow \underset{E}{PFe^{III}\text{–O–}Fe^{III}P}$$

Dimeric complexes of the oxoanions SO_4^{2-} and CrO_4^{2-}, $[(PFe)_2XO_4]$, have been shown to have both ^1H and ^{13}C NMR resonances that are sharp and at very similar isotropic shifts as those of monomeric, high-spin Fe^{III} complexes,[968,1035] suggesting that antiferromagnetic coupling is very weak or nonexistent in these dimeric complexes. Consistent with this, the Fe–Fe separation in $[TPPFe]_2SO_4$ is 6.049 Å.[1036] The geometry of the sulfato ion results in a canting of the porphinato cores at an angle of 24°.

There has been a report of bridged dinitrogen complexes of iron(III) and chromium(III) complexes, formed by reaction of the metallo(III)porphyrinate triflate with $[Re(N_2)(PMe_2Ph)_4Cl]$ to make the Fe-N-N-Re or Cr-N-N-Re bridged complexes.[1037] The Fe^{III} complex has a magnetic moment of about 4.4 μ_B at room temperature, consistent with a $S = 3/2,5/2$ admixed spin state for the iron(III), and a pyrrole-H shift of −3.23 ppm, consistent with the expected weak-field nature of the N_2 ligand.[1037] The structure shows a linear Fe–N–N–Re unit (Fe–N1–N2 = 170°, N1–N2–Re = 177°) with Fe–N bond length of 1.93 Å,[1037] similar to that of the $TPPFe^{III}$-azide complex (1.953 Å).

An intermolecular type of dimer formation has been observed for the unsymmetrically substituted 5-(2-hydroxyphenyl)-10,15,20-tritolylporphyrin complex of Fe^{III}, in which the *o*-OH functions of one molecule are deprotonated and bind as RO^- ligands to the Fe^{III} of a second molecule, which in turn binds its deprotonated *o*–OH function to the Fe^{III} of the first. Despite this intramolecular dimeric structure, the proton NMR spectra reveal pyrrole-H signals in the 80 ppm region at 25 °C, diagnostic of a high-spin Fe^{III} center, and the magnetic moments in solution ($6.0 \pm 0.2\,\mu_B$) and solid-state ($5.91 \pm 0.05\,\mu_B$) match the spin-only value for high-spin Fe^{III}, thus indicating that antiferromagnetic coupling is extremely weak.[953]

A novel intermolecular type of trimer formation occurs with 2-hydroxy-5,10,15,20-tetraphenylporphyrinatoiron(III). Deprotonation of the 2-hydroxy group creates an anionic aryloxo ligand for another Fe^{III} center, and the cyclic trimer thus forms.[277] The metal ions are weakly coupled high-spin Fe^{III} centers ($\mu_{eff} = 5.4 \pm 0.2\,\mu_B$), and the 3-H NMR resonances of this low-symmetry trimer are uniquely found at very negative chemical shifts (−89.8, −94.7 and −99.3 ppm at 291 K) and are very broad (670−690 Hz), while all other β-pyrrole protons resonate in the +82 to +62 ppm region[277] typical of high-spin Fe^{III} in monomeric complexes.[174,175] The structure of the trimeric complex has also been reported.[1038]

6.1.4 *Bridged or Through-space Magnetically Coupled Complexes of High-spin Iron(III) Porphyrins with Other Types of Metal Complexes; Possible Models for Cytochrome Oxidase, Assimilatory Sulfite Reductases, and Sulfite Oxidase*

Cytochrome *c* oxidase (CcO) in mitochondria and in bacterial cells catalyzes the four-electron reduction of O_2 to H_2O by cytochrome *c*, and is the terminal electron acceptor of the electron transport chains of animals and many other organisms (*see* ***Cytochrome Oxidase***). Structures of four different CcO enzymes have been reported.[2–6] Four electrons and four protons are needed to reduce O_2 to $2\,H_2O$, and there are four redox-active metal centers (Fe_a, Cu_A, Fe_{a3}, and Cu_B) that participate in this reduction, in which O_2 is believed to bind to the Fe_{a3} heme, which is in close proximity to Cu_B.[1039,1040] The two iron centers are heme *a* prosthetic groups (*see Prosthetic Group*), Figure 1(d), which will hereafter be referred to as heme *a* and heme a_3. The heme a_3−Cu_B (sometimes called Cu_{a3}) center of the resting oxidized form of the enzyme has been a subject of considerable interest for some years, since it is EPR silent; the same is true of *E. coli* cytochrome bo_3,[1041] which is also called a quinol oxidase because it uses a quinol in place of the Cu_A, the diamond-shaped dicopper center, $[Cu(SR)_2Cu]^{+/0}$, and the spectroscopic investigation of the quinol oxidases is simpler because of the absence of this cofactor. The most widely accepted explanation for this EPR silence is that there is strong ligand-mediated antiferromagnetic (*see Antiferromagnetism*) coupling ($J = 200\,cm^{-1}$ or larger in magnitude) between the Cu^{II} and Fe^{III} centers.[1042–1047] However, it has recently been shown for one form of *Thermus thermophilus* cytochrome c_1aa_3 (another member of the CcO family that has a heme c_1 in place of the Cu_A center) that the Mössbauer spectra could be fit to either strong or weak ($|J| \sim 1\,cm^{-1}$) coupling schemes,[1048–1050] and by a combination of parallel and perpendicular mode EPR and MCD spectroscopies that cytochrome bo_3 (yet another member of the CcO family), which has the same Fe–Cu interacting system in the same structural arrangement, has very weak antiferromagnetic coupling ($J = 1\,cm^{-1}$) for the fluoride,[1041] chloride, azide, and formate-bound complexes.[1051] In contrast to the apparent antiferromagnetic coupling (*see* ***Magnetism of Transition Metal Ions***) of the resting state of CcO,[1042] the cyanide-inactivated form has been interpreted in terms of ferromagnetic (*see Ferromagnetism*) coupling ($J > 100\,cm^{-1}$) between Fe^{III} and Cu^{II}, on the basis of both MCD[1052] and Mössbauer[1053] spectroscopic data. A σ/π orthogonality of the magnetic orbitals of Cu^{II} $((d_{x^2-y^2})^1)$ and low-spin Fe^{III} $((d_{xz},d_{yz})^3)$ with respect to a proposed Fe–CN–Cu bridge provides an appealing rationale for the ferromagnetic interaction.[1054,1055]

In addition to cytochrome *c* oxidase, a protein complex having a very similar fold and arrangement of metal centers is that of the heme-containing nitric oxide reductase (NOR).[1056–1059] This protein complex is found in a number of anaerobic bacteria and archaea, including *Paracoccus denitrificans*,[1060,1061] *Bacillus azotoformans*,[1062] and *Pyrobaculum aerophilum*,[1063,1064] and carries out the enzymatic reaction $2NO + 2e^- + 2H^+ = N_2O + H_2O$. (Although this is only a 2-electron reduction, NORs can also reduce O_2 to $2H_2O$, a 4-electron reduction,[1065–1067] and at least several CcOs can reduce 2NO to $N_2O + H_2O$,[1067–1069] a

2-electron reduction.) There are actually three types of NORs that belong to the heme-copper oxidase superfamily: cNOR (cytochrome *c* dependent), qNOR (quinol-dependent), and qCu_ANOR (qNOR that contains Cu_A at the electron entry site).[1063] Because copper is absent from the heme-containing subunit of these NORs, the binuclear metal center is believed to contain a non-heme iron instead of copper; all of the histidines present in CcO subunit I are conserved in these NORs.[1056,1070,1071] The hemes present are two hemes *b* in the protein called norB (the analog of subunit I of CcO), and, in cNORs, a membrane-bound *c* heme protein (called norC) that apparently takes the place of the Cu_A subunit. These proteins are believed to be extremely ancient, with the menaquinone-containing qNORs possibly being the oldest, the so-called Urenzymes, possibly the precursors to others, including the CcOs.[1063] There is another kind of heme-containing NOR, that being cytochrome $P450_{nor}$ from the denitrifying fungi, *Fusarium oxysporum*[1072] and *Cylindrocarpon tonkinese*.[1073] The structure of the enzyme from *F. oxysporum* has been determined, and shows it to be similar to other cytochromes P450 except for the openness of the heme distal pocket to solvent.[1074] The mechanism of NO reduction to N_2O by this enzyme is believed to involve the intermediate HNO, which can react with itself to produce N_2O and H_2O; a heme-bound HNO complex has been detected.[935,936]

Several types of models of the spin-coupled Fe–Cu centers of CcO were reported between 1980 and 1992,[1075–1083] with the work from 1993 to present having been reported by the groups of Holm,[1084–1091] Karlin[1092–1106] and Collman.[707,1107–1116] The first of the earlier models was the Cu^{II} complex of $\alpha, \alpha, \alpha, \alpha$ -tetrakis(*o*-nicotinamidophenyl)porphyrinatoiron(III) chloride, shown in Figure 8(a).[1075] The long Fe–Cl and Cu–Cl distances determined at room temperatures, as well as the temperature dependence of the magnetic susceptibility, and the Mössbauer spectra, suggest that there may be either a temperature-dependent spin equilibrium between $S = 5/2$ and 3/2, or a quantum-admixed $S = 5/2,3/2$ state, or that some molecules have the chloride ion outside the pocket and thus do not contain chloride-bridged metals.[1075] At low temperatures (4.2–30 K) this complex showed EPR signals from both Fe^{III} and Cu^{II}, indicating little or no antiferromagnetic coupling, because of the σ, π mismatch in orbital symmetry. The existence of these EPR signals at low temperatures, and their loss as a result of dipolar spin relaxation above 40 K, suggested that purely dipolar spin relaxation cannot account for the EPR silence of the oxidized resting state of CcO.[1075] The cyanide-bridged analog of this model compound showed weak ferromagnetic coupling ($J = +0.25\,\mathrm{cm^{-1}}$), and EPR spectra that are not superpositions of the low-spin Fe^{III} and Cu^{II} spectra as a result of a combination of isotropic, anisotropic and asymmetric exchange, dipole–dipole, and Zeeman terms.[986]

A second model of the resting oxidized form of CcO from the same research group, in which the geometry of the Cu^{II} complex was changed to allow orbital overlap between the $d_{x^2-y^2}$ orbital of Cu and the d_{z^2} orbital of high-spin Fe^{III}, has been reported. In this model, also shown in Figure 8(b), a strapped porphyrin having $S–N_{Py}–S$ ligands for the Cu, and a bridging hydroxide (*see Bridging Ligand*) ion between the two metals, produced an $S = 3/2$ spin state at the iron center with weak antiferromagnetic coupling between metal spins.[1076] Another strapped porphyrin, in this case supplying N–S–N ligands for the Cu, and having a μ-oxo bridge between high-spin Fe^{III} and Cu^{II}, showed weak HS Fe^{III} and Cu^{II} EPR signals, and the temperature dependence of the magnetic susceptibility was consistent with antiferromagnetic coupling ($J = -44\,\mathrm{cm^{-1}}$),[1077] Figure 8(c).

Cu^{II} chelates that incorporate potentially bridging ligands have been used to form μ-imidazolato,[1081,1082] μ-carboxylato,[1080] or μ-thiolato[1085,1117] bridged complexes with Fe^{III} porphyrins. In one case, two moles of $TPPFe^{III}$ bind to one $Cu(MNT)_2{}^{2-}$ to form a bridged trimeric complex in which one sulfur of each MNT^{2-} ligand bridges Cu^{II} and Fe^{III}.[1083] In another case, two moles of the Cu^{II} chelate, CuIM, or its Ni^{II} analog, NiIM, bind to TPPFeCl,[1079] OEPFeCl,[1080] or $TPPFeB_{11}CH_{12}$[1081,1082] to form the μ-imidazolato-bridged complex shown in Figure 8(d). The binding constants, β_2, for addition of CuIM to TPPFeCl and OEPFeCl in DMSO are more than a factor of 10^3 larger that those of N-MeIm for the same porphyrins in the same solvent.[1079] Although the enthalpies of formation of the bis(imidazole) complexes are similar, the entropies are much less negative for formation of the CuIM complex, possibly due to intermolecular dimerization of this complex in solution.[1079] The $TPPFe(CuIM)_2{}^+$ has been characterized by X-ray crystallography, and it and its Fe^{II} and Fe^{III} $(NiIM)_2$ analogs have been characterized by detailed magnetic susceptibility and Mössbauer spectroscopic studies.[1081,1082] The effective magnetic moment of the $PFe^{II}(CuIM)_2$ system at temperatures above 20 K is 2.60 μ_B, corresponding to two Cu ions with $S = 1/2$ and $g_{Cu} = 2.12$, while the magnetic moment below 20 K decreases significantly and can be fitted with pairwise antiferromagnetic coupling with $J_{CuCu} = -1.52\,\mathrm{cm^{-1}}$. All parameters for the $Fe^{III}(NiIM)_2$ system are consistent with the $S = 1/2$ state of this system, while the effective magnetic moment of 3.4 μ_B for the $Fe^{III}(CuIM)_2$ system at 300 K corresponds to a susceptibility that is the sum of those of the two analogs. However, as the temperature is decreased, the effective moment rises to a maximum at 8 K, indicating ferromagnetic Fe–Cu coupling ($J = 22.2\,\mathrm{cm^{-1}}$) and an antiferromagnetic, chainlike through-space coupling of Cu^{II} on adjacent units ($J_{CuCu} = -1.87\,\mathrm{cm^{-1}}$). This can be understood in terms of a σ/π orthogonality of the magnetic orbitals of Cu^{II} and low-spin Fe^{III}.[1081,1082]

Three 1:1 Fe:Cu model compounds have been reported, each of which contains a dinuclear anion in which an iron(III) porphyrin and a copper(II) maleonitrile dithiolate are bridged by one of the thiolate anions. The other ligand to Fe^{III} in each case is THF. The cations of the three compounds are either $[TPPFe(THF)_2]^+$, $[TPPGa(THF)_2]^+$, or $[TPPAl(THF)(H_2O)]^+$[1117] (Figure 8(e)). The structural results and the Mössbauer parameters suggest that the Fe^{III} center in

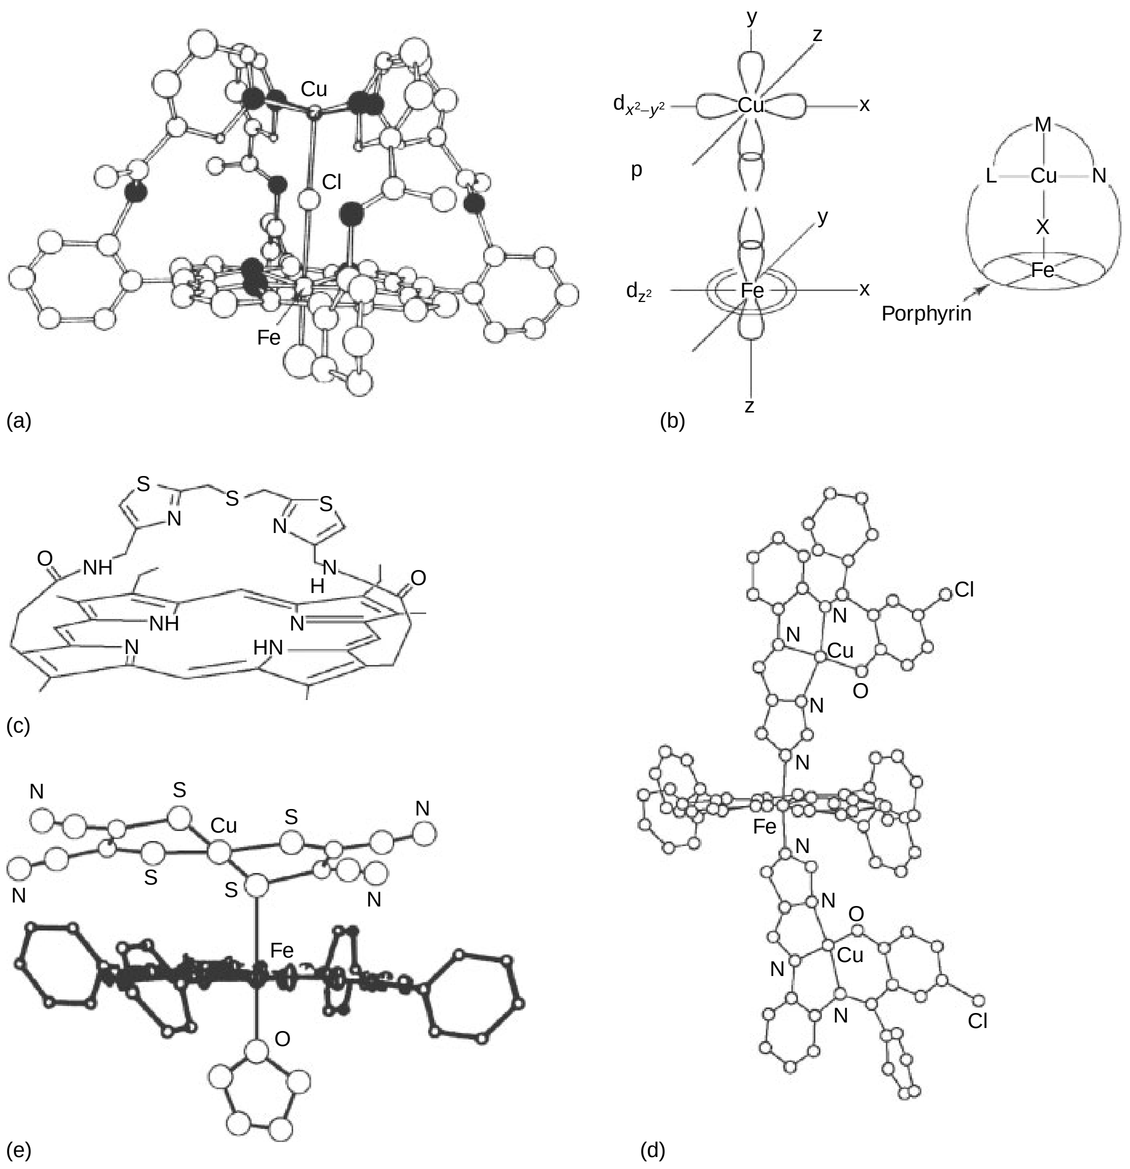

Figure 8 Cytochrome *c* oxidase (CcO) models. (a) The complex formed from iron $\alpha, \alpha, \alpha, \alpha$-tetrakis(*o*-nicotinamidophenyl)porphyrin and Cu^{II}, bridged by a chloride ion;[1075] (b) (left) schematic representation of the orientation of metal atomic orbitals predicted for significant exchange interaction between a single unpaired electron in the d_{z^2} orbital of a high-spin Fe^{III} ion in a porphyrin with an electron in the singly occupied $d_{x^2-y^2}$ orbital of a Cu^{II} ion in a square planar ligand field, via the p orbitals of a single bridging ligand X, and (right) a general ligand system that could maximize such orbital overlap, which was tested by creation of a 'strapped' porphyrin designed to complex a Cu^{II} in the S–N–S ligand strap created by two aliphatic thioethers (L, N) and a pyridine (M), bridged to an Fe^{III} porphyrin through bridging ligand X;[1076] (c) a 'strapped porphyrin designed to complex a Cu^{II} in a similar geometry as that of (b), using the N–S–N ligand strap shown;[1077] (d) a bis(CuIM) complex of $TPPFe^{III}$;[1082] (e) the anionic 1:1 complex of $Cu^{II}(MNT)_2$ with $TPPFe^{III}$;[1117] (f) the cyanide-bridged Cu(Me_6tren) and Cu(Me_5dien) complexes of OEPFe(Py);[1086] (g) the (tris-imidazole)-Cu^{II} model of Collman,[1114] and (h) two views of the oxo-bridged complex of (F_8-$TPPFe^{III}$ with Cu^{II}(TMPA)[1093]

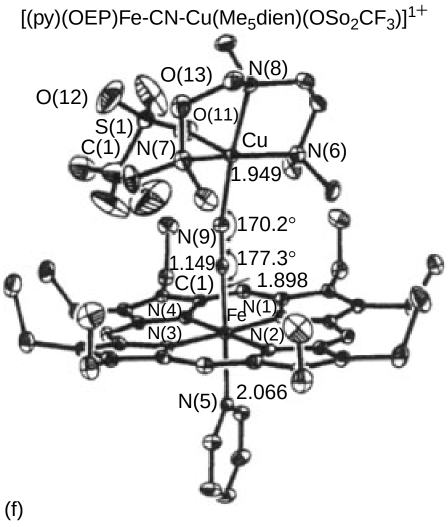
each of the dinuclear anions is intermediate spin ($S = 3/2$). The $Fe^{III}-Cu^{II}$ dimers give rise to no EPR signal. The metal ions are weakly antiferromagnetically coupled in each of the anions; the exchange coupling constants calculated from the magnetic susceptibility data for the compounds having $TPPGa^{III}$ or $TPPAl^{III}$ cations are $J = -17.94$ and $-15.18\,cm^{-1}$, respectively. The absence of EPR signals for the Ga^{III} and Al^{III} compounds is consistent with calculations showing that the values of J and D for these complexes are sufficiently large and that the energies required for allowed transitions are greater than the X-band EPR quantum at the magnetic fields used. The investigators concluded that 'given the existence of a series of 'EPR silent' Fe^{III}/Cu^{II} systems that are not strongly antiferromagnetically coupled, it



(f)

(h)

Figure 8 cont'd

seems necessary to carefully reexamine the basis for the EPR silence of the active site of the resting form of cytochrome *c* oxidase'.[1117]

Holm's group has prepared monomeric 1:1 model complexes consisting of $OEPFe^{III}$ and $Me_6trenCu^{II}$, where tren = triethylenetetramine, or $Me_5dienCu^{II}$, where dien = diethylenetriamine, Figure 8(f), with a weak-field anion present in each case.[1084,1085] Structures of cyanide-bridged complexes have also been reported.[1087] Further characterization of these complexes by multiple-edge XAS,[1088,1091] vibrational spectroscopies,[1090] Mössbauer spectroscopy[1089] and magnetization studies[1089] has been reported. The structures of all fully oxidized cyanide-bridged complexes show linear Fe^{III}-CN fragments (bond angle 176–180°), and any deviations therefrom occur in the Cu^{II}-CN fragment (nearly linear for trigonal bipyramidal-axial and distorted square pyramidal-equatorial complexes (170–174°), and bent in other square pyramidal-equatorial (163°) and square pyramidal-axial (147–159°) and doubly bridged tetragonal octahedral (140°) complexes).[1087] In the bridges of the fully oxidized complexes, decreasing Cu–N–C bond angles correlate with increasing Cu–NC bond distances. Increasing υ_{CN} values correlate with decreasing Cu–N–C angles and increasing Cu–N bond distances, and the values encompass those for cyanide-inhibited oxidized CcO enzymes (2152–2146 cm^{-1}).[1087] The infrared data, together with magnetic and Mössbauer spectroscopic results, which show coupled Fe^{III} and Cu^{II} spins, lead to the conclusion that these enzymes possess a tight [Fe^{III}–CN–Cu^{II}] bridge, rather than a binuclear site in which cyanide is bridged exclusively to one subsite, or interacts weakly with another subsite or is hydrogen-bonded at the uncoordinated end. The existence of the [Fe^{III}–NC–Cu^{I}] bridge in the one-electron-reduced complex, [OEPFe–NC–Cu(Me_5dien)]ClO_4, raises the question of whether a similar atom sequence may occur in biological bridges of the same oxidation state.[1087] The cyanide moiety of this complexes contains two bent M-cyanide bonds, with Fe–N–C = 165.3° and Cu–C–N = 168.9°; this complex has no sixth ligand to the iron.

Multiple-edge XAS studies of the μ-oxo, μ-hydroxo and η^2-cyano complexes that have been characterized crystallographically have provided important benchmarks that can be used to analyze the data from various forms of CcO enzymes,[1088,1091] because the structures of CcO that have been reported[2–6] do not exhibit the discrete bridges anticipated on the basis of exchange coupling between Fe^{III} and Cu^{II} in the fully oxidized enzymes, possibly because one or both metal centers become reduced over the course of X-ray crystallographic data collection or perhaps the microscopic pH around the binuclear center was not consistent with formation of the bridge. For the model complexes it is found that there is a dramatic increase in the amplitude of the Fe–X–Cu long-range multiple scattering pathway as the bridge unit approaches linearity.[1088,1091] The oxo and hydroxo ligated bridges can be differentiated by features in the Fe absorption preedge. Significantly, no EXAFS spectrum of a heme-copper oxidase yet displays the intervening atom effect consistent with a linear Fe–O–Cu bridge.[1088] For the cyanide-bridged model complexes, a strong long range Fe· · ·Cu interaction (4.94 Å) is observed from both the Fe and Cu K-edge data of the linearly bridged complex studied, and this strong interaction is not observed in the K-edge data for either metal for the complex in which the angle deviates significantly from linearity.[1091] These data will be useful for examining cyanide-inhibited CcO.

Resonance Raman ($\lambda_{excit} = 647$ nm) and mid-infrared spectra of the cyanide-bridged model compounds display three isotope-dependent vibrational modes. Two vibrations (2182 and 535 cm^{-1}) show monotonic decreases with increasing mass of the cyanide ligand and could thus be assigned to the C-N stretch and Fe-CN-Cu stretch, respectively.[1089] The C-N stretch was also observed by resonance Raman for the first time. The third vibration, detected with resonance Raman, showed a zigzag-type behavior (495, 487, 493, 485 cm^{-1}) with the ^{12}C–^{14}N, ^{13}C–^{14}N, ^{12}C–^{15}N, ^{13}C–^{15}N isotopomers that is characteristic of a bending vibration. The measurements strengthen the proposal that cyanide bridges the two metal atoms in the cyanide-ligated, oxidized binuclear center of CcO. A quantitative consideration of the vibrational characteristics of cyanide bound to the resting enzyme, in light of the model compound results,[1089] strongly suggests that the binuclear center of the enzyme is flexible and can undergo structural rearrangement to accommodate exogenous ligands.

Mössbauer and magnetization studies of oxo-, hydroxo- and formate-bridged complexes of $[OEPFe–X–Cu(Me_5dien)(OClO_3)]^+$ were interpeted in terms of strong antiferromagnetic coupling between a high-spin Fe^{III} ($S = 5/2$) and Cu^{II} ($S = 1/2$) resulting in an $S = 2$ ground state. The exchange coupling of the hydroxo-bridged complex is substantial ($J = 170\,cm^{-1}$), but is smaller than that of the oxo-bridged complex ($J \geq 200\,cm^{-1}$). The formate-bridged complex maintains an *anti–anti* carboxylate bridged conformation and has $J = +18\,cm^{-1}$.[1090] In light of the recent findings that the antiferromagnetic coupling of the Fe^{III} and Cu^{II} of fully oxidized, resting state CcO is weak,[1048,1051] carboxylate bridging of the model complex metal centers should be considered more carefully.

Karlin's group's work has been reviewed recently;[1106] they have prepared a model complex consisting of *meso*-tetrakis(2,6-difluorophenyl)porphyrinatoiron(III/II) ($F_8TPPFe^{III/II}$) and tris-2-pyridylmethylaminecopper(II/I) ($(TMPA)Cu^{II/I}$).[1092,1093,1105] The structure of the μ-oxo-bridged complex in which both metals are in their oxidized states has been reported,[1093] and is shown in Figure 8(h); the spin state of this complex is $S = 2$. The μ-hydroxo complex has also been characterized structurally.[1093–1095] The μ-peroxo complex has also been prepared by reaction of the Fe^{II} and Cu^{I} precursors with O_2 at low temperatures, and characterized by UV-visible, resonance Raman, Mössbauer and ^1H NMR spectroscopies.[1103] The Mössbauer data indicate that the Fe^{III} center is high-spin ($\delta = 0.57$ mm/s, $\Delta E_Q = 1.14\,mm\,s^{-1}$) and bound to an electron-rich ligand such as a peroxide; the magnetic field dependence is consistent with the complex being an integer spin system. Stopped-flow UV-visible spectroscopy at -94 to $-75\,°C$ revealed the presence of a heme-superoxo intermediate, formed within the mixing time, prior to formation of the heme-peroxo-Cu complex. The overall kinetics are complicated by several side reactions.[1103]

A covalently linked version of this complex, linked via an ether bond from one *ortho*-phenyl position of the porphyrin to an *ortho*- or *meta*-pyridyl group of the TMPA has also been characterized structurally and by ^1H NMR and resonance Raman spectroscopies and EXAFS.[1096] The *ortho*-pyridyl linkage yields a nearly linear Fe-O-Fe bridge (171°),[1096,1098] while the *meta*-pyridyl linkage yields a very bent bridge (141°).[1096] Protonation of the two complexes led to the formation of the hydroxo-bridged complex for the *ortho*-pyridyl-linked complex, but a broken bridge for the *meta*-pyridyl-linked complex.[1096] ^1H NMR spectra of the Fe^{II}/Cu^{I} forms of the *ortho*-pyridyl complex before addition of O_2 show the Fe^{II} center of the complexes to be high-spin in THF-d_8, intermediate-spin in CD_2Cl_2, and low-spin in toluene-d_8.[1098] An additional series of complexes having amide-linked TMPA groups with variable-length links and an amide-linked pyridine ligand for the iron have also been prepared and characterized, and their reactivity with dioxygen investigated in solution.[1100]

Stopped-flow kinetics studies of the O_2 reaction with a 1:1 mixture of the Fe^{II} and Cu^{I} starting materials of another system, $[F_8TPPFe^{II}]$ and $[MePY2Cu^{I}]$ (MePY2 = N,N-bis[2-(2-pyridyl)ethyl]methylamine), show the formation of at least two intermediates (i.e. a superoxo species, $[F_8TPPFe\text{-}O_2]$ first, and then a presumed peroxo-bridged $Fe\text{-}O_2\text{-}Cu$ species) prior to the formation of the final μ-oxo complex $[F_8TPPFe^{III}\text{-O-}Cu^{II}(MePY2)]^+$.[1099] The ^1H NMR spectrum of the latter complex in CD_2Cl_2 exhibits a pyrrole-H resonance at 67.7 ppm, while downfield (23.4 and 18.9 ppm) and dramatically upfield-shifted resonances (-87.7, -155.4 and -189.4 ppm) have been assigned to the pyridyl protons. Protonation of the μ-oxo complex with CF_3SO_3H shifts the

pyrrole-H resonance to 70.3 ppm. The protonation is slow on the NMR timescale.[1099] The ^{1}H NMR spectral properties are consistent with antiferromagnetically coupled high-spin Fe^{III} and Cu^{II} ions ($S = 2$) for the oxo-bridged complex ($\mu_{eff} = 5.05\,\mu_B$). The coupling is weaker for the hydroxo-bridged complex ($\mu_{eff} = 5.60\,\mu_B$).[1099]

The structures of both mono- and bis-cyanide-bridged complexes, having one or two $TMPACu^{II}$ units per F_8TPPFe^{III}, have also been reported.[1097] The 1:1 complex has a low-spin Fe^{III} center bridged to Cu^{II}. The Fe^{III}–CN vector is nearly linear (174.5°) while the 5-coordinate Cu^{II} center has a Cu–N–C angle of 163.8°. The 2:1 complex has a low-spin Fe^{III} center axially coordinated to two cyanide ligands capped on either side by trigonally coordinated [Cu(TMPA)] moieties. The Cu-N-C angle of one of these is 168° while that of the other is nearly linear (175°). The solution magnetic moments ($\mu_{eff} = 2.7\,\mu_B$ for the 1:1 complex and $\mu_{eff} = 3.4\,\mu_B$ for the 2:1 complex) suggest ferromagnetic coupling between the paramagnetic metal ions. This coupling gives rise to an enhancement of the electron spin relaxation rate for Cu^{II} in both complexes, which allows for the observation of the sharp and downfield-shifted TMPA ligand proton signals.[1097]

Both oxo- and hydroxo-bridged complexes containing two $TMPACu^{II}$ covalently linked to the porphyrinate phenyls[1100] or a tridentate derivative containing two 2-ethylpyridine links have been prepared[1099] and characterized by NMR spectroscopy.[1099] Peroxo-bridged complexes of $TMPACu^{II}$ and porphyrin-tethered variants have also been reported.[1101–1103,1105] Investigation of the rates of O_2 binding to $TMPACu^{I}$ has shown that these rates are of the order $k_{O_2} = 1.3 \times 10^9\ M^{-1}s^{-1}$, faster than to 5-coordinate hemes (10^5–$10^8\ M^{-1}s^{-1}$).[1104]

Collman's group has prepared several cytochrome oxidase models since 1994,[1107–1116] the latest of which have three covalently attached imidazoles for binding the $Cu^{II/I}$ on the α face and one on the β face to bind the Fe^{III}, as shown in Figure 8(g).[1114] This complex, as well as the Zn^{II} porphyrin analog, have been characterized by IR, NMR and EPR spectroscopy.[1114] Collman and coworkers have also done extensive studies of the electrocatalysis of O_2 reduction by simple iron porphyrins and iron porphyrin/Cu_B models;[1108,1112] this important work is reviewed in reference.[707] The diamagnetism of many oxygenated heme/Cu complexes, attributed to formation of Cu^{II} antiferromagnetically coupled to the Fe^{III} center via a bridging peroxide unit, does not simulate the O_2-bound binuclear site of CcO (i.e. 2-electron-reduced CcO), which is known to consist of a $Fe^{III}_{a3}O_2{}^{-\bullet}/Cu^{I}_{B}$ complex.[1118] Recently, Collman, Solomon and coworkers have shown that the Co^{II} porphyrin complex with the tris-imidazole-bound copper attached to three pickets above the porphyrin (Figure 8(h)) binds O_2 to form a Co–O_2 complex whose EPR spectra show that the complex can be formulated as Co^{III}–$O_2{}^{-\bullet}$, and that the rotation of the $O_2{}^{-\bullet}$ is hindered when Cu_I or Zn^{II} are bound to the three imidazole pickets,[1115] due to hydrogen-bonding from the picket amide N–H to the superoxide, in direct analogy to earlier studies of the O_2 complex of a mono-*ortho*-acetamido derivative of CoTPP.[285] The Fe^{II} porphyrin analog is paramagnetic in the absence of O_2 but diamagnetic in its presence, with non-shifted ^{1}H NMR spectra indicative of a diamagnetic complex.[1116] The O_2 complexes of both metal porphyrins have resonance Raman spectra that are indicative of non-bridged M^{III}–$O_2{}^{-\bullet}/Cu^{I}$ centers that are direct spectroscopic models of the dioxygen-bound binuclear metal center of CcO.[1115,1116]

The mechanism proposed for the 4-electron reduction of dioxygen to water by cytochrome *c* oxidase may be similar to that proposed for the monoxygenase enzymes, the cytochromes P450, as well as the peroxidases and catalase, all of which are discussed in Section 9 below. DFT calculations of the mechanism of the O–O bond cleavage step, specifically addressing CcO, have been reported[1119] and an excellent overview provided.[1120]

Attempted synthesis of another type of bridged mixed metal system, which involves an iron–sulfur cluster, either $Fe_2S_2(SPh)_4{}^{2-}$ or $Fe_4S_4(SPh)_4{}^{2-}$, bound to a Fe^{III} porphyrin, has been reported.[1121] Such bridged complexes, if they could be formed, would be models of the active site of assimilatory sulfite reductases, which have a siroheme and an Fe_4S_4 cluster that are chemically linked.[41] However, at present, preparation of such bridged heme–Fe_nS_n clusters has not yet been achieved: depending on solvent, the reaction of OEPFeX ($X^- = ClO_4{}^-$ or $CF_3SO_3{}^-$) with either $[Et_4N]_2[Fe_4S_4(SPh)_4]$ (acetonitrile) or $[PPh_4][Fe_2S_2(SPh)_4]$ (acetonitrile or DMF) resulted in ligand substitution, yielding OEPFe(SPh), while reaction of the same Fe_4S_4 complex in DMF or DMSO resulted in a redox reaction, yielding $OEPFe^{II}$.[1121] Thus a successful synthetic approach to model the active site of assimilatory sulfite reductases must eliminate the problems that (1) the affinity of simple Fe^{III} porphyrins for simple thiolates is significantly greater than is that of the iron–sulfur cluster, and (2) that weak or labile Fe^{III} heme axial ligands must be avoided. Presence of an inert axial ligand capable of stabilizing the Fe^{III} oxidation state must be sought.[1121]

Finally, two potential models for the Mo and Fe sites of sulfite oxidase have been prepared in which a hydrotris(3,5-dimethylpyrazolyl)borate complex of oxomolybdenum(V) is covalently attached to one of the phenyl rings of a tetraphenylporphinatoiron(III) derivative in which three phenyl rings carry *p*-Me groups and the other is either a 2,3- or 3,4-catecholate.[281,1122] Although the metals are not directly bridged in these complexes, they are held at fixed Mo···Fe distances. EPR spectroscopy at 4 K shows distance-dependent static dipolar coupling between the Mo^{V} and Fe^{III} centers. At 77 K the dipolar coupling is modulated by rapid relaxation of the Fe^{III} center.[1122] Coordination of two *N*-methylimidazoles to the Fe^{III} centers produce $(S = 1/2)_{Fe}$–$(S = 1/2)_{Mo}$ coupled systems that are not only

sensitive to distance, but also to the orientation of the *g*-tensor of the low-spin Fe^{III}.[281] The ^1H NMR spectra of the bis-N-methylimidazole complexes of the 2,3- and 3,4-catecholatoMo(V) derivatives have been investigated in detail and shown to have a preferred orientation of at least one N-methylimidazole for the 2,3-catecholatoMo(V) derivative,[1123] but two freely rotating N-methylimidazole ligands for the 3,4-catecholatoMo(V) derivative.[1124] The pyrrole-H resonances of the former were assigned on the basis of Homonuclear *J*-Correlated SpectroscopY (COSY) and T_1 relaxation times.[1123]

6.1.5 *Coupled Oxidation of Hemes by H_2O_2 or Its Equivalent, and Relationship to the Reactions of Heme Oxygenase*

In reactions related to those discussed in Sections 8 and 9 that involve peroxidases and cytochromes P450 and their models, it has also been shown that hydroperoxides will oxidize iron(III) porphyrins at one *meso* position to create isoporphyrins.[1125] If the hydroperoxide is H_2O_2, and if the *meso* substituent is H, the first product is a *meso*-hydroxyporphyrin,[1126] also called an oxyporphyrin or oxophlorin, because of the possible tautomeric forms of the free base.[539] Iron oxophlorins are believed to be intermediates in the conversion of heme to biliverdin in both the in vivo process that is catalyzed by heme oxygenase[34] and the in vitro model system that is known as 'coupled oxidation'.[539,1127] Rivera and coworkers have investigated the mechanism and product formation for a heme protein via the coupled oxidation reaction with H_2O_2 as compared to heme oxygenation with O_2 and a reducing agent, and shown that the product distribution is different in the two reactions.[1128] (Octaethyl- and etiooxophlorins can also be synthesized[1129,1130] and iron can be inserted into the free ligand.[539]) The reducing agent can be ascorbic acid or hydrazine, and if hydrazine, it has been shown that in pyridine solution in the presence of O_2, (OEPO)Fe(Py)$_2$, (OEPO)Fe(Py)(N_2H_4) and (OEPO)Fe(N_2H_4)$_2$ are present transiently, although the two hydrazine-containing complexes are eventually converted to (OEPO)Fe(Py)$_2$ before (OEOP)Fe^{II}(Py)$_2$ and (OEB)Fe^{III}(Py)$_2$ are formed.[1131] Treatment of iron(II) porphyrins, (OEP)Fe^{II}(Py)$_2$, (EtioP)Fe^{II}(Py)$_2$, (DeuteroP)Fe^{II}(Py)$_2$, (MesoP)Fe^{II}(Py)$_2$ and (ProtoP)Fe^{II}(Py)$_2$ with H_2O_2 in the strict absence of dioxygen also gave the corresponding oxophlorin complexes,[1132] as mentioned in Section 4.2.2. For the unsymmetrically substituted porphyrins, the four isomeric oxophlorin products are formed in a nonrandom fashion. Solvent effects can produce a significant alteration in the regiospecificity of heme oxygenation.[1132] In the absence of pyridine, the structure of the first stable product, (OEOPFe)$_2$, is dimeric, with the deprotonated hydroxo group of one molecule acting as the anion and fifth ligand to Fe^{III} for the other molecule, and vice versa.[539] Magnetic susceptibility measurements indicate that the *meso*-oxo-bridged dimer is antiferromagnetically coupled, but that the coupling is weak ($J = -12\,cm^{-1}$),[1126] compared to porphyrin μ-oxo dimers. The NMR spectrum confirms this finding, with the methylene protons of (OEPOFe)$_2$ having resonances in the 18–40 ppm region, compared to 24–42 ppm for (OEPOH)FeBr.[539] (OEPO)Fe^{III}(Py)$_2$, is formed upon addition of pyridine, which both deprotonates the *meso*-OH group and also coordinates to the metal.[1133] (OEPOFe)$_2$ can be oxidized chemically by silver perchlorate or silver tetrafluoroborate.[1134] NMR spectra indicate that the oxidation is ligand-based.[1134] (OEPO)Fe(Py)$_2$ can also be reacted with NO to produce a *meso*-linked dimer that has one NO and one Py ligand bound to each heme.[1135] Treatment of (OEPO)Fe(Py)$_2$ with HCl in air produces (OEOP)FeCl$_2$.[540]

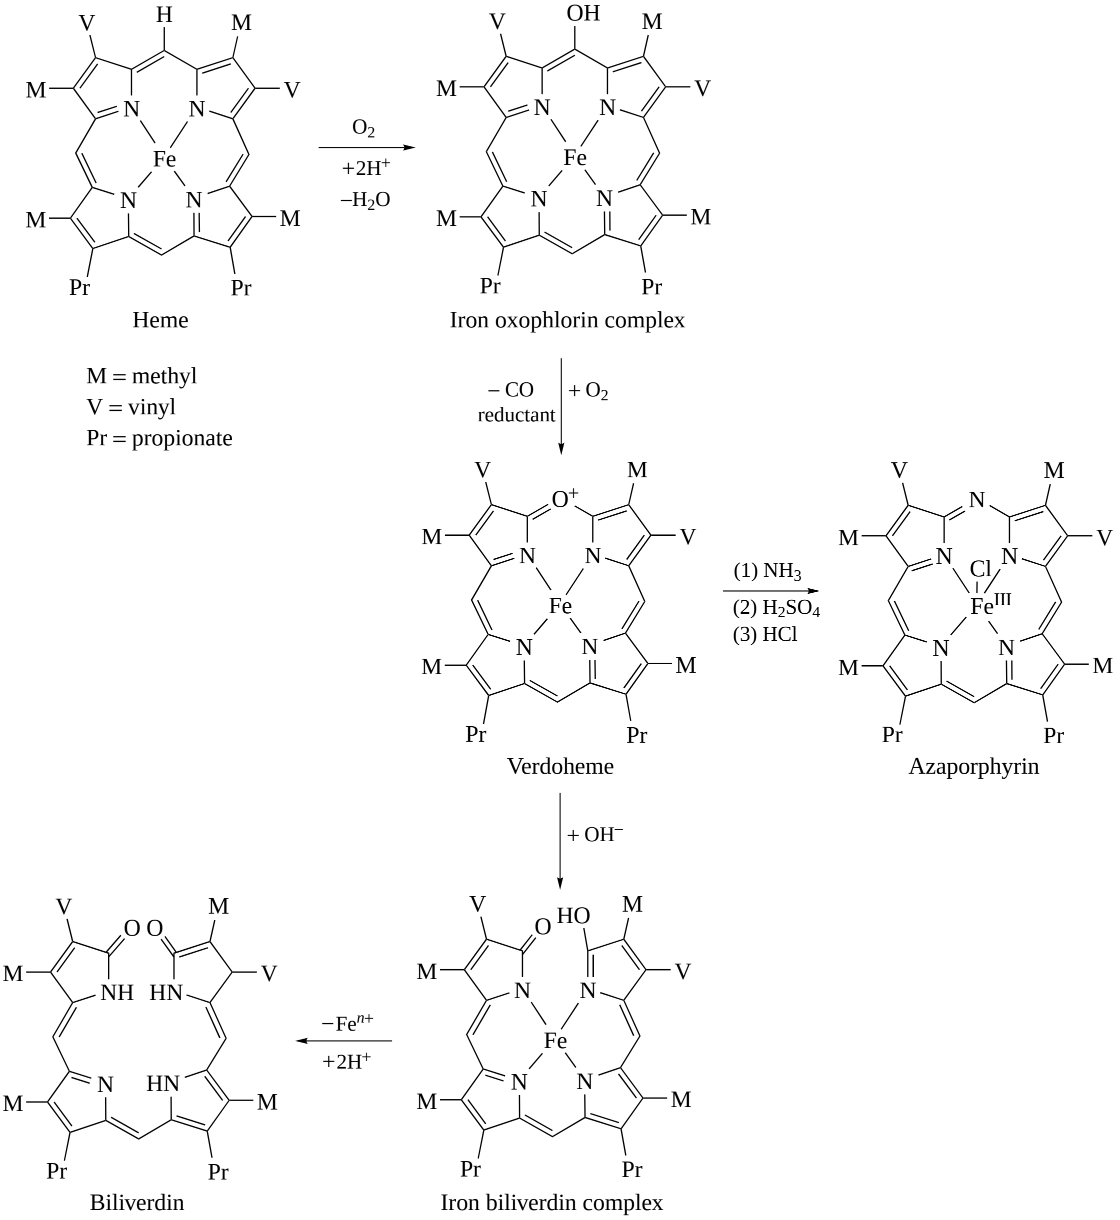
Upon further treatment of (OEPO)Fe(Py)$_2$ with O_2 and a reducing agent such as ascorbic acid, CO is lost from the partially oxidized *meso* position to produce the Fe^{II} or Fe^{III} verdoheme analog [(OEOP)Fe^{II}(Py)$_2$]$^+$ Cl^-. Verdoheme is the green iron complex of the 5-oxaporphyrin macrocycle and can be obtained by reaction of iron porphyrin with dioxygen in the presence of axial pyridine or cyanide, as detailed in Scheme 3 for the analogous natural (protoheme) reactions.[540,1136–1138] Octaethylverdoheme was structurally characterized and was shown to contain the 5-oxaporphyrin macrocycle.[1139] This iron verdoheme complex can be treated with phenylmagnesium bromide to yield the paramagnetic (bromo)(phenyl)iron(III) and diphenyliron(III) OEOP complexes.[1140] Treatment instead with hydroxide or methoxide leads to several different ring-opened biliverdin complexes.[1141] These species are (OEB)Fe^{III}(OH), (OEBOMe)Fe(Py), (OEBOMe)Fe(Py)$_2$ and (OEBOMe)Fe(OMe).[1142] If the [(OEOP)Fe^{II}(Py)$_2$]$^+$$Cl^-$ is instead treated with hydrogen peroxide, the bridged dimeric biliverdin complex [(OEB)Fe^{III}]$_2$ is obtained;[1143] use of unsymmetrical hemins such as 3-demethyl-3-(trifluoromethyl)mesohemin IX leads to the four biliverdin isomers.[1144] Treatment of OEBFe(Py)$_2$ with O_2 in the presence of pyridine yields a tripyrrole complex of iron(III).[1145] The *meso*-NH_2-substituted OEPFe^{II}(Py)$_2$ complex reacts with O_2 to form what appears to be an intermediate in this type of 'de-pyrrolization' of biliverdin-type derivatives, in that it yields a crystalline product that has one dangling pyrrole group in which the amino group is present as a nitrile.[1146,1147] If the [(OEOP)Fe^{II}(Py)$_2$]$^+$ Cl^- is treated with ammonia followed by acid, the octaethylazaporphyrin macrocycle complex [(OEAP)Fe^{III}Cl] is formed,[1148] as also detailed in Scheme 3 for the analogous protoheme system. If the *meso*-CO of OEOP is not lost, then formylbiliverdin is formed.[1149] Its metal complexes have also been investigated, although it was not possible to obtain the iron complex because of its instability.[1149]

At least one example of each of these species has been characterized by X-ray crystallography and ^1H NMR spectroscopy.[539,540,1133–1149] Thus structures of compounds involved in most of the steps leading to the production of biliverdin by the in vitro process of coupled oxidation have

been elucidated. Presumably similar species are involved in the in vivo reactions of the enzyme heme oxygenase, a P450- or peroxidase-like enzyme that, as isolated, contains no heme yet binds heme and then follows a P450-like reaction scheme with electrons and dioxygen, but instead of the Fe^{III} peroxide species forming Compound I (see also Section 9), one oxygen of this group attacks a *meso*-position of the heme and (in several steps) destroys it, forming first *meso*-hydroxyheme and finally biliverdin,[33,34] which, in humans, is then reduced to bilirubin, conjugated with sugars, and excreted in the feces.[33] Heme oxygenases have a histidine that serves as axial ligand to the heme that they destroy.

6.1.6 *Iron(III) Porphyrins as Reduction Catalysts*

The [TPPFeCl]–$NaBH_4$ system in diglyme has been shown to perform remarkably efficiently as a catalyst for the reduction of nitrobenzenes to anilines.[1150] Although both TPPCo and TPPMnCl also catalyze the reduction of *p*-chloronitrobenzene to *p*-chloroaniline, their catalytic activities are much lower than that of TPPFeCl.[1150] Another type of reduction catalyst, in this case of dioxygen to water, begins with carbon-supported chloroiron(III) tetramethoxyphenylporphyrin, which is then heat-treated at 900 °C for one h.[1151] This causes decomposition of the porphyrin to produce metallic, carbidic and oxidic iron, as detected by Mössbauer spectroscopy. The active



Scheme 3

catalytic form seems to be a 6-coordinate Fe^{III} center, which comprises about 8% of the iron content. H_2O_2 is a side product of the reduction reaction, and it causes degradation of the active iron sites. However, an earlier study, in which the samples were heat-treated at increasing temperatures (10 °C per hour) up to the highest temperature (325, 700, 800 °C), and held there for a dwell time of 2 h, found that the Fe–N_4 moiety seemed to be persistent.[1152]

6.1.7 *Photochemistry of High-spin Iron(III) Porphyrins*

Several investigations of photochemical reactions of high-spin Fe^{III} porphyrins have been reported,[1153–1155] and the subject has been reviewed[483] (*see* ***Photochemistry of Transition Metal Complexes***). When bound to anions such as Cl^- or OH^-, Fe^{III} porphyrins are photochemically reduced to Fe^{II}, with production of a radical (Cl• or HO•).[1154,1155] In the case of a cofacial $Fe^{III}-Zn^{II}$ diporphyrin, however, the photochemical reaction produced $[P^-\bullet Zn^{II\cdots}\ PFe^{II}]Cl$ by electron transfer from the Zn^{II} porphyrin to the Fe^{III} porphyrin.[1153] The kinetics and thermodynamics of the back reaction were investigated ($k \sim 10^{10}\ s^{-1}$).[1153]

6.1.8 *Complexes of Iron(III) Porphyrins with Fullerenes*

Cocrystallization of binuclear iron(III) porphyrins, either the μ-oxo dimer, $[(OEPFe)_2O]$, or the oxophlorin, $[(FeOEPO)_2]$, dissolved in benzene solution, with C_{60}, yields solids of formula $C_{60}\cdot\mu$-$O(OEPFe)_2\cdot C_6H_6$ and $2C_{60}\cdot(FeOEPO)_2\cdot 4C_6H_6$.[1156] For the former, each independent molecule of μ-$O(OEPFe)_2$ makes close contact with two fullerene molecules. The Fe-O-Fe angles (150.18 and 151.89°) are markedly bent, with a benzene molecule wedged into the opening between the two porphyrins. Another crystalline form, however, has Fe-O-Fe angles that are more linear (172.16 and 176.2°). The structure of $2C_{60}\bullet\ (FeOEPO)_2\cdot 4C_6H_6$ consists of a centrosymmetric $(FeOEPO)_2$ molecule in which the two macrocycles are connected to one another through axial coordination of the *meso*-oxygen atoms to iron ions in the neighboring porphyrin. Each molecule of $(FeOEPO)_2$ engages a fullerene on its two exposed faces. The distances of the iron from the fullerene in both types of crystalline solids is too far for any bonding interaction, but the work shows that C_{60} can cocrystallize with dimeric metalloporphyrins to yield new solids with interesting supramolecular architectures. A review of earlier work on the reactions of transition metal complexes with fullerenes has been published.[1157]

6.2 Intermediate Spin ($S = 3/2$) Iron(III) Porphyrins

The bacterial cytochromes c' are known to contain five-coordinate heme c, with no distal residues present capable of hydrogen-bonding to endogenous ligands.[1158,1159] Moss and Maltempo have proposed the existence of an intermediate-spin ($S = 3/2$) state with a quantum mechanical admixture of the more common high-spin ($S = 5/2$) state for the protein.[1160–1162] This differs from a simple $S = 3/2 \rightleftharpoons S = 5/2$ equilibrium, in that the EPR and Mössbauer features are unique, rather than simply a superposition of the expected spectra of the two spin states, and the ground state is composed of contributions from each state.[1163] Models for the cytochromes c' have been prepared with Fe^{III} porphyrins bound to weakly coordinating anionic axial ligands such as ClO_4^-,[179,492,1164–1167] $SO_3CF_3^-$,[1168] SbF_6^-,[1165,1166,1169,1170] $C(CN)_3^-$,[1168,1171] and $B_{11}CH_{12}^-$,[1172] or two weakly basic neutral ligands such as tetrahydrofuran,[1173] 3-chloropyridine,[1174,1175] dimethylformamide + N_3^-,[1176] and 3,5-dichloropyridine (in the case of β-pyrrole alkyl-substituted porphyrins such as OEP and etioporphyrin).[1165,1166,1177] These Fe^{III} porphyrins exhibit a broad derivative-shaped EPR feature near $g = 4$[492,1165,1166,1168,1177] and ^1H NMR spectra that show anti-Curie behavior.[171,492,965,1178] Many of these spectral features are similar to those of the cytochromes c', including the EPR,[492,1161,1165,1166,1179,1180] near-IR MCD,[1163] Mössbauer,[1162,1170,1177] and resonance Raman[1181,1182] spectra, and the NMR spectra of *Chromatium vinosum* cytochrome c', but not those of *Rhodospirillum rubrum*, *Rhodospirillum molischianum*, and *Rhodopseudomonas palustris*.[1183]

The dramatic anti-Curie dependence (*see* ***Magnetism of Transition Metal Ions***) of the pyrrole-H resonance of $[TPPFeOClO_3]$ from about −20 ppm at −45 °C to +20 ppm at +54 °C[1184] is a now-familiar hallmark of the ^1H NMR spectra of spin-admixed $S = 3/2,5/2$ model heme species. At low temperatures the $S = 3/2$ contribution to the spin-admixed state usually increases, leading to depopulation of the $d_{x^2-y^2}$ orbital of the $S = 5/2$ state, thus decreasing the large σ contact shift contribution characteristic of simple high-spin five- and six-coordinate Fe^{III} porphyrins.[174,175] However, a study of the temperature dependence of the pyrrole-H shifts of a series of 2,6-phenyl substituted derivatives of $[TPPFeOClO_3]$ showed that either the $S = 3/2$ or the $S = 5/2$ state can be of lower energy, and thus the pyrrole-H resonance can in fact shift in either direction as the temperature is lowered,[492] as shown in Figure 9, where the temperature dependence has been fit with a 2-level expansion of the Curie law appropriate for systems having a thermally accessible excited state.[492,1185] The tendency of the 2,6- or 2,4,6-substituents to stabilize the $S = 3/2$ level decreases in the order $(OMe)_3 \gg (Me)_3 > (H)_5 > (Cl)_2 > (Br)_2$, while $(F)_2$ and $(OMe)_2$ have the tendency to stabilize the $S = 5/2$ level in increasing order, respectively.[492] The tetrakis-(2,4,6-trimethoxyphenyl)porphyrinatoiron(III) perchlorate complex is thus the purest $S = 3/2$ ground-state complex known thus far.[492,1165,1166] The fact that many of the temperature dependences cross each other at temperatures within or near the range of the NMR investigations (Figure 9) suggests the need for caution in using single-temperature measurements to define relative tendencies for spin state stabilization; in spite

of this cautionary note, all of the work discussed below has used a single temperature NMR shift measurement to define relative spin state stabilization.

The tendency of weak-field anions to stabilize the $S = 3/2$ ground state of the spin-admixed 3/2,5/2 systems has been defined in terms of the pyrrole-H shift of the $TPPFe^{III}$ complex at a given temperature, and increases (in reverse order of the actual shifts) in the order ReO_4^- ($\delta_{pyrrole} = +62$ ppm) $<$ $ONC(CN)_2^-$ $<$ BF_4^- $<$ $CF_3CO_2^-$ $<$ $CF_3SO_3^-$ $<$ $C(CN)_3^-$ $<$ ClO_4^- $<$ AsF_6^- $<$ $Co(CB_{11}H_{12})_2^-$ $<$ SbF_6^- $<$ $Ag(CB_{11}H_6Br_6)_2^-$ ($\delta_{pyrrole} = -62$ ppm)[1168,1172,1186] for $TPPFe^{III}$, and $CF_3SO_3^-$ $<$ $C(CN)_3^-$ $\ll$ ClO_4^- $<$ SbF_6^- for $OEPFe^{III}$.[1165,1166,1168] These have been called a 'magnetochemical series' of ligand field strengths.[1186] However, as noted above, this assumes that the temperature dependences of the complexes in the series do not cross (see Figure 9). The perrhenate anion, ReO_4^-, bound to $TPPFe^{III}$ has been shown to favor the $S = 5/2$ component to a much greater extent than ClO_4^-,[1187] and H_2O and OH^- have reversed orders of ligand field strength on the magnetochemical series relative to the spectrochemical series (*see Spectrochemical Series*), with H_2O producing a $S = 3/2,5/2$ spin admixed state ($\delta_{pyrrole} = -43$ ppm) and OH^- producing a $S = 5/2$ spin state ($\delta_{pyrrole} = +82$ ppm).[1188] A low-basicity ligand, 3,5-dichloropyridine, appears to stabilize the $S = 3/2$ ground state in $[OEPFe(3,5\text{-}Cl_2Py)_2]^+$ about as well as ClO_4^- or SbF_6^-.[1165,1166] A study of the dependence of the solution magnetic moment (ranging from 2.0 to 4.4 μ_B) of a large number of $PFe(3\text{-}ClPy)_2ClO_4$ complexes indicated that species with more basic porphyrinate ligands have higher-spin multiplicity.[1189] As a possible explanation, it was suggested that the more basic porphyrins donate more electron density to the Fe^{III} atom and thus decrease its charge attraction for the axial ligands, which results in a decrease of the axial-ligand field, leading to higher-spin multiplicity.[1189] For *para*-substituted derivatives of $[TPPFeOClO_3]$ the $S = 5/2$ contribution, as judged by the pyrrole-H chemical shift at 29 °C, increases in the order *p*-OMe $<$ *p*-H $<$ *p*-Cl $<$ *p*-CF_3,[1165,1166] so electron-donating substituents on the phenyl rings favor the $S = 3/2$ ground state, where the $d_{x^2-y^2}$ orbital is depopulated. Consistent with this, as mentioned above, the 2,4,6-trimethoxy derivative, $[(2,4,6\text{-}(OMe)_3)_4TPPFeOClO_3]$, has the lowest-frequency chemical shift reported for the pyrrole-H (−31 ppm at 29 °C),[492,1165,1166] and thus appears to be the 'purest' $S = 3/2$ complex among tetraphenylporphyrin derivatives. However, comparison of the temperature dependence of the $2,6\text{-}(OMe)_2$ and $(2,4,6\text{-}OMe)_3$-substituted TPP complexes (Figure 9) indicates that *p*-OMe and *o*-OMe have opposite effects on the spin state,[492] and comparison with the *p*-OMe-only complex[1165,1166] (the temperature dependence of whose pyrrole-H shift has not been reported) suggests that substituent effects in this system of methoxy-TPPs are dramatically non-additive.

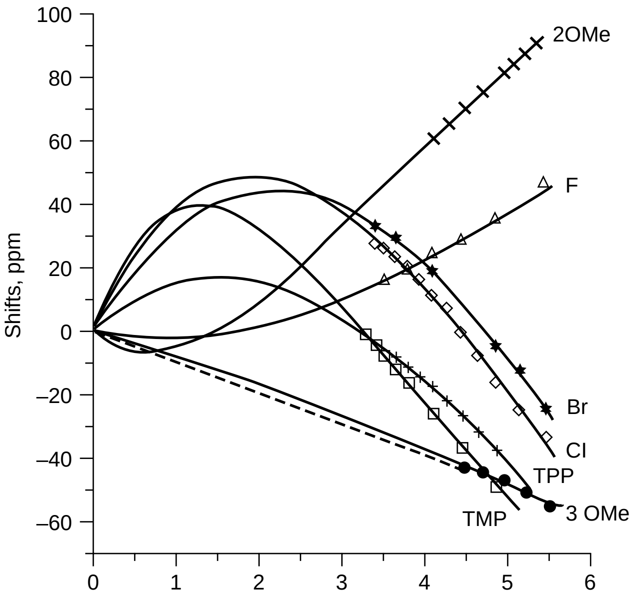


Figure 9 Isotropic shifts of the listed complexes as a function of inverse temperature and fits to equation x (—) or to a 1-level linear fit (- - -): *, $(2,6\text{-}Br_2)_4TPPFeOClO_3$; □, $(2,6\text{-}Cl_2)_4TPPFeOClO_3$; ×, $TPPFeOClO_3$; ◊, $TMPFeOClO_3$; △, $(2,6\text{-}F_2)_4TPPFeOClO_3$; +, $(2,6\text{-}(OMe)_2)_4TPPOClO_3$; •, $(2,4,6\text{-}(OMe)_3)_4TPPOClO_3$. The highly saddled octaethytetraphenylporphyrinato-iron(III) chloride complex has been shown to be spin-admixed, with largely $S = 5/2$ but with some $S = 3/2$ character.[1190,1191] In comparison, both tetraazaporphyrin[163] and phthalocyanine[1192] complexes of chloroiron(III) are pure $S = 3/2$ compounds. XFe^{III} complexes of etioporphycene and etiocorrphycene, where X = F, Cl, Br and I, have been prepared and their structures determined via X-ray crystallography; they have also been investigated by Mössbauer, ^1H NMR, and EPR spectroscopy as well as SQUID magnetometry.[1193] The iodide complex of etioporphycene was found to have a quite pure $S = 3/2$ spin state with only a small amount of $S = 5/2$ spin admixture. In contrast, all of the other complexes, of both etioporphycene and etiocorrphycene, show the $S = 5/2$ spin state with a small amount of $S = 3/2$ spin admixture.[1193]

Crystalline complexes of iron(III) tetramethylchiroporphyrin having two ethanol or one ethanol and one water axial ligands have been structurally characterized and their magnetic moments, Mössbauer, EPR and NMR spectra reported.[1194] The magnetic moment of 3.8 μ_B and quadrupole splitting ΔE_Q of 3.79 mm/s for the mixed ethanol-water-ligated samples strongly supports a $S = 3/2$ state; the pyrrole-H signal is at about −30 ppm at ambient temperature, indicating no population of the $d_{x^2-y^2}$ orbital.[1194] Bis-THF complexes of iron porphyrinates also yield the $S = 3/2$ spin state, and Nakamura and coworkers have proposed that there are two possible electron configurations for these complexes:

$(d_{xz},d_{yz})^3(d_{xy})^1(d_{z^2})^1$ and $(d_{xy})^2(d_{xz},d_{yz})^2(d_{z^2})^1$.[944] The latter, which has two d_π unpaired electrons, should have more negative pyrrole-H chemical shifts than the former. Based upon the typical ambient temperature pyrrole-H shift of ∼−30 ppm of most of these $S = 3/2$ complexes, the latter electron configuration is by far more common. The [OETPPFe(4-CNPy)$_2$]ClO$_4$ complex has been investigated by EPR and NMR spectroscopy[943,1195,1196] and X-ray crystallography.[943] The solution magnetic moments, measured by the Evans method,[1197,1198] are reported to be ∼3.3 μ_B[943] and 4.3 μ_B[1196] at ambient temperatures, both of which depart from the expected spin-only moment of 3.87 μ_B. The reasons for the departure from the spin-only moment are largely the experimental errors inherent in the Evans method (knowledge of the molecular weight of the complex being studied, which depends on whether there are solvent molecules in the crystal lattice, weighing errors, solvent evaporation, relatively few Hz difference in the frequencies of the reference signal in the two compartments of the NMR sample cell). The temperature dependence of the ^{1}H NMR spectra of [OETPPFe(4-CNPy)$_2$]ClO$_4$ shows no evidence of a thermally accessible excited state over the range of the measurements (303–180 K),[943] and thus the complex appears to be a pure $S = 3/2$ system, as also concluded by Nakamura and coworkers.[1196] However, the phenyl-H shift differences, $\delta_m - \delta_p$ and $\delta_m - \delta_o$, are both large and negative, indicating the presence of negative spin density at the *meso*-carbons.[195,943] Careful analysis of the pyrrole-CH$_2$ shifts also shows that they are much larger[943] than expected for either of the proposed[944] electronic configurations of intermediate spin Fe^{III}, $S = 3/2$, but rather indicate that the $d_{x^2-y^2}$ orbital of iron is at least partially occupied.[943] Thus, the combination of negative phenyl-H shift differences and the larger-than-expected pyrrole-CH$_2$ shifts indicates at least partial electron transfer from the porphyrin to the metal, yielding an electron configuration of $(d_{xy})^2(d_{xz},d_{yz})^2(d_{z^2})^1(d_{x^2-y^2})^{(1-x)}$ for the iron, and $(OETPP)^{(2-x)-}$ for the porphyrinate ring.[943]

Five-coordinate iron(III) 2,7,12,17-tetrapropylporphycenes with anions $C_6H_5O^-$, Cl^-, Br^-, I^- and ClO_4^- have been investigated by ^{1}H NMR spectroscopy and found to have spin-admixed $S = 3/2,5/2$ electron configurations.[1199] The pyrrole-H chemical shifts are 65.3, 28.5, −7.8, −49.4, and −77.1 ppm, respectively. This wide chemical shift range suggests that these porphycene complexes are particularly useful for determining the ligand strength in the magnetochemical series.[1199] The chloroiron(III) complex could be reduced in three one-electron steps (Fe^{III}/Fe^{II} and Fe^{II}/π-mono and -dianion radicals) and oxidized in two one-electron steps.[1030] The bis-THF adduct of the same Fe^{III} porphycene yields a pure $S = 3/2$ complex.[1200]

A triclinic crystalline form of [TPPFeOSO$_2$CF$_3$] has been reported to have two crystallographically and magnetically distinct crystal lattice sites, one of which (1) is unique in that its structure is temperature dependent, whereas the second spin-admixed site (2) has a structure that is essentially independent of temperature.[1201] These results suggest different spin ground states for molecules 1 and 2. It was found that molecule 1 pairs form π–π dimers, whereas molecule 2 pairs do not.

Iron(III) tetraphenylporphyrin, in the presence of the most weakly binding anion known, $CB_{11}H_6Br_6^-$, binds weakly to benzene, toluene, *p*-xylene and C$_{60}$ ([60]fullerene), yielding complexes with distinctively short Fe···C contacts in the range of 2.65–2.95 Å.[1202] Dihedral angles of 13–16° between the arene and metalloporphyrin planes are also diagnostic of ligand versus solvate roles. The essential features of the arene coordination can be faithfully reproduced using density functional theory.[1202] In contrast to these structures, as well as those of a number of divalent first-row transition metal OEP complexes co-crystallized with C$_{60}$, C$_{60}$O, C$_{70}$ and C$_{120}$O, OEPFeCl does not have close spacing of metal and fullerene.[1203]

6.3 Low-spin ($S = 1/2$) Iron(III) Porphyrins

Low-spin Fe^{III} porphyrins continue to be of major interest to many investigators, both because of the large number of different low-spin complexes that can be prepared, and because of the relevance of this spin state to a variety of heme proteins. Ligands that give rise to low-spin complexes of Fe^{III} porphyrins include: two imidazoles,[168,174,175,183,194,486,612,618,619,1204–1207] two imidazolates,[1208] two pyridines (for TPPs but not OEP and natural porphyrins for lower-basicity pyridines),[168,174,175,1204,1205,1209–1212] two thioethers,[1213] two thiolates,[1214–1216] two isocyanides,[1217–1219] two phosphines,[1220] two ammonia molecules,[1221] two primary amines (as amino acid esters),[1222] two cyanides,[851,1223–1225] two nitrite ions,[1226,1227] two methoxide ions,[1001] two alkyl peroxide ions,[1001] two dialkylnitrosamines,[1228–1230] two N-hydroxylamines,[1231] two nitrosohydroxylamines,[1230,1232] two N-hydroxyguanidines,[1233] one imidazole and one hydroxide,[432] one imidazole and one cyanide or other strong field anion,[637,1223,1225,1234] one pyridine and one cyanide[1224,1235,1236] or other strong field anion,[1015,1237,1238] one thiolate and one nitrite ion,[1239] one imidazolate and one alkylperoxide ion,[1000] one methoxide and one alkylperoxide ion,[999,1001,1002] one hydroxide and one peroxide ion,[1001] one imidazole and one phosphine,[1220] one pyridine and one phosphine,[1220] one imidazole and one thioether,[1213,1240] one imidazole and one thiolate,[1241] one imidazole and one phenolate,[955] one imidazole and one pyridine,[1236] two different pyridines,[1236] one nonhindered imidazole and one hindered imidazole,[1242,1243] one imidazole and one imidazolate,[1234] one imidazole or pyridine and one carbanion (aryl, alkyl or alkynyl).[966,1244] In addition, five-coordinate Fe^{III} porphyrins having one nitrite[1227] or hydrosulfide[1245] or a σ-alkyl or -aryl ligand[1246,1247] bound to the metal are also low spin. An extensive review of the NMR spectroscopy and a summary of the EPR data of these complexes has appeared,[175] and the reader is referred to this article for more detailed information and complete references to the primary literature.

Axial-ligand combinations found among the low-spin ferricytochromes that are involved in electron transport in a wide variety of cells include two histidine imidazoles (cytochromes b_5,[1248] the *b* cytochrome of sulfite oxidase,[43] the bc_1 mitochondrial protein complex[2–9] and cytochrome b_6 of chloroplasts,[1249] cytochrome *a* of mitochondrial cytochrome *c* oxidase,[2–6] and the bacterial tetraheme proteins called the cytochromes c_3,[1250,1251] as well as other bacterial multiheme cytochromes *c*[1252] (*see* ***Multi-Heme Cytochromes & Enzymes***)) and one histidine imidazole and one methionine thioether (mitochondrial cytochromes *c* and their bacterial counterparts[626,627] (*see* ***Iron: Heme Proteins & Electron Transport***), cytochrome c_1 of the mitochondrial bc_1 protein complex,[7–9] and *E. coli* cytochrome b_{562}[1253]). The axial ligands of chloroplast cytochrome *f* are one histidine imidazole and the N-terminal aliphatic amino group,[1254] those of the heme center of bacterioferritin are two methionine thioethers,[1255,1256] and those of bacterial cytochrome *o* are believed to be two histidine imidazoles.[1257] These axial-ligand combinations (as well as heme substituents) lead to different reduction potentials for each of the above-mentioned cytochromes, as well as different EPR, NMR, Mössbauer, magnetic circular dichroism (MCD), and resonance Raman spectra for each of the cytochromes mentioned. For each of the aforementioned, magnetic spectroscopies have been valuable in establishing the axial-ligand combinations present in these and other heme proteins containing low-spin Fe^{III}. Of these, near-IR MCD spectroscopy at very low temperatures appears to provide the most unique spectra for each axial-ligand combination.[1255] The MCD spectra of several alkylamine and imidazole-ligated Fe^{III} chlorin complexes have also been reported.[819]

The resting state, the low-spin Fe^{III} complexes of the family of monooxygenase and oxidase enzymes known as the cytochromes P450 (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***), have one cysteine thiolate as the proximal ligand[24–31,1241,1258] and a water molecule[1216,1259] as the distal ligand, though the distal ligand may be replaced by a phosphine, imidazole or other strong-field ligand.[1241,1260] The spectral changes that usually accompany the transition from low-spin to high-spin upon binding of substrate are typical of the spin state change itself.[1261] This spin transition is accompanied by loss of the water molecule, and probably a lengthening of the Fe-thiolate bond.[1262,1263] Similarly, the five-coordinate mono-histidine ferriheme forms of a number of proteins, including small molecule (O_2, CO, NO) carriers such as hemoglobin and myoglobin (*see* ***Iron: Heme Proteins & Dioxygen Transport & Storage***) and enzymes such as the large family of peroxidases (including horseradish and other plant peroxidases, cytochrome *c* peroxidase, myeloperoxidase, and lignin peroxidases) (*see* ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***) and the heme a_3 of mitochondrial cytochrome oxidase (*see* ***Cytochrome Oxidase***) readily bind cyanide and other strong-field ligands to produce low-spin Fe^{III} complexes having the common axial ligation of one cyanide and one histidine imidazole.

As might be expected, the preparation and investigation of a wide variety of low-spin Fe^{III} porphyrins with various axial ligands have provided a wealth of valuable information about the electronic, magnetic, and redox properties of the heme proteins. We will first briefly review the possible electron configurations of low-spin Fe^{III} porphyrins, then discuss the phenomenon of ruffling of the porphyrin macrocycle and its consequences, and the preferred orientation of planar axial ligands for the low-spin d^5 electronic configuration. We will then discuss the redox chemistry of, the formation of, and factors that affect, the stability of low-spin complexes and the rates of ligand addition and exchange in low-spin d^5 Fe^{III} complexes, and the preparation of 'synthetic heme proteins' that utilize this information. Other reactions of low-spin Fe^{III} porphyrins, including the very important one of electron self-exchange, as well as autoreduction, will also be addressed. Finally, the preparation of synthetic 'proteins' that bind hemes in a way that models specific naturally occurring heme proteins will be discussed.

6.3.1 Possible Electron Configurations of Low-spin Iron(III) Porphyrins

From the Griffith theory for the *g*-values of low-spin Fe^{III},[1265,1266] using the formulation of Taylor[1267] (see also Section 6.3.3 below), and NMR spectroscopic data, it has been accepted for a number of years that low-spin Fe^{III} porphyrins always have a $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state.[168] This ground state gives rise in many cases to rhombic EPR spectra, for which the relative energies of the d_{xy}, d_{xz}, and d_{yz} orbitals can be calculated,[1267] if the orientation of the three g-values with respect to the molecular axes of the heme center are known: if the largest g-value is aligned along the normal to the heme plane, then indeed, the electron configuration is $(d_{xy})^2(d_{xz},d_{yz})^3$, but if instead the smallest g-value is aligned along the normal, then the electron configuration is $(d_{xz},d_{yz})^4(d_{xy})^1$. Determining the orientation of the largest (or smallest) g-value with respect to the heme normal can be achieved by single crystal EPR[1224,1268,1269] or pulsed EPR spectroscopy.[1002,1270–1275] In the pulsed EPR studies it has been found that the criteria originally used by Taylor[1267] to determine the orientation of the g-values with respect to the molecular axis, the so-called Rhombicity (V/Δ) being less than or equal to 2/3, a purely geometric definition, is actually often violated, as in the cases of $[TPPFe(PzH)_2]^+$,[1270] $[TPPFe(3\text{-}NH_2PzH)_2]^+$,[1273] $[TPCFe(ImH)_2]^+$,[1274] $[OECFe(ImH)_2]^+$,[1276] $[oxo\text{-}OECFe(ImH)_2]^+$,[1276] $[OECFe(4\text{-}NMe_2Py)_2]^+$[982] and $[TPPFe(OCH_3)(OO\textit{t}\text{-}Bu)]^-$,[1002] all of which have the more common $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state in spite of the fact that the Rhombicity is significantly larger than 2/3 in each case (see also Section 6.3.3 below). There are undoubtedly additional cases where knowing the orientation of the largest g-value

with respect to the normal to the heme plane would lead to an unambiguous assignment of the orbital occupation of low-spin iron(III) porphyrins.

The $(d_{xy})^2(d_{xz},d_{yz})^3$ electron configuration gives rise to ^{1}H NMR spin delocalization to protons on the β-pyrrole substituents of the molecule via the filled $3e(\pi)$ porphyrin orbitals, that is P → Fe π bonding, which is symmetry-allowed.[168,174,175] The interpretation of the NMR spectra in terms of MO theory is based upon the fact that for bis-imidazole complexes, π contact shifts are observed at the β-pyrrole positions, while there are negligible π contact shifts at the *meso* positions.[168,174,175] 2D NMR (COSY) studies of unsymmetrically phenyl-substituted derivatives of $[TPPFe(N\text{-}MeIm)_2]^+$ conclusively show that the pattern of spin delocalization to the β-pyrrole positions is exactly that expected for the $3e(\pi)$ orbitals, as modified by the electron-donating/withdrawing characteristics of the substituent,[1264,1277] as shown in Figure 10. However, while the COSY crosspeaks are genuine, Nuclear Overhauser and Exchange SpectroscopY (NOESY) crosspeaks observed in the later study[1277] were subsequently shown to be artifacts, probably arising from overlap of ridges in the 2D spectra; calculations show conclusively that protons on adjacent pyrrole rings are too far apart to yield measurable NOEs in these model heme complexes.[1278] Heteronuclear multiple bond correlation spectra (HMBC) have been shown to be valuable for assigning the α- and *meso*-carbon resonances of these model hemes.[1279]

It has also been shown that with certain kinds of axial ligands (isocyanides,[1217–1219,1275] low-basicity pyridines[621,1280,1281]) or certain modifications of the porphyrin π orbitals (such as occurs in the highly reduced hemes), the relative energies of the d_{xy} and d_{π} orbitals (d_{xz},d_{yz}) can be reversed, leading to an electron configuration that is $(d_{xz},d_{yz})^4(d_{xy})^1$. This electron configuration results in axial (with $g_{\perp} > 2 > g_{\parallel}$),[174,175,621,1217–1219,1280,1281] as shown in Figure 11, or near-axial EPR spectra,[59] and ^{1}H NMR[174,175,1217–1219,1281] and/or pulsed EPR[1275] spectra that show just the reverse types of π spin delocalization patterns: negligible π spin delocalization to the β-pyrrole positions, but large π spin delocalization to the *meso* positions. (It must be noted that because of the temperatures at which EPR and NMR spectra are recorded, 4–77 K that is 180–340 K, respectively, there is not necessarily a direct correspondence between the electron configuration observed by EPR spectroscopy and that observed by NMR spectroscopy.[174,175] This appears to be particularly true of some of the low-spin Fe^{III} complexes of the reduced hemes[1282] (but not for $[TPCFe(ImH)_2]^+$[1274]) and models of the peroxide complex of heme oxygenase.[1002]) However, for this electronic ground state the d_{xz},d_{yz} orbital set, which has proper symmetry for π spin delocalization to the e-symmetry porphyrin orbitals, is filled, and the d_{xy} orbital does not have proper symmetry for overlap with any of the π orbitals of the porphyrin ring if it is flat (Figure 4).

Hence the large π spin delocalization to the *meso* positions suggested at least partial porphyrin π radical character to the electron configurations of these complexes,[174,175,1283] even though the EPR g-values deviate considerably from 2.00 and thus indicate a metal-based unpaired electron rather than a carbon-based free radical. The limit of this π radical character is to convert the electron configuration to that of $(P^{-}\cdot)Fe^{II}$,[199,200] as discussed above in Section 5. It appears that Fe^{III} porphyrins that have a $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state invariably appear to be pushed toward having partial porphyrin π-cation radical character (in terms of both their EPR and NMR spectra), even though the d_{xy} orbital is orthogonal to the π orbitals of a flat porphyrin ring. The reasons for this behavior are related, at least in part, to the almost invariably observed strong S_4 ruffling of the porphinato core[1218,1219,1280,1281] in systems having a predominantly $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state, as is discussed in detail in Section 6.3.2.

In spite of this, however, not all highly ruffled iron(III) porphyrinates have their unpaired electron in the d_{xy} orbital. The 'large g_{max}' EPR signal-producing bis-hindered imidazole complexes discussed in Sections 6.3.2 and 6.3.3 are good examples of highly ruffled heme centers that have the more common $(d_{xy})^2(d_{xz},d_{yz})^3$ electron configuration.

6.3.2 *The Phenomenon and Possible Electronic Consequences of Ruffling of the Porphinato Core in Iron(III) Porphyrins*

There have been a number of investigations of the tendency of metal complexes of the reduced hemes (chlorins and isobacteriochlorins) and Factor F430 to deform from planarity in a manner that is described in terms of the group theory of a symmetrical porphyrin ring as either S_4 saddled (sad), a B_{2u}-symmetry distortion, or S_4 ruffled (ruf), a B_{1u}-symmetry distortion, although other deformations are possible as well.[623–625] In S_4 saddled structures, opposite pyrrole rings, and hence, metal–porphyrin nitrogen bonds, are displaced from planarity, creating a pseudo-tetrahedral distortion in the metal coordination. In S_4 ruffled structures, opposite pyrrole rings are counter-rotated about the metal–nitrogen bonds, such that the metal and the four porphyrin nitrogens are in a plane, but the *meso*-carbons and the β-pyrrole carbons are displaced from this plane in an up–down alternating fashion.[1284] It is fairly well accepted that the facility of ruffling generally increases in the order porphyrins < chlorins < isobacteriochlorins < F430.[68,1285,1286] However, it is now clear that porphyrins may deform from planarity much more easily than assumed heretofore. Crystal and molecular structure determinations for a series of $[TMPFe(L)_2]^+ClO_4^-$ complexes in which L is a pyridine ($4\text{-}NMe_2Py$,[1204] 3-EtPy,[1280] 3-ClPy,[1280] 4-CNPy,[1280] and 3-CNPy[1280]) or a hindered imidazole ($1,2\text{-}Me_2Im$)[1287] show that, as expected from their EPR spectra[1204,1280] discussed more fully in Section 6.3.3, both pyridine and hindered imidazole ligands

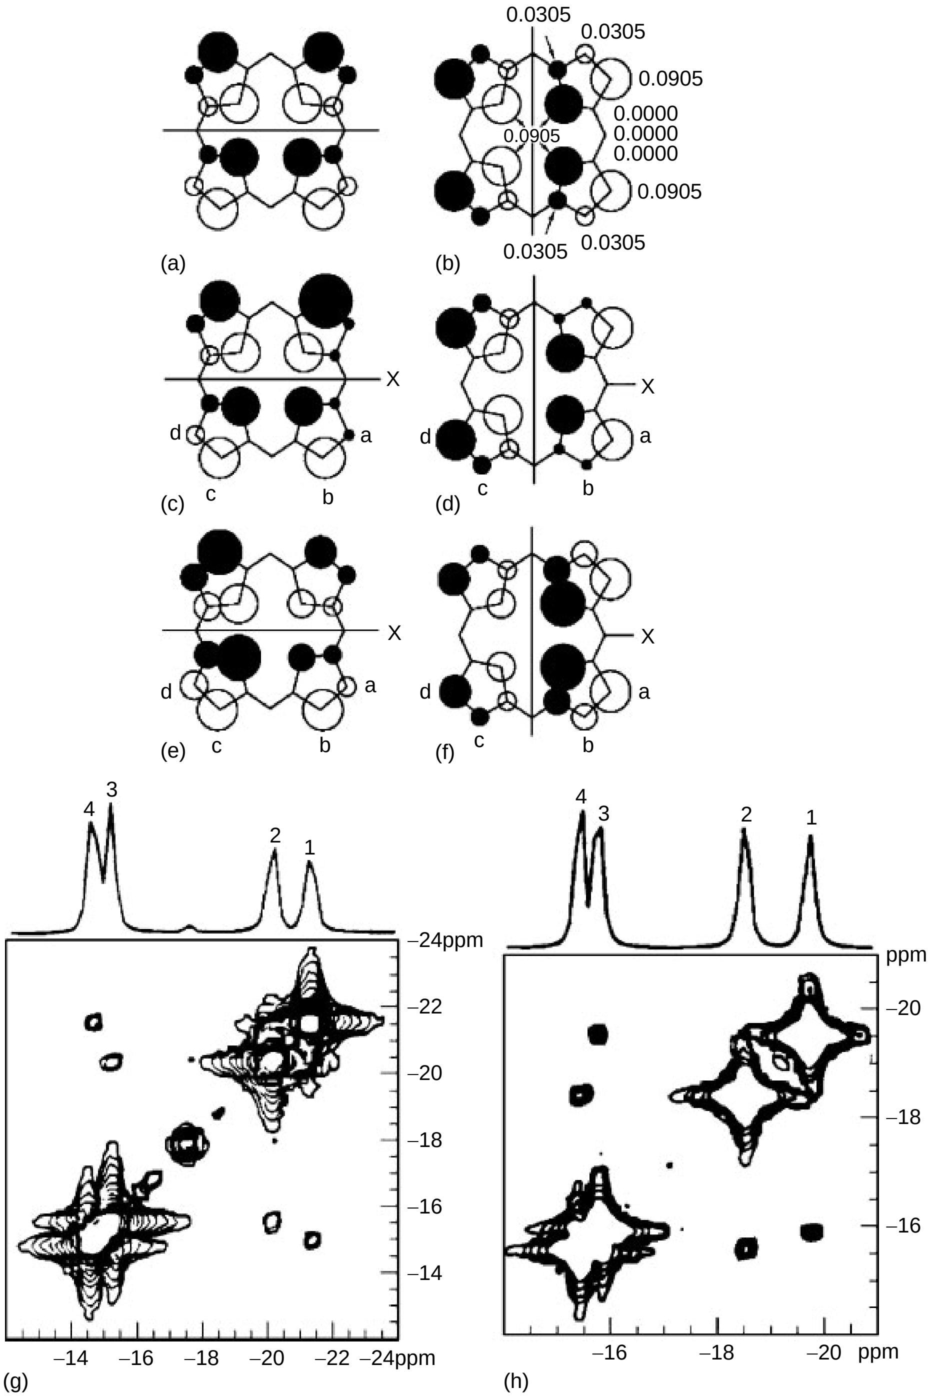

Figure 10 Symmetry properties of and electron density distribution in the filled 3e(π) porphyrin orbitals[221] that have proper symmetry for overlap with the d_{xz} and d_{yz} orbitals of low-spin Fe^{III}. (a, b) Linear combinations of the 3e(π) orbitals that are appropriate for *meso*-substituted porphyrins; (c, d) exaggerated modifications of these orbitals due to the presence of one uniquely substituted phenyl ring, X, if the effect of the substituent is felt only as far as the adjacent pyrrole positions a and b; (e, f) exaggerated modifications of these orbitals if the effect of the unique substituent is felt over all four pyrrole positions a–d. Since we expect the proton attached to the carbon with largest spin density to have the largest hyperfine shift, the coupling pattern predicted by these simple modifications is a,b and c,d or pyrrole-H peaks 1,4 and 2,3 in the case of (c) and (d), or peaks 1,3 and 2,4 in the case of (e) and (f). (g) One- and two-dimensional COSY spectra of the pyrrole-H region of $[(o\text{-OEt})_1\text{TPPFe(N-MeIm)}_2]^+Cl^-$ in CD_2Cl_2 recorded at room temperature. The small peak at −17.5 ppm is due to the presence of a small amount of $[\text{TPPFe(N-MeIm)}_2]^+Cl^-$ in the sample. The COSY spectrum exhibits the 1,4 and 2,3 coupling pattern. (h) One- and two-dimensional NMR spectra of the pyrrole-H region of $[(o\text{-Cl})_1(p\text{-OMe})_3\text{TPPFe(N-MeIm)}_2]^+Cl^-$ recorded at room temperature in CD_2Cl_2. The COSY spectrum exhibits the 1,3 and 2,4 coupling pattern. (Reprinted with permission from Ref. 1264. © 1992 American Chemical Society)

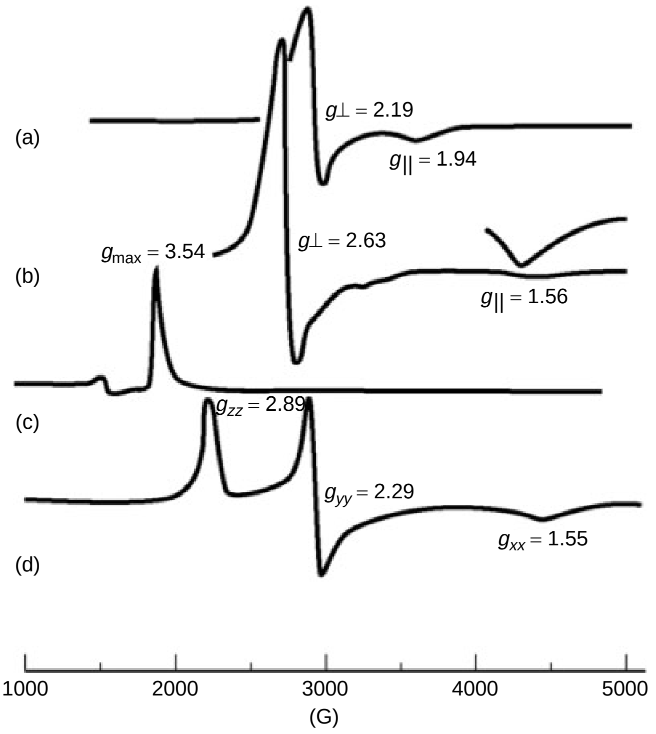

Figure 11 Typical types of EPR spectra exhibited by low-spin Fe^{III} porphyrins. (a) Axial, with small difference between $g_\perp$ and $g_\parallel$, as in the case of $[TPPFe(\textit{n}\text{-BuNC})_2]^+\ ClO_4^-$;[1218] (b) axial, with large difference between $g_\perp$ and $g_\parallel$, as in the case of $[TPPFe(4\text{-CNPy})_2]^+\ ClO_4^-$;[1281] (c) 'large g_{max}', as in the case of $[OEPFe(PMe_3)_2]^+ClO_4^-$ (C. T. Watson, unpublished); and (d) a 'normal' rhombic 'B Hemichrome' EPR spectrum, as in the case of $[TPPFe(N\text{–}MeIm)_2]^+ClO_4^-$[486]

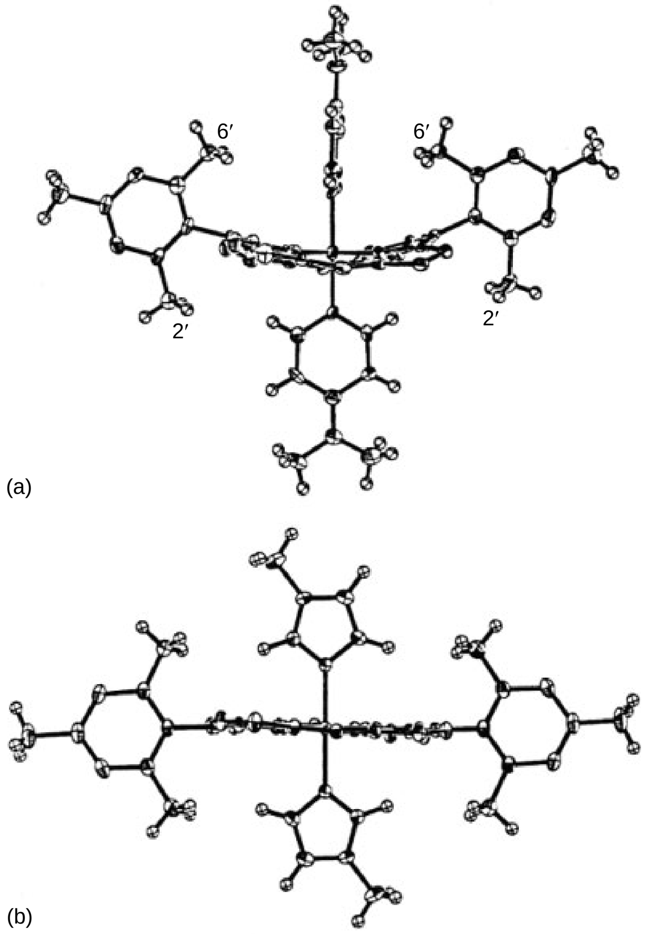

Figure 12 Comparison of ruffled (a) and planar (b) porphyrin complexes of low-spin Fe^{III}: (a) $[TMPFe(4\text{-NMe}_2Py)_2]^+ClO_4^-$; and (b) $[TMPFe(N\text{-MeIm})_2]^+ClO_4^-$[1204]

are aligned in perpendicular planes whose projections on the porphinato core approximately bisect the N_1–N_3 and N_2–N_4 porphinato axes. The nonbonded interactions between the *ortho*-H of the pyridine ligands or the 2-Me of the hindered imidazole ligands and the methyl groups of the porphyrin mesityl rings for this orientation of the axial ligands are believed to produce a strongly ruffled porphyrin core having two oblong 'cavities' at right angles to each other, one above and one below the plane of the porphyrin, which hold the axial ligands in perpendicular planes over the *meso* positions, as shown in Figure 12.

The average displacements of the *meso* carbons from the mean plane of the porphinato core are ±0.36–0.51 Å for the bis-pyridine complexes,[1204,1280] and ±0.71 Å for the bis-1,2-Me_2Im complex.[1287] However, the same ruffling, to an even greater extent among pyridine complexes, is observed for $[TPPFe(4\text{-CNPy})_2]^+ClO_4^-$, with an average displacement of the *meso* carbons of ±0.55 Å,[1281] even though no *ortho*-methyl groups are present on the phenyl rings. Even more striking is the fact that the structure of $[OEPFe(\textit{t}\text{-BuNC})_2]^+ClO_4^-$ also shows severe ruffling, with average displacements of the *meso* carbons of ±0.38 Å,[1218] even though the porphinato plane is totally uncongested. In the last two examples, $[TPPFe(4\text{-CNPy})_2]^+ClO_4^-$ and $[OEPFe(\textit{t}\text{-BuNC})_2]^+ClO_4^-$, it becomes clear that there must be an *electronic* reason for the strong S_4 ruffling. It should be noted that in each of these cases the electron configuration is at least largely $(d_{xz},d_{yz})^4(d_{xy})^1$.[1218,1281]

A molecular mechanics (MM) study of the ruffling of metal complexes of porphine in the absence of axial ligands has shown that MM techniques can be used to simulate the structure of metalloporphyrins containing a wide range of sizes of metal ions and hence a wide range of porphyrin core ruffling.[1284] For the ions Ni^{II}, Fe^{II}, and Zn^{II}, the extent of core ruffling could be satisfactorily reproduced by varying the M–N_P bond-stretching parameters. For the very small P^V ion, specific torsional parameters involving the central ion had to be adjusted to induce the observed ruffling of the porphyrin core. For the very large Pb^{II} ion, it was necessary to reduce the N_P–M–N_P equilibrium bond angle from 90° to 60° to accommodate the observed square-pyramidal coordination geometry about the metal ion.[1284] For low-spin Ni^{II}, which

is known to exist in both planar and ruffled structures, the calculated difference in energy between the two is very small (<1.5 kcal mol^{-1}), and thus for a very modest expense of 1.3 kcal mol^{-1} the porphyrin ring can undergo a core expansion of 0.15 Å to accommodate a change in spin state of Fe^{II} from $S = 0$ to $S = 2$.[1284] It was also found that for Fe^{III} porphyrins a planar core is always more stable than a ruffled core, although the calculated differences are small, and hence metalloporphyrins are therefore capable of adopting a variety of conformations in response to such factors as the orientation of axial ligands and the interaction with their environment.[1284] Thus, it does not seem to be possible at present to predict what conformation the porphyrin ring of a given metalloporphyrin will adopt on the basis of MM calculations.

The hemes of cytochromes *c* are generally quite ruffled, and this is believed to be due to the tight 5-amino acid turn of the Cys-X-Y-Cys-His peptide in which the two cysteines bind covalently to the vinyl groups of the heme and the histidine is an axial ligand to the iron.[623–625] Even in the microperoxidases, for example MP8-Fe^{III}, resonance Raman investigations show clearly that upon displacement of the histidine ligand by an exogenous imidazole molecule, the ν_{10} mode is upshifted in frequency, indicating that the porphyrin skeleton is less distorted when the internal coordination of the proximal histidine to iron is broken; likewise, the out-of-plane distortion mode ν_8 is also shifted to higher frequency.[1288] In contrast to this behavior, bis-(N-acetylated) MP11 shows no tendency to bind more than one exogenous ligand, so the histidine ligand cannot be displaced.[1289]

An additional electronic factor that may favor the ruffled conformation for six-coordinate low-spin Fe^{III} porphyrins having the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state has been suggested.[1281] The d_{xy} orbital is orthogonal to the π orbitals of the porphyrin ring when it is planar; however, when the porphyrin ring is strongly S_4 ruffled the p_z orbitals of the four nitrogen atoms are tilted away from the normal to the mean plane of the porphyrin ring to create a small projection of the p_z orbitals (as partial p_x or p_y character) on the *xy* plane that have proper symmetry to interact with the d_{xy} orbital of the metal. Although the amount of nitrogen p_x or p_y character thus created is small, the overlap with the d_{xy} orbital of the metal should be quite efficient. The remaining nitrogen p_z orbital projections normal to the mean plane of the porphyrin have the symmetry of the near-valence $3a_{2u}(\pi)$ orbital of the porphyrin ring (Figure 4).[1281] This would allow P $\rightarrow$ Fe π back-bonding to occur, producing the observed tendency (in terms of both NMR shifts and EPR *g*-values) toward π-cation radical character of the bis(*t*-butyl isocyanide)[1218] complexes of $OEPFe^{III}$, $TPPFe^{III}$, and $TMPFe^{III}$ and of the bis-pyridine complex of tetra-(*meso*-*n*-C_3F_7)porphyriniron(III)[621] mentioned in Section 6.3.1, and would tend to reinforce the tendency toward S_4 ruffling. However, investigations of the highly saddled octaalkyltetraphenylporphyrin complexes of Fe^{III} bound to two 4-cyanopyridine[943] or *t*-butylisocyanide[1290] axial ligands have shown that although the porphyrinate ring shows no ruffling for [OMTPPFe(*t*-BuNC)$_2$]ClO_4,[1290] the g-values of that complex and the related ones, [OETPPFe(*t*-BuNC)$_2$]ClO_4 and [TC_6TPPFe(*t*-BuNC)$_2$]ClO_4,[1290] are the same ($g_\perp = 2.19 - 2.20$, $g_\parallel = 1.94 - 1.96$) as those of [OEPFe(*t*-BuNC)$_2$]ClO_4,[1218] [TPPFe(*t*-BuNC)$_2$]ClO_4[1218] and [TTPFe(2,6-XylylNC)$_2$]ClO_4.[1219] Similarly, the [OMTPPFe(4-CNPy)$_2$]ClO_4 and [TC_6TPPFe(4-CNPy)$_2$]ClO_4 complexes[943] have very similar axial EPR spectra ($g_\perp = 2.49$, $g_\parallel = 1.6$) to those of [TMPFe(4-CNPy)$_2$]ClO_4[1280] and [TPPFe(4-CNPy)$_2$]ClO_4,[1281] although in the 4-CNPy case it was not possible to obtain structures of the low-spin form, since the crystals were grown at ambient temperatures, where [OMTPPFe(4-CNPy)$_2$]ClO_4 is intermediate spin, $S = 3/2$.[943] However, although the EPR values are the same, indicating the same metal orbital for the unpaired electron (d_{xy}), ^{1}H NMR studies showed significantly less spin delocalization to the $3a_{2u}(\pi)$ orbital of the porphyrinate ring for these saddled porphyrinates.[943,1290] Thus, it must be concluded that a ruffled geometry may well stabilize the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state, but is not necessary for its existence.[1290]

Bis-cyanide complexes of iron(III) synthetic and natural porphyrins have been studied for many years, and were assumed to have the more common $(d_{xy})^2(d_{xz},d_{yz})^3$ electron configuration,[168,1223] but within recent years there have been increasing numbers of reports of the stabilization of the less common $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configuration, often by bulky *meso*-substituents, including in increasing tendency the series H, Me, Et, *i*-Pr,[1291] for which the pyrrole-H NMR resonance is found at -21.7, 8.7, 8.3, 12.8 ppm, respectively, at 248 K in CD_2Cl_2-CD_3OD,[1291] the (1R)-*cis*-caronaldehyde acid methyl ester,[1292] for which the pyrrole-H NMR resonance is found at 11.1, 10.6 ppm,[1292] and the cyclohexyl group,[1293] for which it is found at 12.0 ppm[1293] at 293 K in CD_3OD, respectively, both compounds with very small temperature dependence.[1292,1293] Of all of these listed compounds, only the H-substituted (porphine) complex[1291] clearly has the more common electron configuration, while all of the *meso*-alkyl substituted complexes have the unpaired electron in the d_{xy} orbital, as is also shown by the g-values ($g_{max} = 3.65$ for the porphine complex, $g_\perp = 2.43$, $g_\parallel = 1.73$ for the *meso*-*i*-Pr complex[1291]). The d_{xy} ground state appears to be stabilized by hydrogen-bonding solvents,[1291–1294] and even the original work on the bis-cyanide complexes of $OEPFe^{III}$ and $TPPFe^{III}$ by La Mar, Del Gaudio and Frye showed that there was an overall positive bias of the chemical shifts of the porphyrin as the solvent hydrogen-bonding donor strength increased.[1223] All complexes mentioned above show negative pyrrole-H shifts when non-hindered imidazole ligands are bound to iron instead of cyanide.[1291–1293] Bulky *meso*-aryl substituents also produce what appears to be a $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configuration for the bis-cyanide complex, with $g_\perp = 2.47 - 2.45$ and $g_\parallel = 1.5$ for Me, Et or *i*-Pr groups at the 2,4,6-R-phenyl positions of $TPPFe^{III}$; the pyrrole-H resonance shifts from -11.7 to -5.7 to $+4.4$ to $+6.0$ for the series R = H,

Me, Et, *i*-Pr, respectively.[1295] Nakamura and coworkers have shown the large variation in ^{13}C shifts, for example of the *meso*-carbons of the porphyrin ring, as the electron configuration of the metal changes from $(d_{xy})^2(d_{xz},d_{yz})^3$ to $(d_{xz},d_{yz})^4(d_{xy})^1$ upon change of axial ligand or porphyrin or phenyl substituent,[1291,1295–1297] and this large variation makes it all the more challenging to attempt to calculate the NMR shifts of various nuclei using DFT methods, although two first attempts have been reported.[1298,1299]

Introducing only one *meso*-substituent into $[OEPFe(CN)_2]^-$ yields a shift in the *trans-meso*-H resonance from $+5.5$ ppm to -10.5 ppm at 298 K in the order –CN > –C(O)H > $-NO_2$ > –H > $-C_6H_5$ > –Cl > $-OCH_3$ > $-n$-Bu, and in the *cis-meso*-H resonance from 3.3 ppm to -17.2 ppm in the order –H > –CN > –C(O)H > $-NO_2$ > $-C_6H_5$ > –Cl > $-OCH_3$ > $-n$-Bu.[1300] The bis-cyanide complex of the -H substituted complex (OEP itself) was shown to have the $(d_{xy})^2(d_{xz},d_{yz})^3$ electron configuration many years ago,[1223] so it appears that electron-donating (or bulky) substituents relative to – H shift the electron configuration toward that of $(d_{xz},d_{yz})^4(d_{xy})^1$. Variations in the methylene-H resonances through the series are also observed.[1300] The high-spin chloroiron(III) complexes of these *mono-meso*-substituted OEPs also show quite altered NMR spectra, as well as structures that are no longer domed, as seen for OEPFeCl.[1300] And finally, modification of a pyrrole ring, as in quinoxalineotetraphenylporphyrin (quinoxaline = the N–C–C–N atoms of pyrazine fused to the β,β' positions of one pyrrole ring), also creates a $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configuration for the bis-cyanide and -pyridine complexes (with the exception of the high-basicity pyridine, $4\text{-}NH_2Py$, which, along with ImH, produce the more common electron configuration).[1301] The deviation of the temperature dependence of the ^1H NMR shifts of the bis-cyanide complex from Curie behavior has been suggested to be due to Boltzmann population of four electron configurations:

$$\begin{aligned}(d_{xz})^2(d_{yz})^2(d_{xy})^2(a_{2u})^1 &\rightleftharpoons (d_{xz})^2(d_{yz})^2(d_{xy})^1(a_{2u})^2 \\ &\rightleftharpoons (d_{xz})^1(d_{yz})^2(d_{xy})^2(a_{2u})^2 \\ &\rightleftharpoons (d_{xz})^2(d_{yz})^1(d_{xy})^2(a_{2u})^2 \qquad (24)\end{aligned}$$

In comparison to these cases, the mono-pyrrole-substituted derivatives of $[TPPFe(CN)_2]^-$ show 3-H resonances (the adjacent pyrrole position to that of the substituent) that shift from -44 to -1.5 ppm at 293 K in CD_3OD in the order $-O^-$ > $-NH_2$ > $-NHCH_3$ > –OH > $-OCH_3$ > $-CH_3$ > OBz > –Cl > –Br > –CN > $-NO_2$ > $-Py^+$ > PPh_3^+.[978] Although not recognized at the time of publication of this work, there is likely an increase in the contribution of the $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configuration through this series, for the substituents to the right of $-OCH_3$ in this list show increased alternation in the phenyl-H shifts to produce shift differences $\delta_m-\delta_p$ and $\delta_m-\delta_o$ that are increasingly positive,[978] indicating increasing spin density at the *meso*-carbons that is characteristic of contribution from the less common electron configuration.[195] The bis-cyano complex of 5,10,15,20-tetraphenyl-21-oxaporphyriniron(III), however, shows pyrrole-H shifts that are totally consistent with the more common $(d_{xy})^2(d_{xz},d_{yz})^3$ electron configuration.[536] Interestingly, to the knowledge of the authors, there have been no reports of molecular structure determination of $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configuration bis-cyanide complexes, which would be expected to have highly ruffled porphyrinate rings.

Iron(III) complexes of reduced hemes have been claimed to stabilize the $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state much more readily than iron porphyrinates.[1285,1286] However, in some cases this may be more a result of the choice of axial ligands than to the electronic nature of the reduced heme ligand. It is now clear that iron(III) chlorins, when bound to imidazole,[1274] dimethylphenylphosphine[1302] or aliphatic amine ligands,[1303] have the same electronic ground state as iron(III) porphyrins, that is, $(d_{xy})^2(d_{xz},d_{yz})^3$, whereas when bound to cyanide ions,[61–65,1282,1304] a somewhat different pattern of spin delocalization and thus electron configuration seem to be present. In the case of the bis-cyano complex of siroheme this appears to be a fairly pure $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configuration, and even the mono-cyano complex of the sulfite reductase heme domain (SiR-HP) has shifts that are indicative of this electron configuration,[1304] whereas the mono-cyano complexes of other histidine-bound heme proteins, including met-myoglobin, peroxidase and heme oxygenase, have totally different heme resonance shifts that are indicative of the $(d_{xy})^2(d_{xz},d_{yz})^3$ electron configuration.[1305] However, when bound to the sulfite anion (the substrate) the SiR–HP–SO_3^{2-} shifts are more typical of the $(d_{xy})^2(d_{xz},d_{yz})^3$ electron configuration.[1304]

An interesting case of orbital ground state, one in which the ground state is different from the electronic state that is stable at ambient and physiological temperatures, is the case of the heme oxygenase model developed first by Tajima and coworkers,[999–1001] $[TPPFe(OCH_3)(OO\text{-}t\text{-}Bu)]^-$, which has more recently been examined in detail by pulsed EPR and ^{13}C NMR spectroscopy by Rivera and coworkers.[1002] As mentioned in Section 6.1.1, either a single methoxide or alkyl peroxide ligand alone bound to $TPPFe^{III}$ creates a high-spin complex, $S = 5/2$. However, two of either one or the combination of one of each of the two ligands were shown to yield EPR spectra of an $S = 1/2$ center with very compressed g-values (2.311, 2.150, 1.953 for the mixed-ligand complex).[999–1002] Because these g-values were in between those shown by bis-4-CNPy and bis-*t*-BuNC complexes, both of which have $(d_{xz},d_{yz})^4(d_{xy})^1$ ground states, it was postulated that the methoxide-alkyl peroxide complex, as well as the imidazole-peroxide complex that would be a more direct model of the active form of heme oxygenase,[33,34] might also have a $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state, which, in the natural protohemin, should lead to large ruffling of the porphyrin ring.[1002] This ruffling would bring the terminal oxygen of

the peroxo-bound complex much closer to the *meso*-carbon to be attacked, and the large spin density at that *meso*-carbon in a $(d_{xz},d_{yz})^4(d_{xy})^1$ ground-state heme center could contribute to a possible radical attack by the terminal oxygen of O_2^{2-} or OOH^- on the *meso*-carbon to begin the breakdown of heme.[1002] However, pulsed EPR studies conclusively showed that at 4.2 K the ground state of this model heme complex, $[TPPFe(OCH_3)(OO\text{-}t\text{-}Bu)]^-$, has the more common $(d_{xy})^2(d_{xz},d_{yz})^3$ electron configuration, which should favor a more planar heme.[1002] In spite of this finding, ^{13}C NMR investigations of the *meso*-^{13}C-labeled version of this model heme complex showed that over the temperatures of the NMR investigations (183–303 K) there is a thermodynamic equilibrium between the heme complexes with $(d_{xy})^2(d_{xz},d_{yz})^3$ and $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configurations (and thus also likely between planar and ruffled heme rings) that makes the latter the most stable at physiological temperatures, where heme oxygenation takes place;[1002] hence the hypothesis of a role for the $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configuration in the mechanism of action of heme oxygenase is supported by the data obtained,[1002] and further investigations of this and related systems should be carried out.

A different type of nonplanarity, which is called saddling, the S_4 saddle (sad) deformation, is enforced by β-substituted tetraphenylporphyrins, including octa-(β-alkyl)TPP derivatives[391] (except for one[1306]) or β-Cl_8- or β-Br_8TPP derivatives and β-substituted TPPs having 2,6-phenyl substituents such as 2,4,6-trimethylphenyl (mesityl),[1307] 2,6-dichlorophenyl,[405] and pentafluorophenyl[1308] groups. Structures of Br_8TMPH_2, Br_8TMPNi^{II}, and $Br_8(F_5)_4TPPNi^{II}$ reveal that these complexes are extremely saddled, with the porphyrin nitrogens alternating above and below the plane, and the phenyl rings canted at some angle less than 90° to the porphyrin plane, in order to accommodate the eight large β substituents.[1309] This canting of the phenyl rings in turn enforces the saddle ruffling of the porphyrin ring. The Soret peak of tetraarylporphyrins is strongly red-shifted upon substitution of the eight β-pyrrole positions by alkyl, chloro, or bromo groups.[391,1307–1309] AM1 molecular orbital calculations have shown that the saddle conformation of Br_8TPPH_2 is 59 kJ mol^{-1} more stable than the corresponding planar conformation.[1310] The difference in energy of planar and saddle conformations of Cl_8TPPH_2, however, is less (12 kJ mol^{-1}).[1310] These calculations also show that the energy gap between the HOMO and the LUMO is very little modified by the nature (H, Cl, or Br) of the β substituents, while there is a large shift to lower energy of both the HOMO and LUMO when going from H_8TPPH_2 to Br_8TPPH_2.[1310] However, these calculations also suggest that the *meso* carbons should be in the mean plane of the porphyrin, while X-ray data clearly indicate that the *meso* carbons are 0.1–0.5 Å out of the mean plane.[391,1309] For the Zn^{II} analogs the order of energies of a_{1u} and a_{2u} is reversed for the β-halogenated TPP complexes, making a_{2u} the HOMO in each case.[1310] β-Octafluoro TPP complexes of several first-row transition metal complexes have also been prepared and their molecular structures and ^{19}F NMR spectra investigated.[1311]

The first structures of the chloroiron(III) complex of a β-chlorinated porphyrin, $[Cl_8TMPFeCl]$, and its β-brominated analog have been reported,[1312] and similar complexes with perfluorinated phenyl rings have also been synthesized and characterized structurally.[598,1311] In each case the metal is 0.55 Å above the (distorted) mean plane of the porphyrin, with the C_β atoms being displaced from the mean plane by 0.87 and 0.91 Å, respectively,[598] slightly less than in the metal-free analogs (0.90 and 0.95 Å, respectively).[1309] It would be interesting to see what the conformation of low-spin six-coordinate Fe^{III} complexes would be, if they could be stabilized against the autoreduction that is typically observed when Lewis bases are added to these β-halogenated $TPPFe^{III}$ complexes.[598]

6.3.3 *The Preferred Orientation of Planar Axial Ligands Bound to Low-spin Iron(III) Porphyrins*

During the past few years there have been a number of investigations of the factors that affect the relative orientations of planar axial ligands in Fe^{III} and Fe^{II} porphyrins.[193,194,486,575,586,613,615–1207,1224,1268,1269,1280,1313–1316] One of the main reasons for interest in this question is that among the bis(imidazole)heme-containing cytochromes with known molecular structures that are involved in electron transfer (cytochromes b_5[1248] and c_3[1250,1251]), two types of limiting structures and two types of EPR spectra have been observed. Cytochrome b_5[1248] and three of the four hemes of cytochromes c_3[1250,1251] have the imidazole rings of the two coordinated histidines in nearly parallel planes, while one heme in each of the cytochromes c_3 for which structures are available has the imidazole rings in nearly perpendicular planes.[1250,1251] The EPR spectra of cytochromes b_5[1317–1319] and three of the hemes of the cytochromes c_3[1320–1324] are rhombic, with $g_z \sim 2.9$–3.0, $g_y \sim 2.25$–2.35, and $g_x \sim 1.4$–1.6, typical of the class of heme proteins called 'B Hemichromes' by Blumberg and Peisach.[1325] The fourth has a single feature EPR signal at $g = 3.3$–3.7[1320] that others have called a HALS (highly anisotropic low-spin[1326–1328]) signal and that we have called the 'strong g_{max}[1329]' or 'large g_{max}[486]' signal. The 'large g_{max}' name is now preferred, because the only spectral feature observed generally has a g-value of 3.3 or larger, and the signals are extremely weak compared to normal rhombic signals, as a result of the fact that the transition probability at that maximum g-value depends upon the sum of the squares of the other two g-values divided by the 'large g_{max}' value.[1330,1331] In the case of 'large g_{max}' species, g_x and g_y are much smaller than for normal rhombic signals, while g_z is much larger, and thus all factors lead to much lower signal intensity for the 'large g_{max}' species. An example of this type of EPR spectrum, and a typical rhombic 'B Hemichrome' EPR spectrum, are included in Figure 11. In addition, there are a number of membrane-bound

cytochromes b, including the two b cytochromes of mitochondrial 'Complex III' (also known as ubiquinone-cytochrome c oxidoreductase), as well as chloroplast cytochrome b_6, which also have bis-histidine coordination to the hemes in each case.[1332,1333] These cytochromes b also have 'large g_{max}' EPR spectra[1334–1336] and a wider range of reduction potentials than observed for the cytochromes b_5, b_2, and the b heme of sulfite oxidase, all of which have rhombic, typical 'B Hemichrome', EPR spectra. The reduction potentials of the four hemes of cytochromes c_3 vary over a range of ~200–300 mV,[1320,1337] raising the question as to whether there is a relationship between the axial-ligand plane orientations and their reduction potentials. Zarić and coworkers have surveyed the Protein Data Bank for structures of heme proteins that have at least one histidine ligand, and have interpreted the data obtained with molecular force field computations.[1338] It was found that the imidazole ring of histidine makes important interactions with the propionic acid side chains of the heme and with the histidine backbone. The hydrogen-bonding pattern is obviously not decisive, though it is probably used by nature to fine-tune the orientation of imidazole axially ligated to heme. The imidazole adopts a preferred orientation with respect to its histidine backbone such that the plane of the imidazole ring is practically never parallel to the C_α–C_β bond of its histidine backbone. The interaction of the imidazole with the backbone also influences the orientation of the imidazole with respect to the heme. It was shown that there is an energy minimum when the N-H group of the imidazole is oriented toward the propionic acid groups, and there are energy minima for orientations where the imidazole ring is orthogonal to the plane defined by the C_α–C_β and C_β–C_γ bonds of the histidine, and that these interactions are mainly of electrostatic origin.[1338]

Investigation of the molecular structures, EPR spectra and in some cases Mössbauer spectra of well-defined low-spin Fe^{III} heme model compounds has provided conclusive proof that the 'large g_{max}' EPR signal is correlated with near-axial symmetry,[193,194,486,1224] and in the case of planar axial ligands, with perpendicular alignment of these ligands.[486,1204–1207,1339] The first investigation of this type[486] was of $[TPPFe(ImH)_2]^+$ Cl^-,[612] in which the axial ligands are in parallel planes, and $[TPPFe(2\text{-}MeImH)_2]^+$ ClO_4^-,[618] in which the axial ligands are in perpendicular planes. EPR spectra of crystals from the same batches as those from which the structures were determined showed two overlapping rhombic EPR signals for $[TPPFe(ImH)_2]^+$ Cl^-,[486] consistent with the fact that the crystals contained molecules with two different projections of the parallel imidazole planes on the porphinato core, one molecule having an angle of 6° and the other an angle of 41° to the N_1–N_3 axis.[612] In contrast, the EPR spectrum of crystals of $[TPPFe(2\text{-}MeImH)_2]^+ClO_4^-$ gave a 'large g_{max}' feature at $g = 3.41$;[486] in this case the 2-methylimidazole ligand planes are aligned at 89° to each other, with angles of 32° and −58° to the N_1–N_3 axis of the porphinato core.[618] Mössbauer spectra at 4.2 K in an applied magnetic field (500 G to 6 Tesla) allowed estimation of the two unresolved g-values.[486] In fact, magnetic Mössbauer spectra measured at 4.2 K in a large applied magnetic field (6–7 Tesla) have been very helpful in estimating the two unresolved g-values in a number of model heme systems.[193,194,486,1204,1340,1341] Mössbauer isomer shifts and quadrupole splittings have been calculated using DFT methods for low-spin Fe^{III} as well as other spin states from $S = 0$ to 5/2.[1342,1343]

From the Griffith theory[1265,1266] for the g-values of low-spin Fe^{III}, using the formulation of Taylor,[1267] *Ligand Field Theory* calculations of the relative energies of the d_{xy}, d_{xz}, and d_{yz} orbitals for the two complexes and the idealized parallel and perpendicular orientations of the axial imidazoles were carried out.[486] The crystal field parameters ('Rhombic splitting,' V/λ 'Tetragonality,' Δ/λ, and 'Rhombicity,' V/Δ) can be obtained from the three g-values of the rhombic spectra. The energy separation of the three formerly t_{2g} orbitals of strictly octahedral symmetry, split by the lower-symmetry field of the ferriheme center, in units of the spin-orbit coupling constant λ, can be estimated from the following expressions:[1267]

$$\frac{V}{\lambda} = E_{yz} - E_{xz} = \frac{g_{xx}}{g_{zz} + g_{yy}} + \frac{g_{yy}}{g_{zz} - g_{xx}} \tag{25}$$

$$\frac{\Delta}{\lambda} = E_{yz} - E_{xy} - \frac{1/2V}{\lambda} = \frac{g_{xx}}{g_{zz} + g_{yy}} + \frac{g_{zz}}{g_{yy} - g_{xx}} - \frac{1/2V}{\lambda} \tag{26}$$

The results confirmed that parallel alignment gives the more stable structure. In that work[486] it was also concluded that perpendicular alignment of planar axial ligands could lead to a positive shift in reduction potential of up to about 50 mV over that observed for parallel alignment, all other structural and environmental factors being equal.[486] However, that conclusion relied upon the assumption that parallel and perpendicular ligand plane orientations would be of equal energy for the Fe^{II} complexes, which is now known not to be the case,[575] as discussed in Section 4.1.2 above.

Following that first study of the relationship between EPR spectral type and axial-ligand plane orientation,[486] Strouse and coworkers showed by single-crystal EPR spectroscopy that in cases of parallel alignment of imidazoles bound to low-spin Fe^{III} porphyrins, 'pseudo-Jahn–Teller' distortion (*see Jahn–Teller Effect*) of the porphyrin ligand, particularly in cases where the projection of the imidazole plane on the porphyrin ring makes a small angle with the N_1–N_3 axis, can contribute significantly to the rhombic splitting;[1268,1269] an extension of this has been published recently.[1344] Strouse and coworkers also found that while crystal field stabilization of the parallel orientation is significant for axial ligands such as imidazoles that are strong π donors, for weak π donors, such as pyridine, and nonplanar ligands, such as cyanide, spin–orbit stabilization of the complexes results in equal or nearly equal population of the d_{xz} and d_{yz} orbitals.[1224] Even strong π donor pyridine ligands, such as 4-dimethylaminopyridine, can be forced to bind in perpendicular planes if bulky groups are placed on the 2,6-phenyl positions

of TPP, as in $TMPFe^{III}$, Figure 10 top, and again, a 'large g_{max}' EPR signal is observed, in this case at $g = 3.48$.[1204] Lower-basicity pyridines (decreasing $pK_a(BH^+)$ in the order 4-NH_2Py, 3-EtPy, 3-ClPy, 3-CNPy, and 4-CNPy) have also been shown to bind to $TMPFe^{III}$ in perpendicular planes, but the g-values of the 'large g_{max}' signals shift to progressively smaller values as the basicity of the pyridine decreases (from 3.48 for 4-NMe_2Py to 2.53 for 4-CNPy (but see below)).[1280] The Mössbauer quadrupole splittings of the less-basic pyridine ligand complexes of $TMPFe^{III}$ also become smaller as the basicity decreases (1.75–0.97 $mm\,s^{-1}$ for the same series of pyridines).[1280] The ^1H NMR spectra also change in a linear manner with the pK_a of the ligand (the pyrrole-H resonance shifts from −30.9 to +2.21 ppm at – 80 °C for the series 4-NMe_2Py to 4-CNPy).[1280] Nevertheless, all of these complexes have extremely similar molecular structures, with ruffled porphyrinate rings ($|\Delta C_m| = 0.36–0.43$ Å), large ϕ angles of 29 to 44° and $\Delta\phi$ angles of 90, 87, and 77° for the 3-EtPy, 4-CNPy and 3-ClPy complexes, respectively.[1280] The Fe–N_P bond lengths in all cases are again shorter (1.961–1.966 Å)[1280] than expected for iron porphyrinates having planar porphyrin cores (∼1.988–2.002 Å). Axial ligand-Fe bond lengths vary slightly (1.989, 2.002; 2.001, 2.002; 2.018, 2.006 Å, respectively) but non-systematically for the three complexes.[1280] Because the type of EPR signal of the bis-(4-cyanopyridine) complex is not 'large g_{max}' but rather axial, with $g_\perp = 2.53$, $g_\parallel = 1.56$, and the pyrrole-H chemical shift at – 80 °C is not negative, but rather +2.1 ppm, the results for the entire series of complexes were interpreted as being indicative of a smooth change in the electron configuration of the low-spin Fe(III) porphyrinates from $(d_{xy})^2(d_{xz},d_{yz})^3$, with small energy difference between d_{xz} and d_{yz}, toward $(d_{xz},d_{yz})^4(d_{xy})^1$ as the basicity of the pyridine ligand decreases from pK_a of the conjugate acid = 9.7 to 1.1.[1280] Study of the low temperature MCD spectra of $[TMPFe(4\text{-}CNPy)_2]^+$[1345] and of the corresponding $[TPPFe(4\text{-}CNPy)_2]^+$ complex by X-ray crystallography,[1281] EPR,[1281] Mössbauer,[1281] and NMR[1346] spectroscopies confirmed that the electronic ground state of both of these complexes at low temperatures is the less common $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configuration discussed above in Section 6.3.1. Separately it was shown that for the Fe^{III} complexes of TPP, TMP and its larger alkyl analogs having 2,4,6-ethyl or isopropyl substituents on the phenyl rings, the g_{max} values for the bis-2-MeImH and -benzimidazole complexes shift from 3.40 to 3.13, 3.17, 3.08 and 3.43 to 2.89, 2.91 and 3.01, respectively;[1296,1297] there thus appears to be a tendency for highly ruffled iron(III) porphyrinates with bulky planar ligands in perpendicular planes to move from a pure $(d_{xy})^2(d_{xz},d_{yz})^3$ state toward a $(d_{xz},d_{yz})^4(d_{xy})^1$ state as the degree of ruffling distortion increases, even when the axial ligands are strong σ and π donors.

The isolation of two crystalline forms of $[TMPFe(5\text{-}MeImH)_2]ClO_4$ showed that one form had the axial ligands in approximately parallel planes ('*paral*', $\Delta\phi = 26$ and 30° for the two molecules in the unit cell), while the other had the axial ligands in approximately perpendicular planes ('*perp*', $\Delta\phi = 76°$),[1205] but in fact both of these observed dihedral angles are markedly different from the ideal values of 90° for perpendicular and 0° for parallel.[1205] The planes of the axial imidazoles of *perp*-$[TMPFe(5\text{-}MeImH)_2]^+$ are tilted (by 12.5° and 7.6°) from the heme normal. It is probable that crystal packing effects and/or hydrogen-bonding of the non-coordinated 5-MeImH molecules in the lattice to the N-H proton of the coordinated imidazoles may influence whether the ligands bind in an off-axis manner, since not all mono- and bis-imidazole complexes show this type of distortion. Off-axis binding of imidazole (histidine) ligands has also been seen in a number of heme proteins. *Perp*-$[TMPFe(5\text{-}MeImH)_2]^+$ has a small Mössbauer quadrupole splitting ($\Delta E_Q = 1.78$ $mm\,s^{-1}$ at 120 K) and a 'large g_{max}' EPR signal at g = 3.43, while *paral*-$[TMPFe(5\text{-}MeImH)_2]^+$ has a larger quadrupole splitting ($\Delta E_Q = 2.56$ $mm\,s^{-1}$ at 120 K) and a rhombic EPR signal (g = 2.69, 2.34–2.43, 1.75) in the crystalline state.[1205] These values are similar to those observed for ferriheme centers bound to one imidazolate anion and one neutral imidazole,[1347] and it is interesting to note that one of the 5-MeImH ligands is hydrogen-bound to a 5-MeImH molecule in the lattice in this structure, thus probably imparting partial imidazolate character to that ligand in each of the molecules in the unit cell.[1205]

Molecular mechanics calculations on *paral*- and *perp*-$[TMPFe(5\text{-}MeImH)_2]^+$ provided information about the relative stability of these two non-ideal axial-ligand plane orientations: it was found that to have two ligands in parallel planes with ϕ_1, $\phi_2 = 45°$ and a planar porphyrin core is the maximum energy conformation, while having the two ligands in perpendicular planes with $\phi_1 = -45°$, $\phi_2 = 45°$ with a ruffled core is the minimum energy.[1205] The observed ligand orientation in *perp*-$[TMPFe(5\text{-}MeImH)_2]^+$ ($\phi_1 = -46°$, $\phi_2 = 30°$, $\Delta\phi = 76°$) has an energy only 0.4 kcal/mol higher than the minimum. Having the conformation exhibited by *paral*- $[TMPFe(5\text{-}MeImH)_2]^+$ yields a calculated energy of ∼2.6 $kcal\,mol^{-1}$ above the global minimum, and this conformation is close to the local maximum with ligands over a pair of trans Fe–N_P vectors (ϕ_1, $\phi_2 = 0°$).[1205] Thus, the orientation of axial ligands in *paral*- and *perp*-$[TMPFe(5\text{-}MeImH)_2]^+$ are within ∼2–3 $kcal\,mol^{-1}$ of each other according to the molecular mechanics calculations, with the 'parallel' being slightly higher in energy. However, for low-spin d^5 systems the 'parallel' axial-ligand orientation is stabilized by the Jahn-Teller effect by the rhombic splitting of d_{xz} and d_{yz}, $V = 2–3\lambda$, where λ is the spin-orbit coupling constant for low-spin Fe^{III}. With $\lambda = 400$ cm^{-1}, or 1.14 $kcal\,mol^{-1}$, this stabilization is 2.3–3.4 $kcal\,mol^{-1}$, a stabilization for which molecular mechanics calculations do not account. In this work[1205] it was concluded that relative parallel orientation of axial-ligands is the apparently preferred orientation for most characterized low-spin Fe^{III} porphyrinates having two planar high-basicity axial ligands, with relative

perpendicular orientations being observed only in special circumstances, primarily those of introduced steric effects. The appearance, in the solid state, of ligand orientations approaching the two limiting forms speaks to a near energetic equivalence of conformational isomers. The energy balance between the two forms is the result of crystal field stabilization effects that favor the parallel form, and steric strain effects that favor the perpendicular form.[1205]

Because *meso*-only substituted ferriheme complexes (TPP, TMP, etc.) having perpendicularly arranged axial ligands lying over the *meso*-carbons tend to be highly ruffled (see also Section 6.3.2), it was hypothesized that synthetic iron porphyrinates that were designed to orient the axial ligands close to the N_P–Fe–N_P axes might be better models of the membrane-bound cytochromes,[194] which must carry out reversible redox between Fe^{III} and Fe^{II}, the latter of which strongly prefers non-ruffled porphyrin rings (see below and also Section 4.1.2). To accomplish this, a detailed study of the bis-imidazole- or bis-pyridine-ligated ferriheme complexes of the octaalkyltetraphenylporphyrins, where the alkyl substituents are methyl (OMTPP), ethyl (OETPP) and β,β'-tetramethylene (TC_6TPP), has been carried out.[1348] These dodecasubstituted porphyrin ligands all have saddled porphyrin rings, with two opposite pyrrole rings tilted above, while the other two are tilted below the mean plane of the porphyrin, thus creating two cavities that should help to encourage the axial ligands to bind in perpendicular orientation with the ligand planes lying over or close to the N_P–Fe–N_P axes; the degree of saddling increases in the order TC_6TPP < OMTPP < OETPP, as observed in approximately twenty crystal structures of bis-ligand Fe^{III} complexes.[1348] It was found that such synthetic heme complexes are rich in structural diversity, which allowed crystallization of bis-ligated iron(III) complexes having many different axial-ligand orientations and differing amounts of ruffling admixture to the largely saddled porphyrin cores.[943,1206,1207] For example, with the common non-hindered ligand, N-methylimidazole (N-MeIm), four molecular structures have been obtained, including that of $[OETPPFe(N\text{-}MeIm)_2]Cl$, which has an axial-ligand plane dihedral angle of 73.1° and a 'large g_{max}' EPR feature at $g = 3.27$; that of $[TC_6TPPFe(N\text{-}MeIm)_2]Cl$, which has an axial-ligand plane dihedral angle of 90°, small N_P–Fe–N_P angles (15.3°) yet a large ruffling component to the porphyrin core, and in frozen solution shows both a g_{max} value of 3.14 and a rhombic EPR signal with $g = 1.45$, 2.39, 2.86; that of *perp*-$[OMTPPFe(N\text{-}MeIm)_2]Cl$, which has an axial-ligand plane dihedral angle of 90° yet very large displacement from the N_P–Fe–N_P axes (29°) and has $g_{max} = 3.61$; and that of *paral*-$[OMTPPFe(N\text{-}MeIm)_2]Cl$, which has an axial-ligand plane dihedral angle of 19.5° and a normal rhombic EPR spectrum with $g = 1.54$, 2.51, and 2.71.[1207] The ORTEP and formal core diagrams of the two OMTPP and the OETPP molecules are shown in Figure 13. It is quite surprising to see that such a small dihedral angle as 19.5° can be obtained in these saddled porphyrinates, especially because the ligand in 'wrong' orientation has a very small displacement from the N_P–Fe–N_P axis (5.9°).[1207]

Among the tetramesitylporphyrin and octaalkyltetraphenylporphyrin complexes of iron(III) whose structures have been determined to date, the largest axial-ligand plane dihedral angle that has been observed for which the EPR spectral type is normal rhombic is 30°, for *paral*-$[TMPFe(5\text{-}MeImH)_2]ClO_4$;[1205] the smallest axial-ligand plane dihedral angle that has been observed for which the EPR spectral type is 'large g_{max}' is 70°, for $[OETPPFe(4\text{-}NMe_2Py)_2]Cl$,[1206] with another, $[OETPPFe(N\text{-}MeIm)_2]Cl$, at 73.1°.[1207] Thus, the switch in EPR spectral type from normal rhombic to 'large g_{max}' must occur somewhere between 30 and 70° axial-ligand plane dihedral angles.[194] For comparison to the membrane-bound cytochromes, further investigation of model systems designed to produce perpendicular alignment of axial ligands in low-spin Fe^{II} porphyrins, for example, the iron(II) analogs of the OETPP and OMTPP complexes shown in Figure 13, is needed to better understand the spectroscopic and redox properties of the mitochondrial cytochromes *b* and chloroplast cytochrome b_6, for which all ferriheme EPR signals are of the 'large g_{max}' type, strongly suggesting perpendicular orientation of the two histidines. Since it seems unlikely that axial-ligand plane orientation within the protein matrix changes upon redox (since it is expected to be stabilized by hydrogen-bonding of the histidine N–H to protein main or side chain atoms and to the typically observed close packing of protein residues around the coordinated histidine), these membrane-bound cytochromes,[7–9] and the one heme of cytochrome c_3,[1250,1251] each in their reduced state, may be some of the only examples of Fe^{II} hemes having perpendicularly aligned axial imidazole planes. Or, expressed in another way, whatever the dihedral angles are for the histidine imidazole planes of these proteins, their EPR spectra are typical of those in which the axial-ligand plane dihedral angles are 90° – 70°[1207,1348] – ~58°.[1349]

Calculation of the g-tensors of several low-spin iron(III) porphyrins that have been discussed above via DFT methods, where spin-orbit coupling has been handled by the zeroth order regular approximation to the Dirac equation, has been reported.[532] Although the g-values obtained are not in numerical agreement with those measured by EPR spectroscopy, some interesting trends are observed: (1) the relative orientation of the N-H group of the two imidazoles (or pyrazoles) affects the calculated g-values rather significantly if the ligands lie in parallel planes over two of the *meso*-carbons, but very little if they are in parallel planes over one of the N_P–Fe–N_P axes; (2) two imidazoles in perpendicular orientation lying over the porphyrin nitrogens yield much larger g-anisotropy and more nearly degenerate d_{xz} and d_{yz} orbitals than do two imidazoles in perpendicular planes lying over the *meso*-carbons; (3) the product of the three g-values, $g_x g_y g_z$, is positive for complexes having parallel, but negative for those having perpendicular axial-ligand planes; (4) pyridine ligands in parallel planes lying over one of the

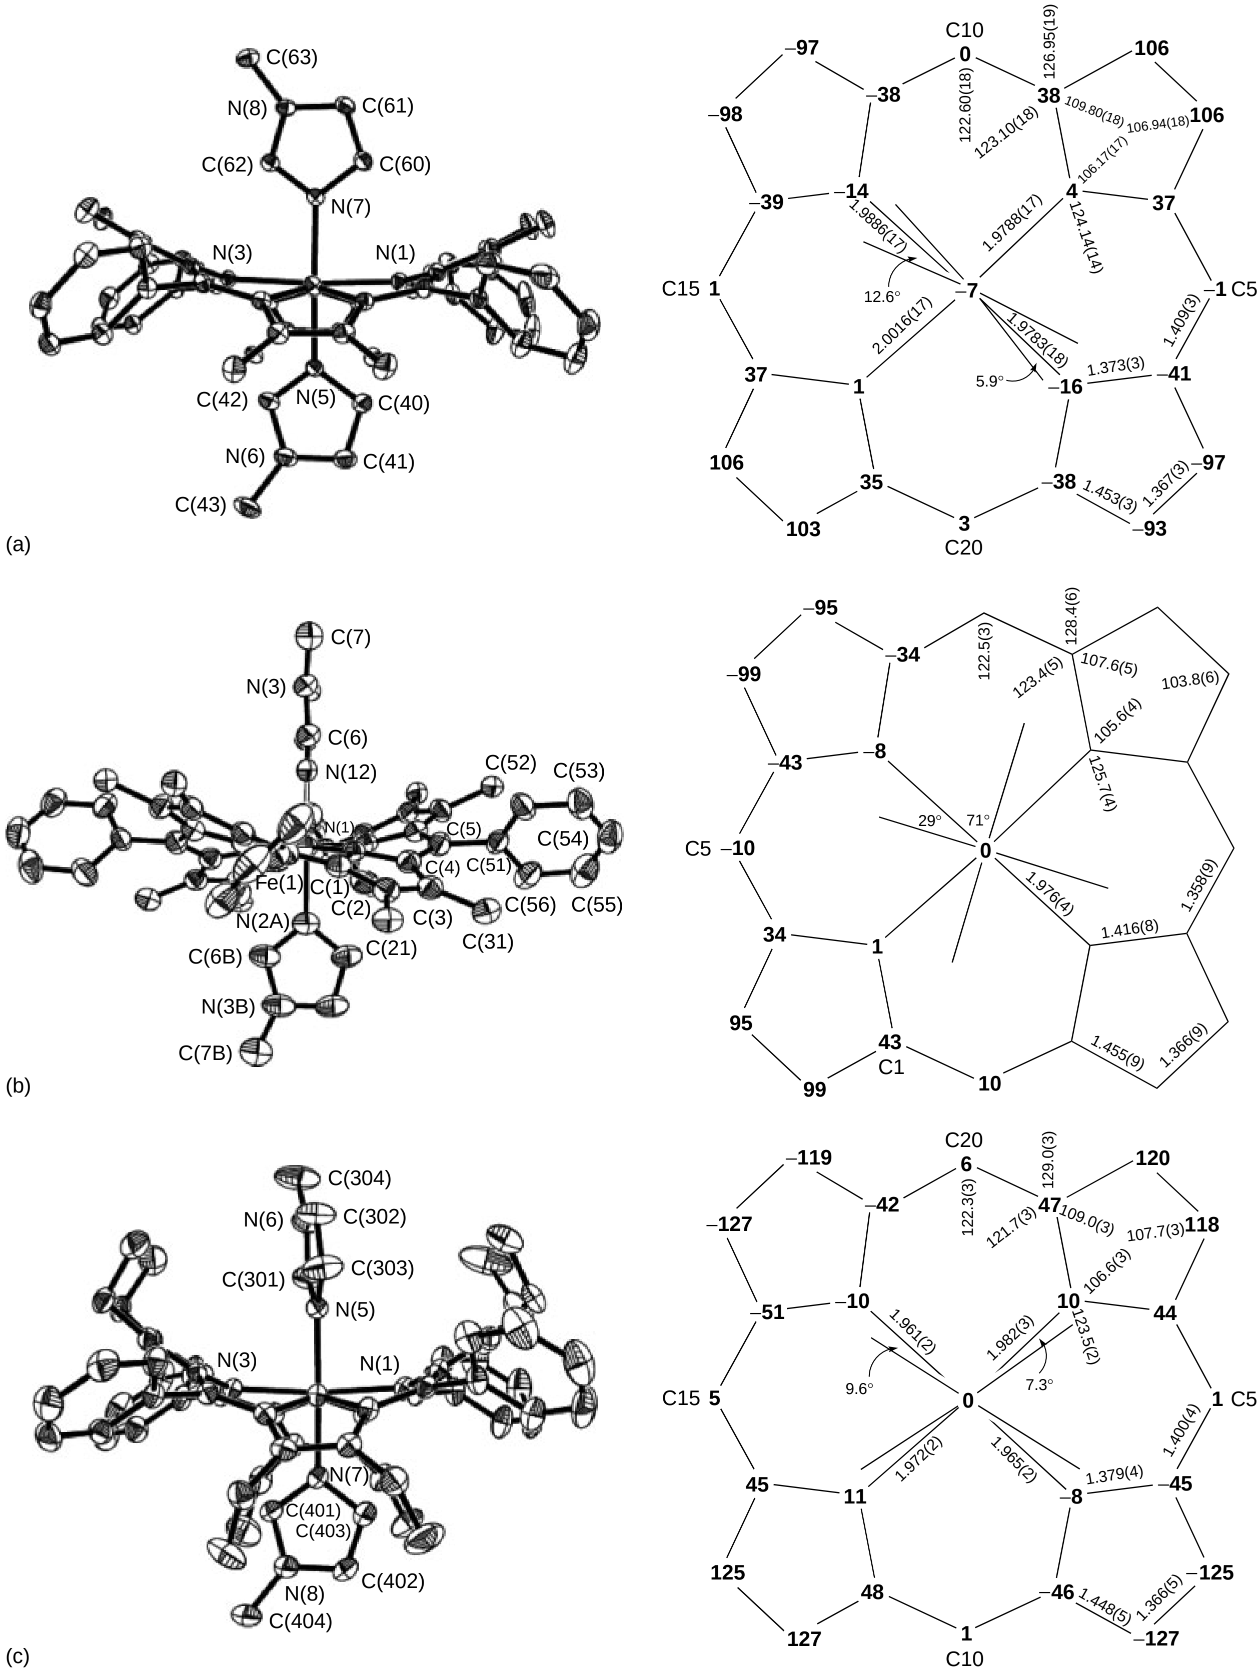

Figure 13 ORTEP and formal core diagrams of (a) *paral*-[OMTPPFe(N-MeIm)$_2$]$^+$, (b) *perp*-[OMTPPFe(N-MeIm)$_2$]$^+$, and (c) [OETPPFe(N-MeIm)$_2$]$^{+}$ [1207]

N_P–Fe–N_P axes yield a normal rhombic set of g-values, while if they lie over two opposite *meso*-carbons a 'large g_{max}' EPR signal is predicted; and (5) pyridine ligands in perpendicular planes over the N_P–Fe–N_P axes yield a predicted perfectly axial g-tensor with $g_z \gg g_x, g_y$, while pyridine ligands in perpendicular planes over the *meso*-carbons are predicted to have a perfectly axial g-tensor with $g_x, g_y \gg g_z$ and all g-values less than 2.0.[532] (These predictions do not take into account spin-orbit mixing of the three occupied d orbitals.) The sensitivity (in that case in terms of spin density) to the relative orientation of the N-H vectors of the imidazoles in parallel planes (point 1) was also shown by spin density calculations on low-spin bis-imidazole ferrihemes via DFT methods,[1350] but this should be further checked. Point 2 is interesting from the point of view of using the octaalkyltetraphenylporphyrins to investigate experimentally the effect of holding axial ligands in perpendicular planes near the N_P–Fe–N_P axes to avoid the ruffling that occurs when axial ligands in perpendicular planes lie near the *meso*-carbons.[194,1207] Point 3 is interesting because it is not possible to determine the signs of the g-values from EPR spectroscopy; Mössbauer should in principle give the relative signs and allow determining the sign of the product, as was shown some time ago by Huynh and coworkers.[1351] Points 4 and 5 suggest that additional parameters need to be introduced into the calculations involving pyridine ligands, for there are no structures known for either ferro- or ferriheme systems in which the ligands lie in parallel planes over one of the N_P–Fe–N_P axes, while if the ligands are high-basicity pyridines and they lie over opposite *meso*-carbons, a normal rhombic EPR spectrum is observed in the absence of bulky *meso*-substituents, and 'large g_{max}' EPR spectra are observed when pyridine ligands (again, high-basicity) lie either over the *meso*-carbons in the presence of bulky *meso*-substituents in perpendicular planes,[194,575,613,615,618–620,943,1193–1205,1280] or close to the N_P–Fe–N_P axes in ferric octaalkyltetraphenylporphyrins in perpendicular planes.[194,1206,1207] Recent DFT calculations have suggested that parallel and perpendicular axial-ligand orientations should be of essentially equal energy for both Fe^{III} and Fe^{II},[1352] but these findings do not explain the near absence of structures of Fe^{II} porphyrinates with perpendicular ligand orientation (see also Section 4.1.2). Other DFT calculations on ferriheme complexes have also been reported.[1353]

NMR studies of several types of low-spin Fe^{III} model hemes having restricted rotation of one or both axial ligands have demonstrated that the pattern of spin delocalization is strongly influenced by the preferred orientation of axial ligands.[175,187,193,796,1123,1124,1242,1243,1354–1360] These results are consistent with the observed patterns of heme methyl resonances of a number of ferriheme proteins,[1360] including cytochromes *c*[1361–1363] and b_5[1364] and metmyoglobin cyanide.[1365] This angular dependence of heme methyl (and *meso*-H) shifts on the orientation of the planar axial ligand(s) (or methionine π-symmetry lone pair) is caused by the preferential spin delocalization to one of the $3e(\pi)$ orbitals (Figure 4) of low-spin Fe^{III} complexes having the $(d_{xy})^2(d_{xz},d_{yz})^3$ electronic ground state, where the orientation of the nodal planes of these *e*-symmetry metal d and porphyrin π orbitals can be shifted to any angle (as long as the two orbitals have nodal planes oriented at 90° to each other), particularly that dictated by the orientation of the nodal plane of the axial ligand(s) (usually π donors). This concept and the plot shown in Figure 14, top left, have proven very valuable in predicting the orientations of heme ligands from the pattern of assigned methyl resonances of heme proteins;[1360] the program is available on the worldwide web.[1366] Besides the major contribution from the contact interaction, there is a smaller, yet important contribution from the dipolar or pseudocontact interaction, and in order to estimate the magnitude and sign of this term, the concept of counter-rotation of the magnetic axes with rotation of the planar axial ligand(s) bound to the ferriheme becomes very important.[1367] Several variants of the angular dependence shown in Figure 14, top left, have been published more recently,[1368–1371] but this simple plot remains a useful, simple means of predicting the approximate orientation of heme ligands, both in proteins[1372] and in model hemes.[1123,1359] In particular, the ^{1}H NMR spectra of the dichelated protohemin cyanide complexes reported by Traylor and Berzinis in 1980,[673] which show eight methyl resonances ranging from 20.4 to 4.8 ppm at 35 °C in DMSO-d_6, or from 30.2 to 3.7 ppm at – 57 °C in DMF-d_7, have been assigned by NOESY/EXSY, COSY, ROESY and DQF-COSY techniques and the nodal planes of the single imidazole ligand in the two isomers have been shown to lie at 100° and 170° counterclockwise of the x-axis of the hemes shown in Figure 14, bottom.[1359] Isomer **I**, with imidazole ligand plane lying at 100° to the x-axis, has heme methyl shifts in the order $3 > 8 \gg 5 > 1$, while isomer **II**, with imidazole ligand plane lying at 170° to the x-axis, has heme methyl shifts in the order $5 > 1 \gg 3 > 8$,[1359] as predicted by Figure 14, top.[1360] The $8 > 5 > 1 > 3$ heme methyl order observed for microperoxidase-8 cyanide[1373] indicates that this fragment of cytochrome *c* has an almost identical histidine ligand plane orientation to that of the cyanide complex of M80A cytochrome *c*,[1374] both with histidine imidazole plane orientation of slightly greater than 45°, whereas wild type cytochrome *c* cyanide has the order $5 > 8 > 1 > 3$,[1375] indicating a histidine imidazole plane orientation of slightly less than 45°.

DFT calculations of spin densities in low-spin ferric porphyrins have been reported, and in some cases they agree quite well with the predictions of Figure 14, but in others exactly the opposite pattern of large and small spin densities are predicted.[1350] Probably the counterintuitive cases are a result of small differences between positive and negative contributions, and additional calculations will need to be done to refine the methods and functionals so that useful predictions of the relationship between axial-ligand plane orientation and spin density distribution can be made.

The possibility that axial-ligand plane orientation might affect the reduction potentials of bis-histidine-coordinated

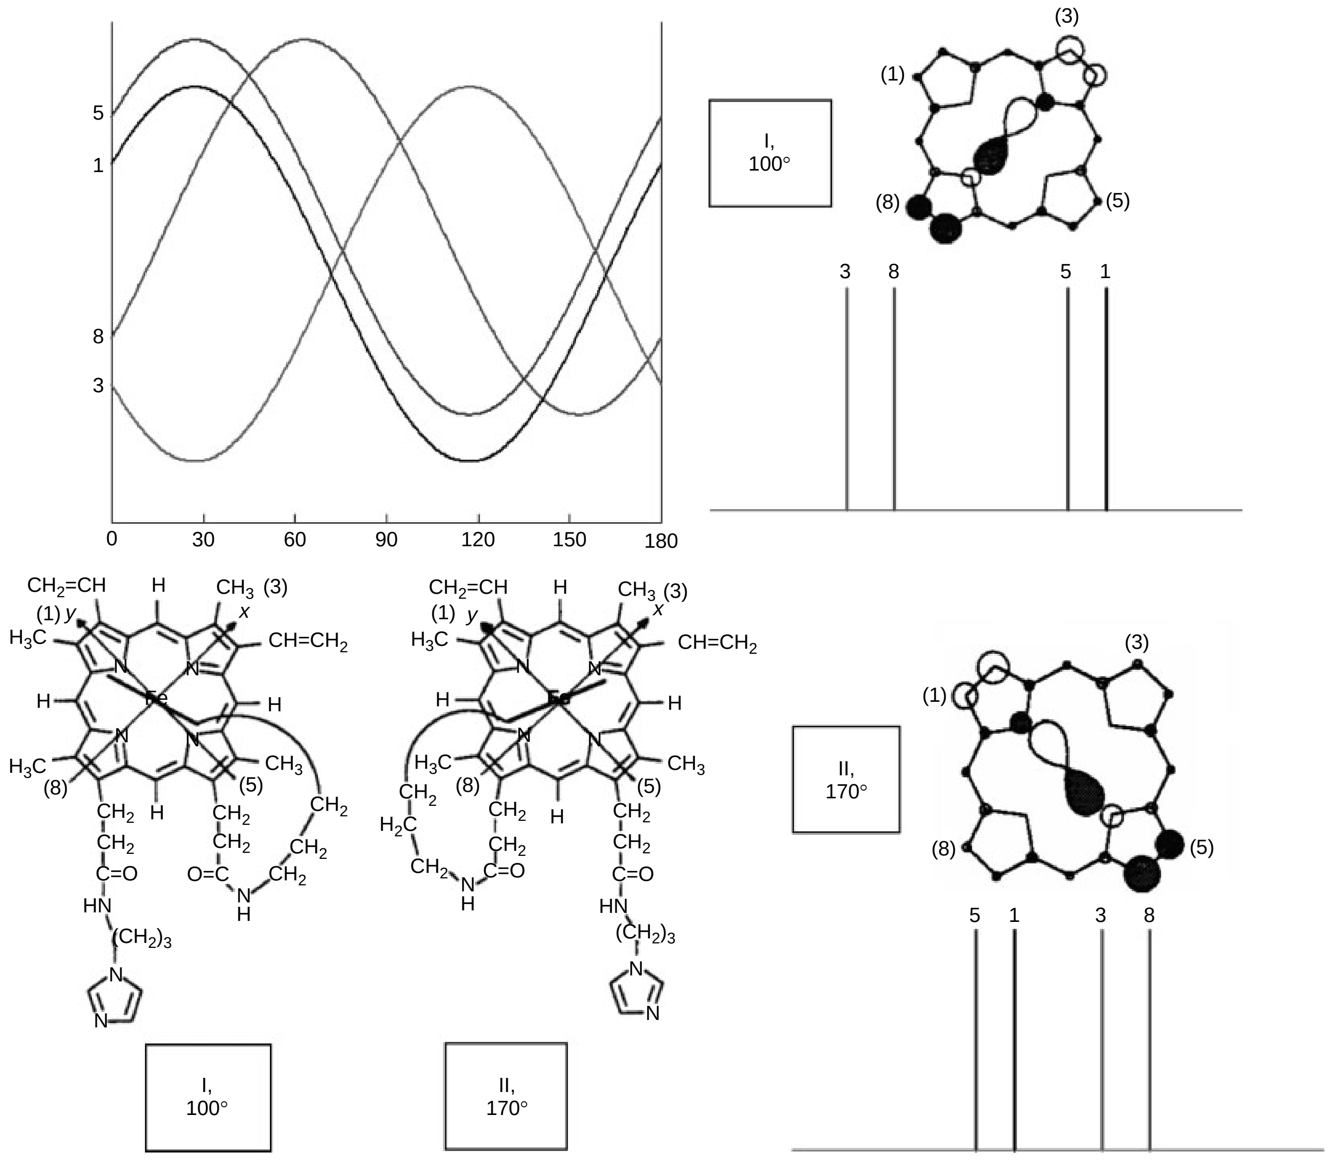

Figure 14 (a): Angular dependence of the heme methyl shifts on axial-ligand plane orientation, as measured from the x-axis of the heme, shown in (c), where the two geometrical isomers of Traylor and Berzinis,[673] here called I and II, are shown. Dihedral angles of axial-ligand planes are measured counterclockwise from the x-axis. (b): Predicted heme methyl shift patterns for isomers I (b) and II (d). Colors: Green – 5-Me, black – 1-Me, blue – 8-Me, red – 3-Me. Angular and spectral plots created with Heme Methyl Shift Patterns, a program available on the web[1359,1360,1366]

cytochromes would have to rely on the fact that the relative energies of the d orbitals of the product, Fe^{II}, remain the same as those of the reactant, Fe^{III}. While it has become clear that low-spin Fe^{III} prefers parallel alignment of planar axial ligands, one might have expected that low-spin Fe^{II} would prefer perpendicular alignment, since for low-spin d^6 there should be no obvious crystal field stabilization associated with removal of the degeneracy of d_{xz} and d_{yz}. As mentioned above in Section 4.1.2, however, of the many molecular structures of porphinatoiron(II) complexes with planar axial ligands that have been published, the vast majority have the axial ligands in parallel planes,[183,575,621] yet the structure of only one isoelectronic Co^{III} complex, [TMPCo(N-MeIm)$_2$]ClO_4, has its axial ligands in perpendicular planes.[1376] Charge iterative extended Hückel theory calculations on electronic effects for a broad selection of representative systems (HS and LS d^5, HS and LS d^6, LS d^7) indicate no preference for parallel rather than perpendicular orientation of the axial ligands, except in the case of low-spin d^5.[1316] However, they do indicate a previously unrecognized orientational preference in the M–N(imidazole) π bond, which favors eclipsed orientations.[1316] This π-bonding interaction was found to be dominated by the metal–imidazole p_π interaction,[1316] thus providing an explanation of why

axial imidazole ligands in metalloporphyrins tend to prefer sterically unfavorable orientations that eclipse equatorial M–N_p bonds.[183] DFT calculations of the energies of both Fe^{III} and Fe^{II} porphyrins with parallel versus perpendicular axial-ligand planes indicated that there is practically no difference in the energies of either oxidation state porphyrin with relative orientation of axial ligands, but the geometries were optimized, which probably means that the porphyrinate ring of the Fe^{II} complexes was planar for both parallel and perpendicular ligand planes (although the Fe^{III} complex with perpendicular ligand planes had a ruffled porphyrin plane), and again, these studies did not take into account the Jahn-Teller effect for low-spin Fe^{III}.[1377] Thus, additional calculations on low-spin Fe^{II} porphyrinates that take into account all of the factors that affect axial-ligand plane orientation must be carried out.

6.3.4 Nitric Oxide Complexes of Iron(III)Porphyrins

As discussed in Section 4.5.3, the first $\{FeNO\}^7$ structures were reported in the mid-1970s.[878,882,883] In contrast, it was some ten years later when the first structure of an $\{FeNO\}^6$ complex was reported: the structures of a five- and a six-coordinate nitrosyl complex of Fe^{III} porphyrinates ([OEPFeNO]ClO_4 and [TPPFeNO(H_2O)]ClO_4), in which the FeNO moieties have electron configuration $\{FeNO\}^6$, and are thus diamagnetic in each case, were reported in 1984.[1378] (The $\{MNO\}^n$ notation was created in 1974 by Enemark and Feltham,[875] to describe these very covalent triatomic fragments where n denotes the number of d electrons on the metal M plus the number of π^* electrons on NO, normally 1, since NO is usually considered a neutral fragment in this notation.) Since then, the structures of a number of 5- and 6-coordinate $\{FeNO\}^6$[1313,1314,1379–1382] complexes, including those of three of the NO-carrying proteins, the nitrophorins from the saliva of the blood-sucking insect, *Rhodnius prolixus*,[1383–1386] have been reported and the topic of the structures and properties of the enzymes has been reviewed.[56,57]

The nitrophorins of the kissing bug, *Rhodnius prolixus*, are unique NO-binding heme proteins, in that they are stable as Fe^{III} heme centers and are not autoreduced by excess NO in the solution as are other heme proteins such as met-myoglobin;[1387] consistent with this property, their reduction potentials are about 300 mV more negative than that of met-myoglobin ($E^\circ \sim 0$ mV vs. SHE at pH = 7.5),[1383,1388] which is easily autoreduced by NO. The function of nitrophorins in the salivary glands of at least two blood-sucking insects[56,57,1389] is to keep NO stable for long periods of time, so that whenever the insect has the opportunity to suck the blood of a mammal or bird, the NO-bound proteins can be injected into the tissues of the victim, which causes the NO to be released by dilution and increased pH to diffuse through the tissues to the capillaries, where it causes vasodilation, thus bringing more blood to the region of the bite. At the same time, in the case of the *Rhodnius* insect, the histamine released from mast cells and platelets of the victim, whose function is to cause itching and swelling and to begin the immune response, is bound by the nitrophorins, called NP1-NP4, thus preventing the detection of the biting insect for a longer period of time and thereby allowing the insect to obtain a more sufficient meal.[56] The structures of the *R. prolixus* nitrophorins show clearly that there is sufficient space in the distal cavity to allow histamine, as well as NO, to bind.[56,1390]

The molecular structures of both insect nitrophorins are unique for heme proteins; the *R. prolixus* nitrophorins have eight-stranded beta-barrel structures, as do other members of the lipocalin protein fold,[1391] closed at one end, with the heme propionates protruding from the open end of the barrel.[56,1384,1385] The heme is quite ruffled, especially when bound to NO,[1384,1385] while in model heme complexes having the same $\{FeNO\}^6$ electron configuration as NP2-NO and NP4-NO and bound to a neutral nitrogen-donor sixth ligand, the heme is planar or slightly domed, with Fe slightly displaced (0.01–0.06 Å) from the plane of the four porphyrin nitrogens in the direction of the axial NO ligand.[1378,1380] The Fe-N-O angle in the models, as well as the proteins, is near linear (but in the proteins is affected by the degree of photoreduction of the heme center by the X-rays); $\{FeNO\}^6$ centers are normally linear or near linear, while $\{FeNO\}^7$ centers are typically quite bent, with angles in the 120–145° range.[185] The NO stretching frequency of $\{FeNO\}^6$ complexes ranges from 1899 to 1921 cm^{-1} in the models[185] and is at 1917 and 1904 cm^{-1} for two populations of NP1-NO.[1383] UV-visible spectra of 5-coordinate $[OEPFeNO]^+$ show the Soret band at 359 nm with a shoulder at 410 nm, and α, β band at 557 nm,[1381] while those of a variety of 6-coordinate complexes (N-MeIm, pyrazole, indazole, pyrazine)[1380] have their Soret bands at 408–410 nm (414, 415 nm for 2-MeImH[1382] and NO_2^-[1379] complexes, respectively), α bands at 524–525 nm (529, 528 nm for 2-MeImH and NO_2^- complexes, respectively), and β bands at 556–558 nm (561, 560 nm for 2-MeImH and NO_2^- complexes, respectively). DFT calculations on model heme-NO complexes have been reported.[1392,1393] Some of these indicate that the HOMO consists of mainly porphyrin contributions, with no p_x,p_y contribution from NO, and thus the electron configuration is Fe^{II}–NO^+.[1393] The strongly ruffled heme ring, a property of the NP-NO $\{FeNO\}^6$ complexes only, is believed to result from steric interaction with the two leucine residues in the distal pocket, that push down on two of the *meso*-carbons of the heme of NP2.[1384,1385] Mutation of either L132 or L122/L132 of NP2 to valine leads to positive shifts of the reduction potential of 88 and 90 mV, respectively at pH 7.5, that is, the heme becomes easier to reduce by about 90 mV when the steric interaction between the leucines and the heme is reduced;[1394] the structures, determined by X-ray crystallography, show less ruffling for the mutants, although perhaps not as much decrease as was expected.[1395]

The structure of the bedbug (*Cimexlectularius*) nitrophorin, called cNP, is also unique for a heme protein; it consists of a

beta-sandwich with the heme on the outside of the sandwich, covered only by a single alpha-helix that carries the cysteine that acts as axial ligand.[1396] The structure of the bis-NO-bound complex that includes the cysteine-SNO, mentioned above, is included in that publication.[1396] The protein fold is very similar to that of a myo-inositol 1,4,5-triphosphate 5-phosphatase enzyme.[1397] Unlike the *Rhodnius* nitrophorins, in the case of the bedbug salivary nitrophorin, histamine does not bind,[1389] and the structure shows that there is not sufficient room in the distal cavity for such a large ligand.[1396] To make up for this, perhaps, the *C. lectularius* protein binds (and releases) *two* molecules of NO at the heme center, one to iron (as a $\{FeNO\}^7$ center) and the other to the cysteine thiolate (as a thionitrosyl group, RSNO) that is the heme proximal ligand in the absence of NO.[1396] To our knowledge, this is the first example of the formation of a thionitrosyl group from a cysteine thiolate that was the heme ligand in the absence of NO. But this reaction does not occur for at least one cytochrome P450, the bacterial P450BM3 from *Bacillus megaterium*.[1398]

A model for the NO-heme-thiolate complex of nitric oxide synthase (NOS)[54] and cytochrome $P450_{nor}$ (nitric oxide reductase)[1074] (as well as the NO-carrying protein, the nitrophorin from the bedbug, *Cimex lectularius*[1396]) has been synthesized and characterized by optical, resonance Raman and EPR spectroscopy and electrochemistry.[1399]

6.3.5 Reduction Potentials of Iron(III) Porphyrins

The redox reactions of iron porphyrins, as for any other metal complexes, provide important insights into the relative stabilities of various oxidation states, and how these stabilities are related to ligation reactions. Because there has been a tendency for inorganic chemists to equate reduction potentials with orbital energies of one of the oxidation states involved in the redox couple, or to talk about the so-called ‘HOMO-LUMO gap’ (the electrochemical potential difference between the reversible $E_{1/2}$ values for formation of a porphyrin π-cation and π-anion radical)[1400] as though it measures something approaching orbital energies, this section has been included to attempt to clarify this misconception. Reduction potentials, in fact, measure the relative thermodynamic stability of the two oxidation states involved in the redox couple (*see* ***Electrochemistry: Applications in Inorganic Chemistry***). For example, in the case of a Fe^{III} porphyrin, a 1-electron reduction to yield the Fe^{II} porphyrin may be written as

$$PFe^{III} + e^- \rightleftharpoons PFe^{II} \tag{27}$$

In fact, this equation is incomplete, because no solvent for the system or anion for the PFe^{III} have been specified. Since electrochemical measurements are not done in the gas phase, but rather in homogeneous solution (or in solid matrices, but that is not the subject of this discussion), the conditions must be carefully specified, because the measured reduction potential will quite likely depend on those chosen conditions to a very great extent. In the case of the reaction specified in equation (27), the use of a potentially coordinating solvent such as dimethylformamide (DMF) or dimethylsulfoxide (DMSO) will yield a very different reduction potential than if a weakly- or non-coordinating solvents such as acetonitrile, benzonitrile, CH_2Cl_2 or $CHCl_3$ were used. This is because, according to the Nernst equation, the measured reduction potential is given by

$$E_c^\circ - E^\circ = -\frac{RT}{nF}\ln\left(\frac{K_{eq}^{III}}{K_{eq}^{II}}\right) \tag{28}$$

where E_c° is the measured potential for the metal ion fully complexed to the porphyrin and solvent molecules of a coordinating solvent (and, depending on the solvent, possibly the anion associated with the Fe^{III} state) in both oxidation states in the presence of a particular anion, probably the same anion as that of the electrolyte, and ideally one that does not bind strongly to Fe^{III}, E° is the measured potential for the metal ion in the absence of the porphyrin and coordinating solvent molecules but with the same anion, and K_{eq}^{III} and K_{eq}^{II} are the products of the binding constants for the porphyrin and solvent molecules to the Fe^{III} and Fe^{II} states, respectively. Since we are not really interested in the free metal ion, we typically take the metal porphyrin itself as our standard state and define E° as being the measured potential for the reduction reaction for that metal porphyrin in a given solvent. Then solvent effects can be evaluated by measuring E° in various solvents – if the junction potential of the reference electrode solution/sample solution interface either remains constant as the solvent is changed, or if it is carefully estimated in each solvent. The problem begins when researchers wish to compare the reduction potentials of two different Fe^{III} porphyrins, for example, $TPPFeOClO_3$ and $(p\text{-}NO_2)_4TPPFeOClO_3$. Now, what is the standard state? By comparing the reduction potentials for two different porphyrins we are really looking at a ratio of ratios of equilibrium constants. We must really go back to the initial reaction, equation (27), and consider how to evaluate the equilibrium constants of equation (28) for the binding of each of the porphyrins to both Fe^{III} and Fe^{II} and the solvent molecules, for buried in the two different reduction potentials measured are their individual $\ln(K_{eq}^{III}/K_{eq}^{II})$ values, and there is no simple way to determine whether the potential shifted in the observed direction as a result of a major effect of the substituents on either K_{eq}^{III} or on K_{eq}^{II}, or on opposite effects on the two, or on some other combination of possibilities. Hence, because reduction potentials measure the *ratio* of the equilibrium constants of the two oxidation states, one cannot extract the effects of one of the oxidation states, and assume that one knows something about orbital energies. Nevertheless, the measurement of reduction potentials and the comparison of those of one complex to those of another is a worthwhile and valid pursuit, as long as one does not attempt to draw conclusions as to what the potentials mean

with regard to the properties of *one* of the two oxidation states involved in the redox couple. Excellent articles on the electrochemistry of porphyrins and metalloporphyrins have been published,[1400,1401] and a large compilation of electrochemical data for these systems is available.[1402]

Electrochemical studies of iron porphyrins have provided valuable information about the stabilities of various oxidation states, and the stabilities of various axial-ligand complexes, as well as the reversibility of a given redox reaction. One of the most widely used methods is cyclic voltammetry, where the potential is scanned linearly at a chosen rate in one direction and then back again, over the chosen potential range. The voltammograms thus obtained are rich in information, not only about the half-wave potentials, $E_{1/2}$, but also, from the shape of the wave, the kinetics of the redox reaction at the electrode. In this section only the potentials are considered, and the reader is referred to useful reference books[1403,1404] and research papers[1405–1408] for detailed information on the kinetics aspects, including electron-transfer kinetics of generation of organoiron(IV) porphyrins and their π-cation radicals.[1409]

For metalloporphyrins, there are quite a number of reversible redox reactions that involve changes in the number of electrons on both the metal and the porphyrin ring. In the case of iron porphyrins, the most frequently studied redox reactions are those involving Fe^{IV}/Fe^{III}, Fe^{III}/Fe^{II}, and Fe^{II}/Fe^{I}, although various investigators have also concentrated on Fe^{I}/Fe^{0} and the reactions of higher oxidation states than Fe^{IV}, as well as porphyrin ring oxidations and/or reductions. The effects of porphyrin ring distortion on the reduction potentials of β-brominated tetraphenylporphyrin complexes of iron have been studied,[1410–1412] as have OETPPFeCl and OETPPFe(R), where R is C_6H_5, C_6F_4H and C_6F_5,[1413] a series of fluorinated dodecaphenylporphyrins,[1414] and the tetrakis(perfluoroalkyl)porphyrinatoiron complexes.[621] Etioporphycene complexes of sigma-bonded metal complexes, either phenyl or chloro as the ligand, have also been studied by cyclic voltammetry.[1415] With regard to the site of the redox reaction (metal-centered or macrocyclic ligand-centered), rules of thumb have developed for metalloporphyrins that suggest that the difference in the potential of the first porphyrin ring oxidation and the first ring reduction is approximately constant for all metalloporphyrins (the so-called ‘HOMO-LUMO gap’), but Kadish and coauthors have pointed out that this is not always the case.[1400] Thus, for metals like iron, for which a number of metal oxidation states exist, it is not always possible to define the site of removal or addition of an electron simply by invoking the ‘HOMO-LUMO gap’, and other methods, often spectroscopic (NMR, EPR, UV–vis, IR, etc.) must be used to determine the electron configuration of the product of the redox reaction of interest. Added to this is the fact that for other macrocycles even less is known about the existence or lack thereof of something like the ‘HOMO-LUMO gap’, and thus it is very risky to try to conclude the site of electron addition or removal based upon the observed reduction potential alone, when the observed reduction potential is determined by the relative stabilities of the two oxidation states involved in the redox couple, as discussed above and represented by equation (28). Hence, it is dangerous to decide the site of electron removal from chloroiron corrolates, their μ-oxo dimers, for various corrole ring substituents, on the basis of observed potential[1416,1417] in the absence of confirmatory spectroscopic data. Nevertheless, the ‘redox gap’ or ‘HOMO-LUMO gap’, $\Delta E_{1/2} = E_{1/2}^{Ox1} - E_{1/2}^{Red1}$ has been reported to be 2.25 ± 0.1 V for porphyrins, 1.85 ± 0.15 V for porphycenes and 2.15 ± 0.08 V for corrphycenes and their metal complexes;[1418] Kadish and coauthors have, however, stated that the value for porphyrins, at least, is not a constant.[1400]

Axial-ligand binding constants, for example to Fe^{III} and Fe^{II} porphyrins, can be measured in favorable cases by measuring the $E_{1/2}$ values for the Fe^{III}/Fe^{II} and Fe^{II}/Fe^{I} waves by cyclic voltammetry as a function of the concentration of axial ligand and then fitting the ligand concentration dependence of the reduction potential observed for each half-reaction to the full Nernst equation,[491,599]

$$(E_{1/2})_c = (E_{1/2})_s - \frac{RT}{nF} \ln\left\{\frac{1 + \beta_1^{III}[L] + \beta_2^{III}[L]^2}{1 + \beta_1^{II}[L] + \beta_2^{II}[L]^2}\right\} \tag{29}$$

where $(E_{1/2})_c$ is the reduction potential measured for the complex at each concentration of axial ligand, $(E_{1/2})_s$ is the reduction potential measured for the iron porphyrinate in the absence of added ligand, [L] is the equilibrium concentration of axial ligand, and the β_n are the overall equilibrium constants for the binding of 1 ($n = 1$) or 2 ($n = 2$) axial ligands to Fe^{III} and Fe^{II} (for the Fe^{III}/Fe^{II} wave) or Fe^{II} and Fe^{I} (for the Fe^{II}/Fe^{I} wave). Thus, for example, $\beta_1^{II} = K_1^{II} = [PFe^{II}L]/[PFe^{II}][L]$ and $\beta_2^{II} = K_1^{II}K_2^{II} = [PFe^{II}L_2]/[PFe^{II}][L]^2$, where all concentrations are those at equilibrium. (Overall charges on the complex have been omitted for simplicity.) In many cases $\beta_1^{III}[L] \ll \beta_2^{III}[L]^2 \gg 1$, and the analogous situation holds for $\beta_1^{II}[L]$ and $\beta_2^{II}[L]^2$, so that equation (29) can be simplified to:[491,599]

$$(E_{1/2})_c = (E_{1/2})_s - \frac{2.303RT}{nF} \log\left\{\frac{\beta_2^{III}}{\beta_2^{II}}\right\} \tag{30}$$

for the Fe^{III}/Fe^{II} wave, as given above for the general case where the solvent is the ligand, in equation (28). Likewise, for the Fe^{II}/Fe^{I} wave, in many cases the binding of axial ligands to the Fe^{I} oxidation state over the concentration ranges utilized for these studies could not be detected, and $Fe^{II}L_2$ is the dominant form of the Fe^{II} state, equation (29) in that case reduces to:

$$(E_{1/2})_c = (E_{1/2})_s - \frac{2.303RT}{nF} \log\beta_2^{II} - \frac{2.303RT}{nF} \log[L]^2 \tag{31}$$

In such cases, $\log \beta_2^{II}$ can be directly determined from the concentration dependence of the Fe^{II}/Fe^{I} potential

using equation (31), and then this value can be utilized in equation (30) with reduction potential data for the Fe^{III}/Fe^{II} couple, where log β_2^{III} is then the only unknown. In many cases, however, it is necessary to use the full equation (29).[491,599]

The observed reduction potentials for the Fe^{III}/Fe^{II} couple in the presence of a large concentration of the axial ligand that is sufficient to fully complex both oxidation states measure the relative stability of the bis-axial ligand complexes of the two oxidation states, in terms of log $\beta_2^{III}/\beta_2^{II}$. The results of some of these measurements of equilibrium constants are discussed in the following section.

6.3.6 *Thermodynamics of Ligand Addition to Iron(III) Porphyrins*

Numerous studies of the thermodynamics of ligand addition to Fe^{III} porphyrins have been reported. Three main methods have been utilized for measurement of binding constants: (1) UV–visible spectroscopic techniques based on Beer's law;[608,1419] (2) electrochemical techniques based on the Nernst equation (equations 26–28);[491,599,607,1420] and (3) NMR techniques based on the relative intensity of peaks that are due to known proton types within the starting material, PFeX, and product, PFe(X)(L) or $PFeL_2^+\ X^-$ [174,175,1421] (*see* ***Stability Constants & their Determination***). In nonaqueous solvents the reaction of ligands with iron(III) porphyrins is found to proceed as in equations (32) and (33):

$$\mathrm{PFeX} + \mathrm{L} \rightleftharpoons \mathrm{PFe(X)(L)} \qquad K_1 \tag{32}$$

$$\mathrm{PFe(X)(L)} + \mathrm{L} \rightleftharpoons \mathrm{PFeL_2}^{+}\mathrm{X}^{-} \qquad K_2 \tag{33}$$

for an overall reaction as in equation (34):

$$\mathrm{PFeX} + 2\mathrm{L} \rightleftharpoons \mathrm{PFeL_2}^{+}\mathrm{X}^{-} \qquad \beta_2 = K_1K_2 \tag{34}$$

The equilibrium constant for equation (34), β_2, is given by equation (35):[608]

$$\beta_2 = \frac{[\mathrm{PFeL_2}^{+}\mathrm{X}^{-}]}{[\mathrm{PFeX}][\mathrm{L}]^2} \tag{35}$$

Note that the units of β_2 are M^{-2}. The intermediate complex, [PFe(X)(L)], can be either six-coordinate, as implied by the parentheses and brackets, or five-coordinate, as a tight ion pair, $[(PFeL)^+\ X^-]$, and is often not detected by UV–visible spectroscopy.[608,1419] However, both NMR spectroscopic investigations[168,1346,1421] and electrochemical measurements[491,599,607] indicate conclusively that the mono-ligand complex is present in measurable concentrations in many cases. Furthermore, kinetic data clearly show that the mono-imidazole complex not only forms, but they also suggest that it is high-spin, six-coordinate, that is, both halide and imidazole ligand are bound to the metal center, at least in low dielectric solvents.[1422] Only the overall binding constant, β_2, could be measured by NMR spectroscopy at 25 °C and below,[1421] while UV–visible techniques sometimes allow estimation of the stepwise constants.[608] As discussed in Section 6.3.5 above, electrochemical techniques allow measurement of the stepwise constants under favorable conditions.[491,599] Ligands for which binding constants to either tetraarylporphinatoiron(III) or protohemin have been measured include imidazoles,[608,1339,1419,1421,1423–1426] pyridines,[491,599,614] cyanide,[1423] and pyridine/water.[1427] Representative values of log β_2 are summarized in Table 3.[1428–1432]

It should also be noted that the product of equations (33) and (34), as written, is an ion pair, and it behaves as a single species. This is the situation for Fe^{III} porphyrins in chloroform, dichloromethane, acetone, and DMF at concentrations of 10^{-5} M and greater.[608] However, at lower concentrations (7×10^{-7} M and below) the constant can only be calculated by assuming that the cation and anion are separate species.[608] The reaction under these conditions is as in equation (36):

$$\mathrm{PFeX} + 2\mathrm{L} \rightleftharpoons \mathrm{PFeL_2}^{+} + \mathrm{X}^{-} \tag{36}$$

and the equilibrium constant for this reaction, which we will call β_{2D}, is as in equation (37):

$$\beta_{2\mathrm{D}} = \frac{[\mathrm{PFeL_2}^{+}][\mathrm{X}^{-}]}{[\mathrm{PFeX}][\mathrm{L}]^2} \tag{37}$$

Note that the units of β_{2D} are M^{-1}, and hence, the sizes of β_2 (equations 34 and 35) and β_{2D} (equations 36 and 37) cannot be directly compared.[608]

Hydrogen-bonding between a coordinated N–H imidazole and the ion-paired anion greatly enhances the binding of the axial ligands in low-polarity solvents, as is evidenced by the approximately 10^3 increase in size of β_2 when L is changed from N-MeIm to ImH in $CHCl_3$.[608] This effect decreases as the polarity of the solvent increases. It has also been reported that under conditions where equations (34) and (35) are obeyed, the binding of *N*-methylimidazole is greatly enhanced by the presence of a hydrogen-bond donating substituent on at least one phenyl ring of the TPP derivative that can stabilize the anion of the ion-paired product.[1428] If the hydrogen-bonding group is acetamido (NHCOMe), the enhancement in log β_2 increases in the order H ∼*ortho* ≪ *para* ≪ *meta*, as a result of the favorable structure of the ion-paired product when the H-bonding group is in the meta position of the phenyl ring.[1434] Hydrogen bonding of coordinated ImH to other additives, such as *ortho*-phenanthroline, not only stabilizes the complex, but also shifts the Fe^{III}/Fe^{II} reduction potential cathodically by over 100 mV,[1435] thus indicating a significant stabilization ($\approx$2.4 kcal mol^{-1}) of the Fe^{III} oxidation state when strong H-bond acceptors are present. Hydrogen bonding of an imidazole N–H to a polar or anionic group is thus an important way to modulate the reduction potentials of heme proteins.

The effect of porphyrin substituents on the size of the binding constants β_2 has been investigated in detail.[608,1419,1421]

Table 3 Equilibrium constants for addition of imidazoles and pyridines to Fe^{III} porphyrins

Note: Deuteroporphyrin IX dimethyl ester (DPDME).

It has been found that in noncoordinating solvents, electron-donating substituents on the phenyl rings of substituted tetraphenylporphyrin complexes of Fe^{III} stabilize the complex, that is the Hammett ρ value is negative.[608,1419,1421] This behavior is opposite to that typically expected for Lewis base reactions with Lewis acids, and in particular other metallotetraphenylporphyrins, including V^{IV},[1436] Co^{II},[787] Ni^{II},[1436] and Zn^{II},[1437] and also opposite to that observed for the reaction of N-methylimidazole with TPPFeCl in DMSO, where the starting material is $[TPPFe(DMSO)_2{}^+]Cl^-$.[1079] The reason for this opposite behavior has been explained in terms of the oxidation state of the metal (+3 rather than +2, with VO^{2+} behaving as a +2 unit). Hence, the product of equations (33), (34), or (36) has a formal positive charge at the metal center, whereas the reactant does not, and the reaction is favored by electron-donating substituents, which can help to stabilize the positive charge on the metal center of the product.[608,1419]

More detailed investigations of the binding of N-methylimidazole to a series of unsymmetrically substituted tetraphenylporphyrins have revealed that both tetra-*para*- and mono-*para*-phenyl substituted derivatives of TPPFeCl should be viewed as behaving 'anomalously', compared to either tetra-*meta*-substituted derivatives or unsymmetrically *para*-substituted derivatives of the type $[(p\text{-X})_x(p\text{-Y})_{4-x}$TPPFeCl].[1419] The reason for this 'anomalous' behavior in the symmetric tetra-*para*-substituted compounds is believed to be nonadditivity of the substituent effects, that is due to the direct conjugation of the fourth phenyl ring in the product, $[(p\text{-X})_4TPPFe(N\text{-}MeIm)_2]^+\ Cl^-$, which is necessary to remove the formal positive charge from the Fe^{III} center. The unsymmetrical multiply *para*-substituted TPP derivatives are also believed to engage in direct conjugation between phenyl and porphyrin ring, but they appear to choose to utilize the 'least willing' substituent in this conjugation. For the series of six complexes $[(p\text{-Cl})_x(p\text{-NEt}_2)_{4-x}TPPFe(N\text{-}MeIm)_2]^+\ Cl^-$ it was also found that variation in the energy of the Q_o electronic band with the intensity ratio of the Q_o to Q_v transitions is consistent with an important role for direct conjugation in these low-spin complexes, but not in the high-spin chloroiron(III) starting materials.[1419] Evidence for direct conjugation between phenyl rings and the porphyrin ring has also been supplied by Traylor and coworkers[1438] and Milgrom,[1439] who showed that tetrakis(p-hydroxyphenyl)porphyrins and their metal complexes can be oxidized by two electrons to a diquinone form that requires direct conjugation between two phenyl rings and the porphyrin, and by Worthington *et al.*[1440] The latter workers found electrochemical evidence (an additional reduction wave) for direct conjugation of 4-methylpyridinium groups when these replace one or more phenyl rings of $TPPH_2$.[1440] The sequential protonation of the tetra-(p-dimethylaminophenyl)porphyrin free base has been studied by optical and NMR spectroscopy, and shown to yield

charge transfer excited states that produce hyperporphyrin spectra[1441] and unique ^{1}H NMR shifts.[1442]

The equilibrium constants for binding various nitrogen-donor ligands to iron(III) complexes of tetrakis(2,6-disubstituted phenyl)porphyrins (where the 2- and 6-substituents are F, Cl, Br, OMe) and the tetrakis(2,4,6-trimethylphenyl)porphyrin, also known as tetramesitylporphyrin, TMP, have been measured by several workers[491,599,614,1339,1346,1421–1429] (Table 3). It is interesting to note that rather than hindering the binding of axial ligands, most of the above substituents appear to aid this binding, in the approximate order of the sizes of the substituents (H < OMe < Me < Cl < Br).[491,599] This appears to be due in part to electron donation (field effects) from the *ortho*-substituents,[245] as well as from a stabilization that is due to ruffling of the porphyrin core.[1204,1280,1339] Note that the order is different from that observed for the binding of the same series of ligands to the same series of 2,6-disubstituted TPP complexes of Fe^{II} (OMe $\ll$ H $\ll$ Me $\sim$ Cl $\sim$ Br) discussed in Section 4.1.2.

Further investigations, by NMR spectroscopy, of the steric effects involved in the binding of imidazoles to a series of alkylated phenyl analogs of TMPFeCl, where all methyl groups are replaced by either ethyl or isopropyl groups, have been reported.[1426] At $-35\,°C$ the stabilities of the N-MeIm complexes of the 2,4,6-substituted $TPPFe^{III}$ derivatives increase in the order H $\ll$ *i*-Pr $\sim$ Me < Et, and for the 1,2-Me_2Im complexes H $\ll$ Me $\sim$ *i*-Pr $\sim$ Et. In all cases, β_2(N-MeIm) > β_2(1,2-Me_2Im), but by very different factors: H ($\approx 10^5$), Me (240), Et (10^3), *i*-Pr (160). Clearly, increasing the bulkiness of the *ortho*-phenyl substituents both increases the stability of axial-ligand complexes and also greatly enhances the stability of complexes of hindered axial ligands over those of $TPPFe^{III}$. While the formation of the $TPPFe^{III}$ complex suffers a large loss in bond strength when N-MeIm is replaced by 1,2-Me_2Im ($\Delta H° = -26.5$ vs. $-20.6\,\mathrm{kcal\,mol^{-1}}$), the same is not true for the TMP and related complexes ($\Delta H°$ ranging from -27.2 to -28.0 (N-MeIm) and -27.8 to $-29.1\,\mathrm{kcal\,mol^{-1}}$ (1,2-Me_2Im)). However, while the entropies of complex formation of the two TPP complexes are very similar, those for the TMP and related complexes are much more negative for the hindered than the nonhindered imidazole ($\Delta S° = -69$ to $-76\,\mathrm{J\,mol^{-1}\,K^{-1}}$ (N-MeIm) and -86 to $-91\,\mathrm{J\,mol^{-1}\,K^{-1}}$ (1,2-Me_2Im)), indicating the loss of internal rotation of the 1,2-Me_2Im ligands upon binding to the TMP and related porphyrin complexes, but not $TPPFe^{III}$, at low temperatures.[1426] Competitive binding of 1- and 2-methylimidazole to $TMPFe^{III}$ revealed that formation of the sterically more hindered complex, $TMPFe(2\text{-MeImH})_2]^+Cl^-$, is favored over either the mixed-ligand complex, $TMPFe(2\text{-MeImH})(N\text{-MeIm})^+Cl^-$, or the nonhindered $TMPFe(N\text{-MeIm})_2{}^+Cl^-$.[1424,1425] The increased stability of the sterically hindered porphyrin complexes was explained in terms of attractive, rather than repulsive, interactions between the *ortho*-methyl groups of the mesityl rings and the π system and/or the 2-alkyl substituent of the coordinated imidazoles.[1424] The existence of such attractive forces appears to be borne out by molecular mechanics calculations.[1281,1287] However, another important contributing factor must be that an N–H imidazole was used for the 'hindered' ligand while a N–Me imidazole was used for the 'non-hindered' ligand. There is a difference in the size of β_2 of N′10−1000 for these two classes of imidazole ligands.[608]

In contrast to the case of imidazoles binding to tetraphenylporphyrins, Wang *et al.*[1423] have demonstrated that binding of cyanide to high-spin protoporphyrin IX iron(III) chloride in DMSO-d_6 is a two-step process as shown in equations (38) and (39), and whether DMSO acts as a sixth ligand for the mono-cyano complex is not known:

$$\mathrm{PPFe(DMSO)_2{}^+ + CN^- \rightleftharpoons PPFe(CN)(DMSO)_{1/0}} \quad (K_1) \tag{38}$$

$$\mathrm{PPFe(CN)(DMSO)_{1/0} + CN^- \rightleftharpoons PPFe(CN)_2{}^-} \quad (K_2) \tag{39}$$

The binding constants K_1 and K_2 were found to be 1.9×10^4 and $1.1 \times 10^3\,\mathrm{M^{-1}}$ at $20\,°C$, respectively. Imidazole binding, however, is an overall two-step process, and only the formation of the bis-imidazole complex can be observed. The overall binding constant is $6 \times 10^4\ \mathrm{M^{-2}}$ at $20\,°C$.[1423] It should be noted that since the starting material already has the chloride ion dissociated, the overall $\beta_2 (= K_1K_2)$ is not directly comparable to the β_2 values for the addition of imidazoles to synthetic hemins in $CDCl_3$.[1421] In fact, it should be stressed that solvent plays an important role in determining not only the coordination state of the high-spin starting material, but also the degree of ion pairing of the product.[608]

For water-soluble porphyrins, including T(*p*-M)PyPFe^{III} and (*meso*-$\alpha,\alpha,\alpha,\alpha$-tetrakis[*o*-(*N*-methylnicotinamido) phenyl]porphinato)iron(III), α^4-(TMINP)Fe^{III}, however, the addition of cyanide in basic aqueous solution again appears to be an overall two-step at one time process, with log $\beta_2 = 13.56$ at pH 10.4 (T(*p*-M)PyP) and 14.7 at pH 10.2 (α_4-(TMINP)).[1024] At lower pH, however, T(*p*-M)PyPFe^{III} can bind CN^- in a stepwise fashion: at pH 6.5, a maximum of about 72% of the porphyrin is in the 1:1 cyano complex, while at pH 9.6, less than 8% is in the form of the 1:1 complex.[1024]

6.3.7 *Kinetics of Axial Ligand Addition to Iron(III) Porphyrins*

The reaction of *N*-methylimidazole with TPPFeCl proceeds rapidly according to the overall equation (34) to give the low-spin complex $TPPFe(N\text{-MeIm})_2{}^+\ Cl^-$, but the stepwise kinetics could be studied in various solvents by stopped-flow kinetics.[1422] The rate

law is consistent with the steps shown in equations (40–42):

$$\text{TPPFeCl} + \text{N-MeIm} \underset{\text{fast}}{\overset{K_1}{\rightleftharpoons}} \text{TPPFe(N-MeIm)Cl} \tag{40}$$

$$\text{TPPFe(N-MeIm)Cl} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \text{TPPFe(N-MeIm)}^+\text{Cl}^- \tag{41}$$

$$\text{TPPFe(N-MeIm)}^+\text{Cl}^- + \text{N-MeIm} \underset{k_4}{\overset{k_3}{\rightleftharpoons}} \text{TPPFe(N-MeIm)}_2{}^+\text{Cl}^- \tag{42}$$

For the case where $k_3[\text{L}] \gg k_2$, this mechanism gives rise to a predicted equation (equation 43) for the observed rate constant:

$$k_{\text{obs}} = \frac{k_1 K_1[\text{L}]}{1 + K_1[\text{L}]} \tag{43}$$

Analysis of the kinetic data in terms of equation (43) shows that the equilibrium constant for formation of the mono-*N*-methylimidazole complex (equation 35) shows a small solvent dependence ranging from 22 to $0.3\,\text{M}^{-1}$ (acetonitrile and CHCl_3, respectively), but the rate constant k_1, for dissociation of the high-spin six-coordinate complex, shows a larger solvent dependence, ranging from 360 to $0.7\,\text{s}^{-1}$ (CHCl_3 and *n*-chloropropane, respectively). The size of k_1 is strongly dependent on the ability of the solvent to hydrogen bond to the departing chloride in the transition state, and low concentrations of potential hydrogen-bonding additives such as trifluoroethanol and phenol have a large accelerating effect on k_1.[1422] Similar effects were found for the reaction of *N*-methylimidazole with the corresponding protoporphyrin IX and protoporphyrin IX dimethyl ester complexes of chloroiron(III)[1443] and for the reaction of imidazole (HIm) with TPPFeF and (PPDME)FeF.[1444] In the latter case, the first intermediate to form is, as before (equation 40), the six-coordinate high-spin PFe(HIm)F, and the second is PFe(HIm)F···HIm in which an external imidazole is hydrogen bonded to the fluoride.[1444] It has also been shown that reaction of hindered imidazoles such as 2-MeImH and 1,2-Me_2Im with TPPFeCl introduces a steric strain with the porphyrin ring that causes about a factor of ten decrease in the formation constant, K_1 (equation 40), and a factor of ten or more increase in the rate of chloride ion dissociation (equation 41).[1445]

The binding of apomyoglobin to hemin can also be thought of as an axial ligation reaction of a Fe^{III} porphyrin, for indeed, all heme proteins except the cytochromes *c* have non-covalently attached heme groups. The equilibrium constant for binding hemin to apomyoglobin has been estimated as $10^{14}\,\text{M}^{-1}$ at neutral pH.[1446] This value is determined by a complex set of nonspecific hydrophobic (10^5–10^7), specific, mainly ionic (10^3–10^4) and covalent (His-Fe, 10^3–10^4) interactions.[1446] Olson and coworkers have investigated some of the factors that affect the equilibrium constants and rates of hemin dissociation in some 100 different metmyoglobin mutants.[1447] It was found that mutations of the proximal histidine (His-93 (F8)) and the nearby leucine (Leu-89 (F4)) can result in >100 fold increases in the rates of hemin loss at pH 5 and 7. Some replacements of the contact residues His-64 (E7), Val-68 (E-11), His-97 (FG3), Ile-99 (FG5), Thr-39 (C4), and Tyr-103 (G4) cause >10-fold changes in the rate of hemin dissociation. Substitutions of the noncontact residues Leu-29 (B10), Phe-46 (CD4), and Gly-65 (E8) can also increase the rate of hemin loss >10-fold. The key structural factors stabilizing bound hemin in myoglobin are (1) hydrophobic interactions between apolar residues in the heme pocket and the porphyrin ring, (2) the coordinate bond between His-93 (F8) and the Fe^{III} atom, and (3) hydrogen bonding between distal residues and coordinated water.[1447] It has also been shown that many heme proteins, including bovine microsomal cytochrome b_5,[1448] will release their heme to apomyoglobin at pH 7.0, indicating that the binding constant of hemin to the bovine b_5 is less than $10^{14}\,\text{M}^{-1}$.

'Heme rotation' is another aspect of the binding and dissociation of hemin from a number of heme proteins. Protohemin is an unsymmetrical molecule (Figure 1(c)), and if one of the two heme orientations is significantly more thermodynamically stable than the other in a given protein pocket, then the initial 50–50 mixture of the two heme orientations that exists upon mixing the apoprotein with hemin and random binding of this hemin to the protein will change over time until the equilibrium ratio of the two is reached.[1449] For cytochromes b_5, that ratio is ~90:10 for the rabbit and bovine microsomal proteins,[1449–1451] ~95:5 for the chicken microsomal protein,[1452] 62:38 for the rat microsomal protein,[1453] and 47:53 for the rat outer mitochondrial protein.[1454] While the half-lives of heme rotation are on the order of 12 hr for the bovine microsomal cytochromes b_5,[1450,1455] it has been shown that the half-life is much longer for the rat outer mitochondrial protein, in that it requires heating the protein to 65 °C for several hours to reach the equilibrium mixture of heme orientations.[1454] Thus rat outer mitochondrial cytochrome b_5 represents the first documented example of a cytochrome b_5 exhibiting a thermodynamic preference for hemin isomer B and in which hemin is kinetically trapped under physiologically relevant conditions.[1454,1456] The hemin is tightly bound to the protein, and is not released to apomyoglobin at pH values as low as 5.2.[1454,1456] Two hydrophobic patches that are largely responsible for the relative kinetic inertness of outer mitochondrial cytochrome b_5 have been identified and studied, and two point mutations were identified that make the protein strongly favor hemin orientational isomer B (I32L, A:B = 1:4.0) or isomer A (L71S, A:B = 5.2:1).[1457] Hemin release from isomers A and B can be kinetically resolved in some of the rat outer mitochondrial cytochrome b_5 mutants.[1457]

6.3.8 Kinetics of Axial-ligand Exchange on Low-spin Iron(III) Porphyrins

La Mar and Walker[1458] first reported investigations of the dynamics of axial-ligand exchange in the low-spin Fe^{III} complex $[TPPFe(N\text{-}MeIm)_2]^+Cl^-$ in $CDCl_3$ by observing line broadening of the coordinated *N*-methyl peak of N-MeIm as a function of temperature. It was established that, even in the presence of excess ligand, ligand exchange proceeds by a dissociative mechanism involving a five-coordinate $PFeL^+$ X^- transition state (equations 44 and 45):

$$[PFeL_2]^+X^- \rightleftharpoons [[PFeL]^+X^-]^\ddagger + L \quad k_1 \tag{44}$$

$$[[PFeL]^+X^-]^\ddagger + L^* \longrightarrow [PFeLL^*]^+X^- \quad \text{rapid} \tag{45}$$

Satterlee *et al.*[1346] extended these studies to characterize the axial lability of various imidazoles and pyridines in bis-ligated low-spin Fe^{III} complexes of synthetic porphyrins, including tetraphenyl-, octaethyl-, and tetra-*n*-propylporphyrins. For L = *N*-methylimidazole, typical rate constants k_1 are 35–100 s^{-1} for TPPFeCl and T-*n*-PrPFeCl, and 950 s^{-1} for OEPFeCl; typical activation parameters determined in this study are $\Delta H^\ddagger = 17\text{–}20$ kcal mol^{-1}, $\Delta S^\ddagger = 15$ -19 J mol^{-1} K^{-1}.[1346] More recently it has been shown by a combination of saturation transfer, linewidth analysis and lineshape analysis in the intermediate exchange rate region that, as for the TPP complexes, ligand exchange in sterically more hindered tetramesitylporphinatoiron(III) complexes is also dissociative.[1424,1425] In both the TPP and TMP complexes the axial lability of coordinated imidazoles increases with increasing steric bulk of the base; that is, 2-methylimidazole complexes have larger dissociation rate constants ($k_1 = 8.9 \times 10^3$ s^{-1} for $[TPPFe(2\text{-}MeImH)_2]^+$ and 1.1×10^5 s^{-1} for $[TPPFe(1,2\text{-}Me_2Im)_2]^+$; 18 s^{-1} for $[TMPFe(2\text{-}MeImH)_2]^+$ and 100 s^{-1} for $[TMPFe(1,2\text{-}Me_2Im)_2]^+$) than the corresponding *N*-methylimidazole species ($k_1 = 120$ and 7 s^{-1} for the TPP and TMP complexes, respectively).[1425] The increased lability is believed to be due to the steric repulsion between the alkyl substituent in the 2-position of the imidazole ring and the porphyrin macrocycle. Overall, TPP complexes are more labile than their TMP counterparts. However, the stability of the TMP complexes is invariably greater than their TPP counterparts, as discussed in Section 6.3.6 above. In fact, the rate constants are inversely proportional to the equilibrium constants, β_2,[1425] suggesting that this reaction indeed proceeds as described by equations (41) and (42), and that $\beta_2 \propto K_2 = k_f/k_r$, where $k_r = k_1$.

For a number of mono-*ortho*-substituted derivatives of $[TPPFe(N\text{-}MeIm)_2]^+$, including a series of $[(o\text{-}CONR_2)_1TPPFe(N\text{-}MeIm)_2]^+$ complexes having amide R groups of varying sizes, large effects are observed in the rate constants for exchange of one of the two unique *N*-methylimidazole ligands, with the rate constants being determined partly by the electronic effect and partly by the size of the *ortho* substituent.[246] However, the NMR spectra themselves, in combination with kinetics data obtained from analysis of the line broadening of the *N*-methyl peaks of the two coordinated N-MeIm ligands, indicate that for these and selected other *ortho*-substituted complexes, the *N*-methylimidazole ligand that dissociates most rapidly is the one on the *opposite* side of the porphyrin plane from the *ortho*-substituent, probably due to buckling of the macrocycle to accommodate the substituent. Such buckling is expected to have the effect of strengthening the Fe–N bond of the ligand on the same side of the porphyrin plane as the substituent and weakening that of the ligand on the opposite side of the plane.[246] Similar results have been reported for ligand exchange on Ru^{II} 'picnic basket' porphyrins.[270]

The rate of axial water exchange on the water-soluble porphyrins $TMPyPFe^{III}$ and $TPPSFe^{III}$ have been investigated by ^{17}O NMR.[1459] For the former at 25 °C, $k_1 = 7.8 \times 10^5$ s^{-1}, $\Delta H^\ddagger = 13.8$ kcal mol^{-1} and $\Delta S^\ddagger = 14.7$ J mol^{-1} K^{-1}, and for the latter at 25 °C, $k_1 = 1.4 \times 10^7$ s^{-1}, $\Delta H^\ddagger = 13.7$ kcal mol^{-1} and $\Delta S^\ddagger = 20.2$ J mol^{-1} K^{-1}.[1459] Note that although the rate of dissociation of water from the pentapositive complex, $T(p\text{-}M)PyPFe^{III}$, is a factor of a hundred slower than from the trinegative complex, $TPPSFe^{III}$, the activation parameters are nearly identical.

Photodissociation of a N-methylimidazole ligand from $[OEPFe(N\text{-}MeIm)_2]^+$ has been studied using resonance Raman detection.[1460] The rate constants for ligand dissociation and association are $k^- = 5.3 \times 10^3$ s^{-1} (as compared to 950 s^{-1} for the non-photoactivated dissociation[1346]) and $k^+ = 3.7 \times 10^7$ s^{-1}, respectively.[1460]

6.3.9 Kinetics of Iron(III) Porphyrin Axial-ligand Rotation and Porphyrin Ring Inversion

Nakamura and Groves[1354] first reported the coalescence behavior observed in the proton NMR spectra of the pyrrole-H, *o*-Me, *p*-Me, and *m*-H resonances of $TMPFe(2\text{-}MeImH)_2^+$ as the temperature is lowered from room temperature to −48 °C. They correctly ascribed this behavior to a slowing of axial-ligand rotation as the temperature is lowered, and calculated activation parameters from complete lineshape analysis of the two *p*-Me signals of the TMP ligand. For the rotation of 2-MeImH ($\Delta H^\ddagger = 54 \pm 1.7$ kcal mol^{-1}; $\Delta S^\ddagger = 3.7 \pm 1.6$ J mol^{-1} K^{-1}) and $1,2\text{-}Me_2Im$ ($\Delta H^\ddagger = 52.7 \pm 3.3$ kcal mol^{-1}; $\Delta S^\ddagger = 5.2 \pm 3.6$ J mol^{-1} K^{-1}).[1354] Although their proposed structure of the low-temperature complex, in which ligand rotation is hindered, was later modified on the basis of NOESY investigations of this system,[187] the activation parameters clearly describe the barriers to rotation of the two 2-substituted imidazoles. These barriers are considerably lower than those for axial-ligand exchange,[1346] and clearly represent a totally different kinetic process. The rates of simultaneous 2-MeImH rotation and porphyrin ring inversion of $TMPFe^{III}$, $2,6\text{-}Cl_2TPPFe^{III}$ and $2,6\text{-}Br_2TPPFe^{III}$ bound

to two 2-MeImH, and of $TMPCo^{III}$ bound to two 2-MeImH and 1,2-Me_2Im axial ligands were measured over a wide temperature range by 2D NOESY/EXSY methods,[1461] and yielded somewhat different activation parameters for the two metals: While the $\Delta H^\ddagger$ values were similar in all cases, ranging from 46 to 51 kJ mol^{-1}, the $\Delta S^\ddagger$ values were quite small in magnitude for Fe^{III}, but much larger and negative for Co^{III} (−63, −84 J mol^{-1}K^{-1}, respectively).[1461] Different solvation effects, due to the anion used in each case (ClO_4^- vs. BF_4^-, respectively),[1461] may have led to the different entropies of activation. Saturation transfer[1462] and ^{1}H transverse relaxation rate[1463] methods yielded quite similar rates and activation parameters to those obtained by NOESY/EXSY techniques.[1461] Additional measurements of the rates of ligand rotation/porphyrin inversion have been reported for $TMPFe^{III}$-related systems with 2-MeImH and other hindered axial ligands, measured by DNMR (line-broadening) techniques, have also been reported;[1464,1465] in these studies, the authors believed that the axial ligands were 'fixed' at just below the lowest temperatures they used for their measurements, but the NOESY/EXSY measurements[1461] make it quite clear that chemical exchange continues until some 50–75 degrees lower in temperature than can be detected from 1D measurements, and that at even lower temperatures than that, chemical exchange is simply too slow to be detected by NMR techniques. Thus, axial ligands in these iron porphyrin complexes should not be thought of as 'fixed'.

Similarly, for the octaalkyltetraphenylporphyrinato-iron(III) complexes, the rates and activation parameters for the five-coordinate complexes OETPPFeCl, F_{20}OETPPFeCl, OMTPPFeCl and TC_6TPPFeCl,[1466] and for bis-ligated complexes of $OETPPFe^{III}$, where the axial ligands are 4-NMe_2Py,[1466] N-MeIm,[1466] and 4-CNPy[943] could be measured by NOESY/EXSY and/or DNMR techniques. The results show that the rate constants for ring inversion of the porphyrin cores of PFeCl, extrapolated to 298 K, decrease in the order TC_6TPP > OMTPP > F_{20}OETPP > OETPP ($k_{298} \sim 4.4 \times 10^7$, 2×10^5, 73 and 16 s^{-1}, respectively); $\Delta H^\ddagger$ increases in the order TC_6TPP < OMTPP < F_{20}OETPP < OETPP (34, 46, 47, 54, with errors of ±1–2 kJ mol^{-1}, respectively), and the $\Delta S\ddagger$ changed from small positive to larger negative (16, 11, – 52, – 42, with errors of ±4–7 J mol^{-1} K^{-1}, respectively).[1466] For bis-ligand complexes of $OETPPFe^{III}$, the rates of ring inversion were fastest for the cylindrical ligands (*t*-BuNC, CN^-; $k_{298} \sim 2.6 \times 10^6$ s^{-1} for both) and slowest for 4-CNPy (overall $S = 3/2$; $PFe^{II}\pi$-cation radical) ($k_{298} \sim 59$ s^{-1}); among $S = 1/2$ complexes, the extrapolated rate constant at 298 K is larger for the bis-4-NMe_2Py complex (970 s^{-1}) than for the bis-N-MeIm complex (174 s^{-1}). The $\Delta H^\ddagger$ values for these bis-ligand complexes are 40, 58, 32, 49, and 59 kJ mol^{-1}, respectively, and the $\Delta S^\ddagger$ values are 13, 73, −104, −22, and −3 J mol^{-1} K^{-1}, respectively, for the series of ligands listed.[1466] The $\Delta S^\ddagger$ values are probably dominated by solvation effects (DMF for the bis-cyanide complex, CD_2Cl_2 for the others), but the reason for the very negative value for the bis-4-CNPy complex is not clear.

The free energy barrier to inversion of the chloroiron porphyrin π-cation radicals of OMTPP and OETPP have been reported and compared to those of the starting materials.[1467] For [OMTPPFeCl]$SbCl_6$ the barrier to ring inversion was found to be 4 kcal mol^{-1} (16.8 kJ $^{-1}$ mol) higher than for the neutral complex, while that for [OETPPFeCl]$SbCl_6$ is about 2 kcal mol^{-1} (8.4 kJ mol^{-1}) higher than that of the neutral complex. Because these are single point measurements, the enthalpy and entropy contributions cannot be deconvoluted.

6.3.10 *Kinetics of Reduction of Low-spin Iron(III) Porphyrins*

The kinetics of reduction of low-spin water-soluble Fe^{III} porphyrins by superoxide,[1024,1468,1469] $CO_2^{-}\cdot$,[1024] dithionite,[1470] ascorbic acid,[1471] and phenols in the presence of hydrogen peroxide[1472] have also been reported. For T(*p*-M)PyPFe^{III} and α^4-TMINPFe^{III}, reduction by $CO_2^{-}\cdot$ is close to diffusion controlled ($k = 1.4 \times 10^{10}$ and 6.1×10^9 M^{-1} s^{-1}, respectively, at pH 5.6),[1024] while rate constants for $O_2^{-}\cdot$ reduction are about two orders of magnitude slower (1.2×10^8 and 8.1×10^8 M^{-1} s^{-1}, respectively, also at pH 5.6).[1024] The reader is referred to the original literature for further details of these investigations.

6.3.11 *Autoreduction of Iron(III) Porphyrins*

Several investigators have shown that Fe^{III} porphyrins in solution are autoreduced by certain ligands. Examples of such cases are the autoreduction of tetraphenylporphinatoiron(III) chloride in the presence of piperidine,[1473] primary amines,[1474] cyanide,[1024,1475] thiols and phosphines,[1475,1476] or hydroxide or alkoxide ions or solid sodium hydride.[1477] Magnetic resonance techniques (NMR and EPR) have been successfully employed to probe the mechanism of the autoreduction and to characterize reaction intermediates and final products.[1473–1482] It is believed that the autoreductions proceed by similar pathways for a variety of ligands and involve an intramolecular electron transfer to give Fe^{II} species and ligand radicals. The mechanisms of such reactions are relevant to the understanding of both the activation of coordinated ligands in certain hemoproteins and modes of intramolecular electron transfer in cytochromes.[1473]

Detailed ^{1}H NMR and EPR spectroscopic studies performed in DMSO solution demonstrated that the autoreduction of tetraphenylporphinatoiron(III) chloride in the presence of piperidine or potassium cyanide leads to the formation of the corresponding six-coordinate, diamagnetic dicyano or bis(piperidine) Fe^{II} complexes, $[TPPFe^{II}(CN)_2]^{2-}$ or $[TPPFe^{II}(Pip)_2]$, which are identified by their characteristic pyrrole-H shifts at 8.8–9.0 ppm.[1473–1482] In addition to the Fe^{II} complexes, a cyanide or a piperidine radical is formed,

indicating that the iron reduction is accompanied by one-electron oxidation of the ligand molecules. The generation of the cyanide radical during the reduction of Fe^{III} suggests that the mechanisms for the autoreduction of the dicyano complex involves homolytic bond cleavage according to the overall reaction in equation (46):

$$PFe^{III}(CN)_2{}^- \longrightarrow PFe^{II}(CN)^- + {}^{\bullet}CN \qquad PFe^{II}(CN)^- \xrightarrow{CN^-} PFe^{II}(CN)_2{}^{2-} \quad (46)$$

(The •CN radicals appear to dimerize rapidly to produce dicyanogen, NCCN.[1475]) The reduction rate of $[TPPFe^{III}(CN)_2]^-$ depends on a variety of factors. Light and increased cyanide concentrations accelerate the reduction, while small amounts of water inhibit the reaction. Reoxidation of the dicyano Fe^{II} complex by molecular oxygen leads directly to the formation of the low-spin complex, as opposed to μ-oxo dimer formation, because of the presence of excess strong-field ligand (i.e. the reaction with O_2 is probably outer-sphere). Autoreduction of a series of dicyanoiron(III) porphyrins studied by White-Dixon *et al.*[1476] showed that the rate of autoreduction depends on porphyrin structure. TPP complexes autoreduce faster than protoporphyrin IX species and much faster than deuteroporphyrin derivatives, for which no autoreduction was observed.[1008] For water-soluble porphyrins, $T(p\text{-}M)PyPFe^{III}(CN)_2$ (charges omitted) is autoreduced by excess cyanide, while α^4-$TMINPFe^{III}(CN)_2$ is not.[1024]

In benzene or DMF solution, primary and secondary amines having an α-CH react with Fe^{III} porphyrins to give bis(amine) adducts of Fe^{II} porphyrins, plus one mole of the corresponding imine (equation 47):[1474]

$$2PFeCl + 5RNH_2 \longrightarrow 2PFe^{II}(RNH_2)_2 + R'CH{=}NH + 2RNH_3{}^+Cl^- \quad (47)$$

The reaction path entails two successive reversible ligation steps, followed by two one-electron reductions of the bis(amine)-ligated low-spin Fe^{III} adduct. In benzene the kinetics are biphasic. The second ligation is rate limiting [k_1(ligation) > k(reduction) > k_2(ligation)]. In DMF the first reduction step is rate limiting. The influence of nonreducing amines, porphyrin substituents (proto > TPP > meso > OEP > deutero), axial ligands, and deuteration of the substrate upon the kinetics leads to the formulation of the first reduction step as a reversible outer-sphere electron transfer to the porphyrin periphery. This is followed by a rapid conversion of the generated aminium cation radical to an α-aminocarbinyl radical. The latter completes the reduction in an irreversible second step. The authors pointed out the relevance of this system to the monoamine oxidase reaction of cytochrome P450.[1474]

Shin *et al.*[1477] have shown that Fe^{III} complexes of tetraphenylporphyrins and etioporphyrin undergo autoreduction in DMSO solution by addition of hydroxide or alkoxide ions or solid sodium hydride. The autoreduction leads to the formation of the corresponding five-coordinate hydroxo-iron(II) ($S = 2$) complexes. This reduction can be followed easily by NMR spectroscopy.

6.3.12 Electron Self-exchange between Low-spin Iron(III) and Iron(II) Porphyrins

To understand the pathway of electron transfer in proteins such as the cytochromes, it is essential to determine the role of the protein in controlling the rate of electron transfer between two cytochrome molecules[1478–1481] (*see* ***Long-range Electron Transfer in Biology***; ***Iron: Heme Proteins & Electron Transport***). Accurate assessment of the role of the protein requires knowledge of the factors that control electron transfer in hemes themselves. Hence, the electron self-exchange rate constants between two hemes free in solution have been determined by NMR spectroscopy using ^1H line-broadening techniques. White-Dixon and coworkers have employed this method to determine electron self-exchange rate constants in a variety of heme model compounds with the goal of establishing how changes in porphyrin or axial-ligand structure and in macrocycle saturation affect the exchange rates.[1476,1482–1484] Saturation transfer and 2D EXchange SpectroscopY (EXSY) experiments are now additional NMR methods for measuring the rates of electron exchange in model hemes (equation 48), if the reactions are in the slow exchange region of the NMR timescale.[491]

$$PFe^{III}L_2{}^{(n)} + PFe^{II}L_2{}^{(n-1)} \rightleftharpoons PFe^{II}L_2{}^{(n-1)} + PFe^{III}L_2{}^{(n)} \quad (48)$$

The electron self-exchange rates for various N-methylimidazole complexes determined at −21 °C in CD_2Cl_2 are found to be in the range of $5{-}8 \times 10^7\ M^{-1}\ s^{-1}$ for various phenyl-substituted TPP complexes and do not vary in a regular fashion with increase of steric crowding on the periphery of the porphyrin macrocycle.[1008,1482,1483] Similar rate constants were measured for systems with sterically bulky imidazole ligands, such as N-butylimidazole. Hence it was concluded that increasing the steric bulk at either the heme site or on the axial ligand has almost no effect on the rate of electron exchange. However, complexes with axial imidazoles bearing NH groups have self-exchange rate constants that are a factor of 2–3 smaller than those with N-alkylimidazole substituents.[1008] This suggests that hydrogen bonding or complete deprotonation of the axial imidazole nitrogen atom may play a role in controlling electron-transfer rates.[1476] However, this is a complex system, and the role of anions that hydrogen-bond to the axial imidazole N-H group needs to be elucidated, for such anions could serve as bridges between the N-H groups of two molecules, one having Fe^{III} and the other Fe^{II} oxidation states, or on the other hand, the anions might serve to organize

the solvent to a greater extent for the N-H imidazoles, and thus create bulkier species that cannot approach each other as closely as the non-H-bonding imidazole case.

Changes in the degree of saturation of the macrocycle affect the rate constants in a minor way. Similar rate constant values are obtained for both the porphyrin and the octaethylisobacteriochlorin (OE*i*BC) complexes, thus indicating little effect of the macrocycle on the electron-transfer rate, perhaps as a result of counterbalancing effects in either the inner or outer sphere reorganization and orbital occupation.[1484]

The value of the rate constant obtained for the heme undecapeptide, MP11 ($1.3 \times 10^7\,M^{-1}\,s^{-1}$), is comparable to those of other model compounds.[1485] The rate constants for model hemes and the heme *c* undecapeptide are approximately a factor of 10 larger than those found in cytochromes with 80–90 amino acids. This argues further that the heme exposure to the solvent seems not to be a major factor controlling the rate constants for electron self-exchange in cytochromes.[1485]

MP11 has been reacted with a peptide containing a photoactive ruthenium(II) tris-bipyridyl moiety at one end and a histidine that coordinates to the heme at the other end.[1486] Photoexcitation of the Ru^{II} results in rapid ($k_{ET} > 10^7\,s^{-1}$), reversible ET to the ferric heme. Clear evidence for reversible photoinduced ET was observed in time-resolved luminescence and transient resonance Raman studies of the MP11-RuProHis samples.[1486] In a separate study a photoreactive RuII tris-bipyridyl donor was covalently attached to MP11.[1487] This arrangement eliminates complications arising from the equilibrium complexation of ruthenium donor and heme acceptor required for the model systems just described, and leaves an axial position in the octahedral geometry of the heme iron open for ligation. Various optical spectroscopies and molecular modeling calculations were employed to characterize the equilibrium properties and interchromophore interactions of RuMP11. Preliminary luminescence quenching, transient absorption, and transient resonance Raman studies demonstrated that rapid reversible electron transfer can be photoinduced in this system.[1487]

6.3.13 *Synthetic Ferriheme Proteins*

There have been a number of reports of the preparation of synthetic peptides that are designed to bind to hemes in similar fashions to how they are bound in various heme proteins.[1488–1521] The types of peptide systems designed include (1) four-helix bundles in which each peptide is covalently attached to a 'corner' of a porphyrin scaffold and in which the bundle is oriented perpendicular to the porphyrin plane,[1488–1490] (2) preformed four-helix bundles that bind one,[1491–1494] or more[1496–1505] metalloporphyrins via bis-His coordination, usually with the heme plane oriented parallel to the helices, (3) disulfide-dimerized peptides that bind a single metalloporphyrin via bis-His coordination,[1504,1507] (4) reversible complexes formed between a water-soluble Fe^{III} porphyrin and amphiphilic peptides bearing centrally located His residues,[1508,1509] (5) porphyrin-spanning peptides either covalently attached to *meso*-phenyl rings[1510] or bound via metal-to-ligand coordination[1511] and (6) bis-peptide adducts of metalloporphyrins in which His ligands within each peptide coordinate to the porphyrin-bound metal ion.[1512–1518] There have been three recent reviews of this subject.[1519–1521]

The main reasons for the preparation of these synthetic heme proteins are to allow probing the effects of individual amino acid side chains on the properties of the heme centers, notably their reduction potentials and the stability of the Fe-histidine bonds in the two oxidation states (see Sections 6.3.5 and 6.3.6), and the stability of the 3- or 4-helix bundles with heme bound that are often used for creation of these synthetic proteins. Some of the 4-helix bundle maquettes, designed to bind only one hemin molecule per peptide, bind hemin to one peptide with dissociation constants of as low as 65 nM; addition of a second equivalent of hemin results in binding a second heme molecule to the other peptide of the 4-helix bundle with dissociation constants in the range of 35–800 nM.[1503] (In comparison, the K_d for hemin dissociation from myoglobin is ~10 fM,[1446] meaning that it forms a factor of 10^5–10^6 more stable complex, as discussed in Section 6.3.6.) The equilibrium reduction midpoint potentials, $E_{m7.5}$, determined in the monoheme state range from −156 to −210 mV versus SHE and in the diheme state range from −144 to −288 mV. An observed heme–heme electrostatic interaction (>70 mV) in the diheme state indicates a syn global topology of the di-α-helical monomers, as shown in Figure 15. The results of this study illustrate that conservative hydrophobic amino acid changes near the heme-binding site can modulate the E_m by up to ±50 mV and the K_d by an order of magnitude. Furthermore, the effects of multiple

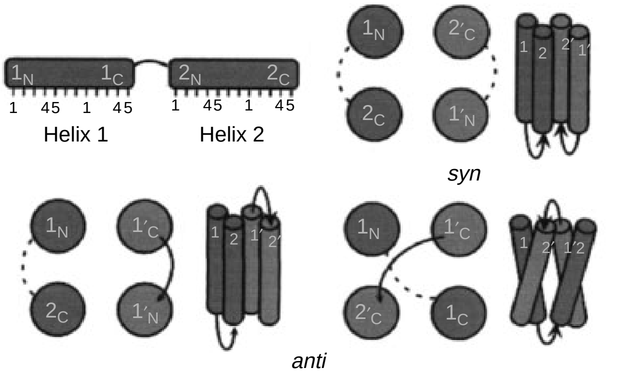

Figure 15 A dimeric, four-helix bundle can adopt six distinct topologies. The topology diagrams shown are for the three possible clockwise-turning helical bundles. Counterclockwise-turning helical bundles are also possible and have interfacial interactions different from their clockwise-turning correlates. single amino acid changes on E_m and K_d do not appear to be additive.[1503] Another study showed that the contribution of His-Fe coordination to the difference in reduction potentials of two hemoprotein models was of the order of 90 mV, which is comparable to effects due to local electrostatic interactions (50–80 mV) and proton coupling (>100 mV) in other systems, but pales in comparison to heme solvent exposure effects (∼500 mV, based upon investigations of MP8 and comparison to cytochrome *c*[1522]) and ligand changes (>150 mV).[1516] It was pointed out that there are two limiting situations, one for the synthetic heme proteins, in which reduction potential differences are dominated by the relative affinities of the ligands for Fe^{II} and Fe^{III}, and the other, for the case of the electron-transfer hemoproteins, in which reduction potential differences are dominated by structural changes that alter heme solvent exposure; a decrease in solvent exposure results in positively shifted reduction potentials.[1516] Investigations of the electrochemistry of cytochromes *c* and b_5 have led to the conclusion that the protein matrix mimics the behavior of a low dielectric solvent and shields the heme from the solvent;[1523] it appears that naturally occurring heme proteins are much better in shielding the heme than are the synthetic heme proteins.[1516]

The 4-helix bundles typically have up to 124 amino acids, and thus have molecular weights of over 15 000 Daltons, at least as large as some naturally-occurring heme proteins. NMR studies indicate that the synthetic proteins in general show more dynamics of the polypeptides than do naturally occurring 4-helix bundle proteins.[1503,1504] One crystal structure of such a maquette scaffold, with 1-letter amino acid sequence {[CGGG EIWKL HEEFLKK FEELLKL HEERLKKM]$_2$}$_2$, not bound to heme, has been solved using MAD phasing and refined to 2.8 Å resolution.[1524] The structure shows that the maquette scaffold is an antiparallel four-helix bundle with ‘up-up-down-down’ topology. No pre-formed heme-binding pocket exists in the protein scaffold. Unexpected inter-helical crossing angles, residue positions and translations between the helices were found. The crossing angles between the parallel helices are – 5° rather than the expected +20° for typical left-handed coiled-coils. Deviation of the scaffold from the design is likely due to the distribution and size of hydrophobic residues – the maquette scaffold did not exhibit knob-in-hole packing. This structure points out that four identical helices may interact differently in a bundle, and heptad repeats with an alternating [HPPHHPP]/[HPPHHPH] (H = hydrophobic, P = polar) pattern are not a sufficient design criterion to generate left-hand coiled-coils.[1524] A 4-helix bundle modeled after the heme-binding core of the cytochrome *b* portion of the cytochrome bc_1 protein complex of mitochondria[7–9] binds two ferrihemes to yield a complex that has a broad ‘large g_{max}’ EPR signal at g = 3.35. In this model, histidine imidazole planes were held in approximate perpendicular orientations via inclusion of residues designed to be hydrogen-bond acceptors from the imidazole N-H groups.[1504]

6.3.14 Synthesis and Properties of Five-coordinate Low-spin Iron(III) Porphyrins Having σ-Alkyl or σ-Aryl Groups

Reports of the synthesis of a number of low-spin Fe^{III} complexes bound to one alkyl, aryl, or silyl axial ligand have appeared.[998,1244,1246,1525–1529] The three major synthetic methods are (1) the reaction of the chloroiron(III) porphyrin with the Grignard reagent (*see Grignard Reagents*) of the desired alkyl or aryl group,[1525,1527] (2) the reaction of the chloroiron(III) porphyrin with a lithium alkyl,[1529] and (3) the reaction of the four-coordinate Fe^{II} porphyrin with an alkyl halide.[998] The group 14 anions are expected to be extremely strong σ-donors, and indeed, they are able to stabilize both low-spin Fe^{II}[1530] and low-spin Fe^{III} in the five-coordinate state, except when four or five electronegative fluorine atoms are present on the aryl ring, in which case the five-coordinate complexes are high spin.[1527,1531] It has been shown that σ-alkynyl complexes of $TPPFe^{III}$ can be prepared from lithium acetylides.[966] However, in this case the five-coordinate PFe^{III} complex is high spin, although it becomes low spin upon addition of a nitrogen base to the sixth coordination site.[966]

^1H NMR studies have shown that for the low-spin five-coordinate σ-alkyl and σ-aryl Fe^{III} complexes, porphyrin β-pyrrole–H and –CH_2 shifts are indicative of the ‘normal’ $(d_{xy})^2(d_{xz},d_{yz})^3$ ground state, with spin delocalization via P → Fe π bonding.[1244] The NMR resonances of α-H of alkyl groups have been detected by Li and Goff, who reported the ^2H NMR spectra of [d_8-$TPPFeCD_3$] and [d_8-$TPPFeC_2D_5$] in toluene at 25 °C, recorded over a very large spectral width at 55 MHz.[1532] For the CD_3 group, $\delta_{obs} = 532$ ppm; for the C_2D_5 group, δ_{obs} for the CD_2 is 562 ppm, with the CD_3 signal at −117 ppm. These are the largest chemical shifts reported thus far for iron porphyrins; the low frequency of the ^2H nucleus makes possible the use of spectral bandwidths that correspond to such a large chemical shift range. Widths of the α-CD_3 and -CD_2 resonances are reasonably narrow, 80 and 115 Hz, respectively, in both THF and toluene.[1532] In light of the expected narrowing of deuterium resonances of up to a factor of 42 over those of protons[1532] at the same molecule positions, it is not surprising that α-CH_3 and –CH_2 signals have not been detected. Both high- and low-spin σ-bonded aryl-, alkyl-, and perfluoroaryliron(III) porphyrins have been characterized, including not only NMR and EPR spectra but also Mössbauer spectra.[1533] For low-spin alkyl and aryl complexes, isomer shifts were found to vary over the range $0.28 < \delta$ Fe(80–95 K) $< 0.34\ mm\ s^{-1}$ and quadrupole splittings $2.6 < \Delta E_Q < 3.57\ mm\ s^{-1}$, while for the high-spin complexes $TPPFe(C_6F_4H)$ and $OEPFe(C_6F_5)$, δ Fe(80–85 K) = 0.53 and $0.23\ mm\ s^{-1}$ and $\Delta E_Q = 0.48\ mm\ s^{-1}$ and unresolved, respectively.[1533]

The σ-alkyl complexes of $TPPFe^{III}$ can be reduced with $LiHBEt_3$ or $KHB(i\text{-}Bu)_3$ in benzene/THF to yield diamagnetic $[TPPFe^{II}R]^-$ (R = *n*-propyl or ethyl).[1530]

These complexes are easily reoxidized by dioxygen to $TPPFe^{III}R$.[1530] Alkyliron(III) porphyrins will undergo CO and CO_2 insertion into the Fe–C bond, forming acyliron(III) (PFeC(O)R) and alkyl carboxylate (PFeOC(O)R) complexes, respectively.[1529]

Addition of *N*-methylimidazole or pyridine to either five-coordinate low-spin or high-spin σ-alkyl, σ-aryl, or σ-alkynyl Fe^{III} porphyrins produces low-spin mixed-ligand complexes.[966,1244] NMR results indicate that upon adding a sixth ligand the aryl anion acts as a π donor, rather than a π acceptor, toward low-spin Fe^{III}, in that the electron configuration is $(d_{xy})^2(d_{xz},d_{yz})^3$. Interestingly, however, the planar nature and potential π donor character of the aryl ligand is not sufficient to produce a resolved rhombic EPR spectrum for $[TTPFe(C_6H_5)]$; instead, a 'large g_{max}' signal at $g = 3.54$ is observed, with a broad feature at about $g \sim 1.7$,[1534] indicating near-degeneracy of d_{xz} and d_{yz}, probably due to the strong σ-donor nature of the aryl ligand. Addition of pyridine shifts this signal to $g = 3.86$ and the broad feature to higher field (lower g-value).[1534]

Exposure of σ-alkyl complexes to dioxygen leads to insertion of O_2 into the Fe–C bond, with the formation of the corresponding alkyl peroxide (equation 49):[998,1535]

$$PFe^{III}CHR_2 + O_2 \longrightarrow PFe^{III}OOCHR_2 \qquad (49)$$

The alkyl peroxide then can decompose to give $PFe^{III}OH$ and $O{=}CR_2$, or, if a tertiary alkyl group, σ-$CR'R_2$, is involved, $PFe^{IV}O$, HOR′, and OCR_2, as discussed in Section 8.1 below. Acyl complexes such as $PFe^{III}C(O)C_4H_9$ react with dioxygen to yield only PFe^{III} carboxylate complexes and the μ-oxo dimer, PFe^{III}-O-Fe^{III}-P, with no evidence of ferryl complexes being formed.[1536]

A series of iron(III) σ-bonded porphycenes have been characterized by electrochemistry, EPR, NMR and optical spectroscopy and in one case X-ray crystallography.[1537] The macrocyclic ligand was etioporphycene, and the aryl group R was C_6H_5, 3,5-$C_6F_2H_3$, 3,4,5-$C_6F_3H_2$, or 2,3,5,6-C_6F_4H. All of the complexes appear to have the less common $(d_{xz},d_{yz})^4(d_{xy})^1$ electron configuration, based upon their EPR spectra, which have g-values ranging from 2.34–2.29 and 1.94–1.92.[1537]

The methyliron(III) corrphycene complex has been prepared and is stable in the absence of dioxygen; the methylcobalt(III) complex is stable even in the presence of dioxygen.[1538] Radiolytic reduction occurs at the metal center to produce Fe(II) and Co(I) corrphycenes, which are also stable; upon further radiolytic reduction in neutral solutions they yield species with chlorin-like spectral signatures. In alkaline solutions, species with phlorin-anion-like characteristics are produced.[1538]

7 IRON(III) PORPHYRIN AND CORROLE π-CATION RADICALS AND THEIR REACTIONS

7.1 Iron(III) Porphyrin Radicals

One-electron oxidation of Fe^{III} porphyrins may lead to either Fe^{III} porphyrin π-cation radicals or Fe^{IV} porphyrins, depending upon the axial ligation of the metal ion and the reaction conditions. In this section we will consider the systems that have been formulated as Fe^{III} porphyrin π-cation radicals, and in the next section those that have been formulated as Fe^{IV} porphyrins.

Only a few Fe^{III} porphyrin π-cation radicals have been characterized structurally,[1539–1541] since they are quite reactive species. They have been characterized mainly by NMR spectroscopy, magnetic susceptibility measurements, and a diagnostic band in the IR spectrum in the region of 1270–1295 cm^{-1}.[1542] Their main use has been as chemical oxidants of porphyrins, metalloporphyrins, and so on.[206]

In view of the three different spin states observed for Fe^{III} porphyrins, it is not surprising to find that all three have been observed for the one-electron ring-oxidized complexes. Some high-spin, monomeric Fe^{III} porphyrin radicals, including $[TPPFeCl]^+$, give rise to antiferromagnetically coupled $S = 2$ species,[203–205,1539] while others, including $[TPPFe(OClO_3)_2]$, give rise to noninteracting $S = 5/2$, $S = 1/2$ species;[205,1539,1540] spin-admixed $S = 3/2,5/2$ Fe^{III} complexes give rise to spin-admixed π-cation radical species of either $S = 5/2,3/2$[208,1540] or $S = 3/2,5/2$[209] ground ($S = 1$) states; and low-spin Fe^{III} porphyrins give rise to low-spin ferromagnetically coupled Fe^{III} π-cation radical species.[207]

Chemical or electrochemical oxidation of [TPPFeCl] in the presence of perchlorate or hexafluoroantimonate salts, or chemical oxidation with a Fe^{III} porphyrin π-cation radical of higher oxidation potential, produces a $S = 5/2$, $S = 1/2$ antiferromagnetically coupled (effectively $S_{tot} = 2$) five-coordinate $[TPPFeCl]^+$ $(3a_{2u})^1\pi$-cation radical.[205,1539] The same is true of the chlorin complex $[TMCFeCl]^+$.[1543] The X-ray crystal structure of $[TTPFeCl]SbF_6$ consists of isolated five-coordinate $[TPPFeCl]^+$ units, in which the porphyrin macrocycle is strongly S_4 ruffled.[205,1539] In comparison, in the solid state, $[OEPFeCl]ClO_4$ exists as a tight cofacial π–π dimer with an interplanar separation of 3.24 Å, a lateral shift of 0.2 Å, a twist angle between the two rings of 31.2°, an Fe–Fe distance of 4.112 Å, and has strong coupling of the $S = 1/2$ radical spins on the two porphyrin rings, with Fe^{III} in the high-spin state.[1541] In solution, there are no near IR absorption bands caused by dimer formation, as seen with the π-cation radicals of a number of other OEPM complexes discussed in the next paragraph.[1541] The NMR spectra of these $[PFeCl]^+$ complexes suggest that in the case of β-pyrrole-substituted porphyrins the electron is removed from the $1a_{1u}(\pi)$ orbital (Figure 4), as evidenced by the small isotropic shifts of the *meso*-H resonances.[206]

Several metallooctaethylporphyrin π-cation radicals have been examined in methylene chloride solution. For [OEPM]Y, where M = Cu, Ni, Zn, Pd, or VO and Y = ClO_4^- or $SbCl_6^-$, are found to dimerize to form $[OEPM]_2^{2+}$.[1544] These dimeric species are characterized by the appearance of a new, strongly concentration-dependent near-infrared absorption band, found in the region of 900–960 nm for all compounds except the vanadyl complex, whose band was found at 1375 nm. Equimolar solutions of these π-cation radicals and their analogous neutral OEPM derivatives react to form new binuclear species, $[OEPM]_2^+$, in which the single radical electron is delocalized over both porphyrin rings.[1544] These mixed-valence π-cation radicals bear a formal relationship to the oxidized special pair of photosynthetic reaction centers, and also display a near-infrared absorption band that is distinctly different from the π-cation radical dimers. The equilibrium constants and ΔH and ΔS values for both equilibrium processes have been determined, and the differences interpreted in terms of the much stronger solvation of the π-cation radical compared to the neutral porphyrin.[1544]

The β-oxochlorin derivative [3,3,7,8,12,13,17,18-octa-ethyl-(3*H*)-porphin-2-onato(2-)] iron(III) chloride, [Fe(oxoOEC)Cl], and its π-cation radical derivative [Fe(oxoOEC)Cl]$SbCl_6$ have been prepared and studied by X-ray crystallography, IR, UV–vis/NIR and Mössbauer spectroscopies and by temperature-dependent magnetic susceptibility measurements.[1545] The macrocycles of both [Fe(oxoOEC)Cl] and [Fe(oxoOEC)Cl]$SbCl_6$ are saddled, and the latter is also slightly ruffled. The inter-ring mean plane separation and the lateral shift of the rings are both larger for the π-cation radical (4.82 and 8.79 Å, respectively). A broad near-IR absorption band appears at 1415 nm for the π-cation radical in solution.[1545] Solid-state magnetic susceptibility measurements for the π-cation radical resulted in a large temperature dependence of the magnetic moment that is best fit with a model that includes a zero-field splitting parameter D of 6 cm^{-1}, antiferromagnetic intermolecular iron–iron coupling ($2J_{Fe-Fe} = -0.14\,cm^{-1}$), and antiferromagnetic radical–radical coupling ($2J_{r-r} = -13\,cm^{-1}$).[1545]

The π-cation radicals of PFe–O–FeP species, the μ-oxo dimers of Fe^{III} porphyrins, are convenient chemical oxidants of the chloroiron porphyrins,[206] and they are interesting species in their own right. Those in which P = TPP or one of its derivatives have NMR shifts that suggest the same $(a_{2u})^1$ ground state for the porphyrin π-cation radical, this time delocalized over the two porphyrin rings.[206]

The neutrally charged μ-nitrido dimer of TPPFe, $[(TPPFe)_2N]$ and its phthalocyanine[1546,1547] and mixed-macrocycle[1548] counterparts, are isoelectronic with the π-cation radical of the μ-oxo dimers discussed above, but they have a different electron configuration.[1549] NMR shifts are more consistent with their description as delocalized system having two $Fe^{3.5+}$ rather than a delocalized porphyrin π-cation radical. This complex readily reacts reversibly with dioxygen to produce an EPR-active species that has $g_{\parallel} = 2.07$, $g_{\perp} = 2.01$.[1550] Although the EPR parameters are very similar to those of the superoxide ion,[1551] and the spectral change did not occur when the complex was dissolved in a nonpolar solvent such as toluene,[1550] the authors preferred to consider the reaction to involve weak binding between O_2 and $[(TPPFe)_2N]$. One-electron oxidation with I_2/Ag^+ produces a complex that is believed to consist of $Fe^{IV}-N^{-3}-Fe^{IV}$,[1549] with the metals strongly antiferromagnetically coupled. This complex has a magnetic moment less than 1.8 μ_B at room temperature. Unlike $[(TPPFe)_2O]^+$ or $[(TPPFe)_2O]^{2+}$, both of which autoreduce in the presence of pyridine, $[(TPPFe)_2N]^+$ readily coordinates one or two pyridine ligands; stepwise addition can be observed by monitoring the pyridine *o*-H resonances at −1.26 ppm (1:1) and −1.46 ppm (2:1).[1549] Structures of two six-coordinate complexes of this oxidation level, $[(THF)(TPP)Fe\text{-}N\text{-}Fe(Pc)(H_2O)]^+$[1552] and [(THF)(TPP)Fe-N-Fe(Pc)(THF)][1553] have been reported. The structure of $[(TTPFe)_2N]SbCl_6$ has also been reported,[1554] and shows shorter Fe-N distances and porphyrin plane separations than does $[(TPPFe)_2N]$, consistent with the higher charge on the metal. Structures of $[(TPPFe)_2C]$[1555] and $[(OEPFe)_2C]$[1556] have also been reported. $[(TPPFe)_2N]^+$ can be further oxidized by one electron to produce $[(TPPFe)_2N]^{2+}$ in good yield.[1557] This complex is formulated as a Fe^{IV}–$Fe^{IV}$$\pi$-cation radical (one electron removed from one of the porphyrin rings).[1557]

One-electron electrochemical oxidation of $[TPPFe(ROH)_2]ClO_4$, where ROH is water or ethanol, in the presence of perchlorate salts produces $[TPPFe(OClO_3)_2]$, a six-coordinate complex, described as a $S = 5/2$, $S = 1/2$, noninteracting high-spin species because of its room-temperature magnetic moment in the solid state ($\mu_{eff} = 6.5 \pm 0.2\,\mu_B$).[205] Its NMR spectrum at 25 °C in CD_2Cl_2 suggests a π-cation radical of a_{2u} type.[205] Non-Curie dependence of the ^1H NMR shifts has indicated that in this spin-admixed state the ground state is largely $S = 5/2$.[208] The magnetic moment in solution, $4.8 \pm 0.4\,\mu_B$, is much lower than that observed in the solid state,[205] suggesting antiferromagnetic coupling between the a_{2u} (π) electron (Figure 4) and the spin-admixed Fe^{III}.[208]

The complexity of the behavior of Fe^{III} porphyrin radicals, and those of tetramesitylporphyrin in particular, is demonstrated by the properties of $[TMPFe(OClO_3)_2]$ in various solvents.[209] This π-cation radical of Fe^{III} was prepared by oxidation of $[TMPFeOClO_3]$ with iron(III) perchlorate and isolated before dissolution in CD_2Cl_2. ^1H NMR investigations indicate that, in the case of the TMP complex, the $S = 3/2$ ground state is greatly favored over the spin-admixed 3/2,5/2 or 5/2,3/2 ground states. Treatment of the latter Fe^{III} porphyrin π-cation radical complex with two equivalents of sodium methoxide produced the electron configuration isomer, the d^4 Fe^{IV} porphyrin complex,[209] as discussed in Section 8.

Although complexes of the type $[PFe(ImH)_2]^+$ could not be electrochemically oxidized to π-cation radicals, titration of high-spin $[(p\text{-}OMe)_4TPPFeCl]ClO_4$ in CD_2Cl_2 with imidazole at −38 °C produced a transient complex whose NMR spectrum was consistent with transient formation of the

radical species $[(p\text{-OMe})_4TPPFe(ImH)_2]^{2+}$.[207] Warming to room temperature causes immediate reduction to the Fe^{III} porphyrin. ^1H NMR shifts (large and negative at the *meso* positions) are indicative of an $a_{2u}(\pi)$ ground state for the radical.[207] The magnitudes of the shift differences, $\delta_m - \delta_p$ and $\delta_m - \delta_o$, are very large and positive at 235 K, +52.5 and +62.1, indicating ferromagnetic coupling between the iron and porphyrin unpaired electrons,[195] as suggested by Reed and coworkers,[1558] and not the Fe^{IV} configuration suggested from DFT calculations.[1559] In a planar porphyrin ring, a low-spin Fe^{III} center with $(d_{xy})^2(d_{xz},d_{yz})^3$ electron configuration would not have the proper symmetry to interact with the $a_{2u}(\pi)$ porphyrin orbital, yet the proximity of the spin density on the four porphyrin nitrogens would strongly favor ferromagnetic coupling. The large phenyl-H shift differences are not at all consistent with metal-centered unpaired electrons.

As an illustration of the chemical reactivity of these $Fe^{III}\pi$-cation radicals, $[TPPFe(ClO_4)_2]$ reacts with nucleophiles such as nitrite ion or triphenylphosphine to produce the mono-β-substituted Fe^{III} porphyrins.[1560–1562] The products were isolated as the six-coordinate dichloride complexes, $[(2\text{-}NO_2)TPPFeCl_2]$ and $[(2\text{-}PPh_3)TPPFeCl_2]$, respectively; the latter was characterized by X-ray crystallography and ^1H NMR spectroscopy in CD_2Cl_2 as the bis-imidazole complex.[1560]

7.2 Chloroiron(III) and Other Iron Corrole Radicals

The corrole macrocycle lacks one of the *meso*-carbons of the corresponding porphyrin ring (Figure 1(x),1(y)), and produces a trinegative ligand that is said to stabilize higher oxidation states of transition metals,[165] although it is now clear that this is not necessarily the case. A number of different chloroiron corrolates have been synthesized,[479,1563–1567] and these complexes were first believed to consist of Fe^{IV} bound to chloride and the trinegative macrocycle,[1563,1564] and in fact, there have been recent claims that this is the case.[1568,1569] However, these claims ignore the ^1H NMR data,[1563,1565–1567] as well as other magnetic data[211] and DFT calculations.[211,1570] All of these chloroiron corrolates exhibit magnetic moments consistent with $S = 1$ systems.[1563,1565–1567] However, the NMR spectra of octaalkylcorrolatoiron(III) chloride complexes at room temperature exhibit *meso*-H resonances at +172−177 ppm for the 5,15-H and +183 −189 ppm for the 10-H,[1563,1565] indicating, in analogy to the 5-coordinate $ClFe^{III}$ porphyrinate π-cation radicals discussed above,[203–205,1539] the presence of large negative spin density at the *meso*-carbons that is consistent with the presence of corrolate π-cation radicals. At the same time, *meso*-triphenylcorrolatoiron(III) chloride and its *p*-phenyl substituted analogs have large alternating sign phenyl-H isotropic shifts, such that the phenyl-H shift differences, $\delta_m - \delta_o$ and $\delta_m - \delta_p$, are large and negative,[195,1566,1567] a clear sign of large negative spin density at the *meso*-carbons in these triphenylcorrolates. Magnetic susceptibility measurements are only consistent with the formulation $S = 3/2$ Fe^{III} antiferromagnetically coupled to a $S = 1/2$ π-cation radical corrolate$^{2-}\bullet$, while magnetic Mössbauer spectra could be interpreted either as $S = 1$ Fe^{IV} or as $S = 3/2$ Fe^{III} antiferromagnetically coupled to a $S = 1/2$ π-cation radical corrolate$^{2-}\bullet$, although the isomer shift ($+0.21\ mm\ s^{-1}$) is indicative of iron(III).[211] DFT calculations were extremely informative in showing that the chloroiron corrolates have −0.22 to −0.26 spin density at each *meso*-carbon, as well as smaller negative spin densities (−0.07 to −0.12) at each nitrogen, and alternating positive and negative spin density around the corrole ring.[211] The net spin density on the entire corrolate ring is −0.7 to −0.8, or nearly one unpaired electron with spin opposite to the sign of the spin on the metal.[211] The d_{z^2} unpaired electron on the out-of-plane Fe^{III} was found to be important in mediating the antiferromagnetic coupling to the unpaired electron in the $a_{2u}(\pi)$-type orbital of the corrolate ring; as in the porphyrinate ring (Figure 4), this orbital has very large amplitude at the *meso*-carbons and the nitrogens, but essentially no amplitude at the β-pyrrole carbons.[211] The DFT calculations, showing approximately 1/4 of an unpaired electron with negative spin at each *meso*-carbon,[211] were thus quite consistent with the NMR shifts of the chloroiron octaalkylcorrolate *meso*-H of +170−190 ppm.[1563,1565]

In contrast to the results for the chloroiron corrolates, the phenyliron 7,13-dimethylhexaethyl-corrolate had much smaller *meso*-H shifts of 53.4 and 49.4 ppm at 303 K, the magnetic susceptibility and magnetic Mössbauer spectra could be interpreted as either $S = 1$ Fe^{IV} bound to a simple corrolate^{3-} or $S = 3/2$ Fe^{III} antiferromagnetically coupled to a $S = 1/2\pi$-cation radical corrolate$^{2-}\bullet$, although the isomer shift (−0.10 mm/s) was much more consistent with Fe^{IV}.[211] Thus DFT calculations were required to fully interpret the experimental data; they showed that while the corrolate ring had overall spin density of nearly zero, there was negative spin density (−0.04 each) at the *meso*-carbons and the nitrogens (−0.03 each), and alternating spin density at the other carbons of the ring.[211] Thus it could be concluded that while the net spin density on the corrolate ring was nearly zero, the corrolate ligand is certainly not ‘innocent’, in that it has non-negative spin densities of alternating sign on adjacent atoms of the ring that add up to nearly zero. The excellent correlation between ^1H NMR chemical shifts[195,211,1563,1565–1567] and DFT-calculated spin densities[195,211] provides confidence that ^1H NMR shifts can be used in the future to predict the existence of radical character on the macrocycle. In fact, a record NMR study of $[OECFe(t\text{-BuNC})_2]^+$ showed a pyrroline-H chemical shift of +132 ppm,[982] while $[TPCFe(t\text{-BuNC})_2]^+$ has a pyrroline-H chemical shift of −36 ppm,[1315] both at 298 K. DFT calculations showed that a ruffled chlorin ring has negative spin density at the C_∞, thus producing a negative chemical shift for the pyrroline-H, while a planner chlorin ring has large positive spin density at the C_∞ positions, thus yielding a positive chemical shift for the pyrroline-H.[982]

Both the chloroiron and phenyliron octaalkylcorrolates can be oxidized electrochemically by two or three one-electron processes, and reduced by two one-electron processes.[1571] One-electron reduction of each produces the simple $[XFe^{III}Corr]^-$, while one-electron oxidation of each produces the $[XFe^{IV}Corr^{2-}\bullet]^+$ π-cation radicals. The nitrosyl complex of iron(III) octaethylcorrolate has been formed and both it and its 1-electron oxidized product have been characterized structurally and electrochemically.[1572]

If the chloroiron octaalkylcorrolates are reacted with Lewis bases such as imidazole[1565] or cyanide,[1573] the complexes retain overall spin $S = 1$, but from the NMR shifts (bis-imidazole complex at 203 K: 7,13-CH_3 at −9.7 ppm, CH_2 at 37.1, 11.9, −11.1 ppm, *meso*-H at −188.5(1) and −161.3(2) ppm;[1565] bis-cyanide complex at 303 K: 7,13-CH_3 at −18.7 ppm, CH_2 at 81.5, 23.3 and −17.2 ppm, *meso*-H at −450(1) and −364(2) ppm[1573]) it is clear that the complexes consist of $S = 1/2$ Fe^{III} either uncoupled or weakly ferromagnetically coupled to a $S = 1/2$ π-cation radical corrolate$^{2-}\bullet$; clearly the degree of coupling differs for the two bis-ligand complexes. Notably, the *meso*-H signals moved ∼536 and ∼633 ppm upfield upon cyanide addition, which indicates a reversal in the spin of the macrocycle unpaired electron.[1573] The bis-cyanide complex is not stable, and over an hour's time it autoreduces to a simple $S = 1/2$ Fe^{III} corrolate^{3-} complex that loses one cyanide ligand to prevent having a total 2− charge on the complex.[1573] Thus, this is a case where an axial ligand serves as a reducing agent of the macrocycle and not of the metal.

A number of other metallocorroles also appear to have radical character on the macrocycle. These include the 4-coordinate Mn complex of 7,13-dimethyl-2,3,8,12,17,18-hexaethylcorrolate, which is nominally Mn^{III} but in terms of ^1H NMR shifts appears to be Mn^{II} bound antiferromagnetically to a corrolate radical (*meso*-H resonances at 70.5(2) and 25.0(1) ppm), overall $S = 1$,[1574] as in the $ClFe^{III}$ case.[1565,1566] The phenylcobalt octaethylcorrolate has g-values that suggest a largely metal-based electron (1.967, 2.004, 2.112), but also has large ^1H ENDOR couplings for the ethyl protons; DFT calculations indicate that there is significant spin density on both the macrocycle and in the cobalt d_{yz} orbital.[1575] Copper *meso*-triarylcorrolates, both *meso*-triphenylcorrolate[1576] and β-octafluoro-*meso*-triphenylcorrolate,[479] have been shown to have a diamagnetic $S = 0$ Cu^{III} ground state but an excited state that is $S = 1/2$ Cu^{II} coupled antiferromagnetically to an $S = 1/2$ π-cation radical corrolate$^{2-}\bullet$. The excited state is much more highly populated over the temperature range of the NMR measurements for the non-fluorinated triphenylcorrolates.[1576] The structure of CuTPCorr shows the molecule to be highly saddled.[1576] The corresponding silver complex, AgTPCorr, is slightly saddled, but shows no evidence of paramagnetism; thus the metal is Ag^{III} bound to an 'innocent' corrolate^{3-} anion.[1577] The As, Sb and Bi octaethylcorrolates are also simple M^{III} complexes of 'innocent' corrolate^{3-} anions; the electrochemical oxidation of these and their methyl complexes have also been reported.[1578]

Iron,[1579,1580] manganese,[1581,1582] rhodium[1580] and chromium[1583] tri-(pentafluorophenyl)corrolates have been shown to be potent catalysts for aerobic oxidation of organic molecules, and reduced iron and cobalt corrolates have been shown to be active in CO_2 reduction.[1584]

8 IRON(IV) PORPHYRINS AND THEIR REACTIONS

Five types of Fe^{IV} porphyrin complexes have been reported, all of which have spin state $S = 1$: (1) the deep red, five-coordinate ferryl, $(Fe^{IV}{=}O)^{2+}$, complexes[1585] and the six-coordinate adducts of these ferryl complexes, the $(B)(Fe^{IV}=O)^{2+}$ complexes;[213,1585,1586] (2) the Fe^{IV}−phenyl complex;[1587] (3) iron(IV) carbene complexes;[593–596,1588–1595] (4) iron(IV) hydrazine complexes; and (5) the six-coordinate d^4 complex $[TPPFe(OMe)_2]$[209] mentioned briefly in Section 7 above. The ferryl and Fe^{IV}−phenyl cases have direct application to active states of heme proteins, particularly the cytochromes P450, peroxidases, catalases, and related enzymes.

8.1 Five- and Six-coordinate Ferryl, $(FeO)^{2+}$, Porphyrin Complexes

Ferryl complexes have been implicated in the reaction mechanisms of peroxidases and cytochromes P450.[24–32,36,38,1596] For horseradish peroxidase, two intermediates are spectroscopically detectable.[13] Compound I, formed upon addition of peroxide to the resting Fe^{III} form of the enzyme, is a green species that is formally two oxidation levels higher than the resting state, and is widely believed to consist of an $(Fe^{IV}{=}O)^{2+}$ unit complexed by a porphyrin π-cation radical. The $[(P^-\bullet)\ Fe^{IV}{=}O]^+$ complexes are discussed in Section 9. Compound II, which is red, and is obtained upon one-electron reduction of Compound I, also possesses a $(Fe^{IV}{=}O)^{2+}$ unit, in this case complexed by a normal porphyrin dianion, $PFe^{IV}{=}O$. The fifth ligand, provided by the protein in the various enzymes, is a cysteine thiolate for the cytochromes P450,[24,25,1597] nitric oxide synthases (NOS)[1598] and chloroperoxidase (CPO),[1599,1600] a histidine for horseradish peroxidase (HRP),[1601] heme oxygenase (HO)[32,34] and cytochrome *c* peroxidase (CCP),[1602,1603] and a tyrosine for catalase.[1604]

As in the case of horseradish peroxidase, several synthetic metalloporphyrins in the presence of H_2O_2 have been found to be potent catalysts for the chemiluminescent oxidation of luminol or isoluminol.[1605] The microperoxidases, mainly MP8 and MP11, have been shown to act as functional peroxidase enzyme models.[1606–1612] However, they are readily inactivated within one min of catalytic turnover,[1612,1613] and incorporation into a molecular sieve

(MCM-41) does not afford protection from inactivation.[1611] Cytochrome P450-type enzymes not only include those that carry out hydroxylation and epoxidation reactions, but also aromatizations, such as estrogen synthetase,[29,30,1614] and oxidations of heteroatoms. Nitric oxide synthases,[50,1615] which have very similar heme-thiolate active sites, oxidize a nitrogen atom of the guanidine group of arginine to nitric oxide. Since detailed discussion of the chemistry of peroxidases and catalases is given in the article entitled (*see* ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***) and of mono- and dioxygenases in the article entitled (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***), the presentation in the present article has been abbreviated.

Model heme complexes containing the ferryl unit and a nonoxidized porphyrin ring have been prepared and investigated by ^{1}H NMR spectroscopy at low temperatures by Balch and La Mar and coworkers[213,215,1585,1616] and by resonance Raman spectroscopy by Nakamoto and coworkers.[1617] The ferryl species have been produced by several means, including

(1) thermal decomposition (at $-30\,°C$) of the μ-peroxo dimer of PFe^{III}, formed from reaction of 2 PFe^{II} with molecular oxygen at $-70\,°C$ (equations 23a, b above),[1585,1618]
(2) by base-catalyzed cleavage of the μ-peroxo dimer at similar low temperatures (equation 50):[213,1585,1586,1618]

$$\underset{Fe^{III}(O_2{}^{2-})Fe^{III}}{PFe\text{–}OO\text{–}FeP} + 2B \longrightarrow \underset{(B)(Fe^{IV}O)}{2(B)PFeO} \quad (50)$$

(3) by base-catalyzed cleavage of $PFeOOCR'R_2$ complexes (equation 51):[215,1618–1620]

$$PFe\text{–}OO\text{–}CR'R_2 + B \longrightarrow (B)PFe^{IV}O + \cdot OCR'R_2 \quad (51)$$

(a) In the absence of a radical trap (equation 52):

$$(B)PFe^{IV}O + \cdot OCR'R_2 \xrightarrow{H^+} PFe^{III} + \underset{>50\%}{HOR'} + \underset{90\%}{O{=}CR_2} + B \quad (52)$$

(b) In the presence of radical trap (equation 53):

$$(B)PFe^{IV}O + \cdot OCR'R_2 \xrightarrow{H^+} PFe^{III} + \underset{10-20\%}{O{=}CR_2} + \underset{80-90\%}{HOCR'R_2} \quad (53)$$

(yields given for $R' = R = Me$);[1620]

(4) by oxidation of PFe^{III} with hydrogen peroxide[1619,1621] or hypochlorite[1622] under basic conditions (equations 54 and 55)

$$2PFe^{III}(H_2O)_2 + H_2O_2 \longrightarrow PFe^{IV}O + 5H_2O \quad (54)$$

$$2PFe^{III} + OCl^- \longrightarrow 2PFe^{IV}O + Cl^- \quad (55)$$

(5) by oxidation of $PFe^{III}OH$ with organic peracids (equation 56):[218,1619]

$$PFe^{III}OH + m\text{-}ClC_6H_4C(O)OOH \longrightarrow PFe^{IV}O + H_2O + m\text{-}ClC_6H_4CO_2H \quad (56)$$

or (6) by electrochemical oxidation of hydroxide or methoxide complexes of ‘protected’ (from μ-oxo dimer formation) Fe^{III} porphyrins such as $TMPFe^{III}$, $(2,6\text{-}Cl_2)_4TPPFe^{III}$, $(2,6\text{-}Br_2)_4TPPFe^{III}$,[1619,1623,1624] or $(2,4,6\text{-}Ph_3)_4TPPFe^{III}$, also called $TTPPPFe^{III}$.[1625] In cases (3)–(5) above, the Compound I state, $[PFe{=}O]^+$, may be formed initially, but the Compound II state, $[PFe{=}O]$, is the only product detected spectroscopically. The kinetics of equations (50–56), including the formation of the Compound I precursor, have been studied in detail by several groups.[1619,1626–1630] The Compound I state is readily reached by reaction of an iron(III) porphyrin with iodosylbenzene,[29,1631–1635] potassium monopersulfate,[1636] or an amine *N*-oxide,[1637] and these reagents are frequently used for generation of the hydroxylation catalysts of the Compound I level that are discussed in Section 9.

Bruice and coworkers have investigated the electrochemical oxidation of hydroxide- and methoxide-ligated Fe^{III} 2,6-disubstituted tetraphenylporphyrins and report that one-electron oxidation produces the Fe^{IV}–oxo porphyrins, analogous to Compound II of peroxidases; removal of another electron produces the Fe^{IV}–oxo porphyrin radicals analogous to Compound I.[1623,1624,1638] However, in the corresponding Mn porphyrin case, the two-electron oxidized species is believed to be $P^{2-}Mn^V = O$, rather than $P^{-}\bullet\, Mn^{IV} = O$.[1638] The first and second one-electron oxidation potentials are separated by about 100 mV in dry CH_2Cl_2 and overlap in wet CH_2Cl_2.[1624] A third one-electron oxidation, presumably to the Fe^{IV}–oxo porphyrin dication, one-electron more oxidized than Compound I, has a potential in wet or dry CH_2Cl_2 between 300 and 460 mV more positive than the second oxidation, depending on the porphyrin substituents.[1624]

Both the five- and six-coordinate ferryl porphyrin complexes have very small ^{1}H NMR isotropic shifts of all resonances. The Curie plots for all resonances are strictly linear, and the observed shifts extrapolate to nearly to the diamagnetic positions for each type of proton.[1585] NMR results for the six-coordinate adducts indicate that the axial ligand, which is located *trans* to the strongly π-donating oxo ligand, has very characteristic proton shifts. Investigation of imidazole and pyridine adducts of synthetic ferryl porphyrins and ferryl myoglobin led to detection of broad, weak axial histidine resonances at -11 and -16 ppm in ferryl myoglobin at 35 °C.[1616] There is significant spin delocalization from the d_{xz},d_{yz} orbitals of the metal to the p_x and p_y orbitals of oxygen in both the model compounds and ferryl myoglobin.[1616] The small observed shifts are entirely consistent with theoretical calculations,[1639–1642] which indicate substantial π interaction between iron and oxygen orbitals and effective localization of

unpaired spin density within the $(Fe^{IV}{=}O)^{2+}$ unit, a significant amount of which may be localized on the oxygen, in line with the reactivity of this group.[24,1596] $TMPFe^{IV}{=}O$ reacts with substituted styrenes with a reactivity that is very unlike that of the 1-electron oxidized complex $[TMPFe^{IV}{=}O]^+$.[1643]

The *N*-methylimidazole complex of $(2,6\text{-}Cl_2)_4TPPFe^{IV}=O$ has been characterized by ^1H NMR, UV–visible, resonance Raman, and Mössbauer spectroscopies.[218] The Fe=O stretching frequency varies inversely with the donor strength of the sixth ligand: THF ($841\,cm^{-1}$) < DMF ($829\,cm^{-1}$) < N-MeIm ($818\,cm^{-1}$). Likewise, although the Mössbauer isomer shifts are essentially constant ($0.07–0.09\,mm\,s^{-1}$), quadrupole splittings vary inversely with axial-ligand donor strength: THF ($2.08\,mm\,s^{-1}$) < DMF ($1.81\,mm\,s^{-1}$) < N-MeIm ($1.35\,mm\,s^{-1}$).[218]

Oxoiron(IV) tetraphenylchlorin complexes have been prepared as the first models of a reaction intermediate in the catalytic cycle of cytochrome *d*.[1644] Optical absorption spectra show a characteristic red-shifted band at 630 nm as observed in the oxoferryl intermediate of cytochrome *d*, and the proton NMR spectra of the N-MeIm complex exhibit very small hyperfine shifts of the pyrrole protons, as is true for oxoferryl porphyrin complexes. The pyrroline protons of the saturated pyrrole ring show unusual splitting into upfield and downfield resonances. The N-MeIm complex also shows normal $Fe^{IV}{=}O$ stretching frequencies as compared to the corresponding oxoferryl porphyrin complexes.[1644] And finally, for iron porphycenes, both peroxo and ferryl intermediates have been detected by ^1H NMR spectroscopy during the oxygenation of the Fe^{II} complexes.[1645]

8.2 Five-coordinate Iron(IV) Phenyl Porphyrins and Related Cytochrome P450-inactivating Complexes

One-electron oxidation of phenyl iron(III) tetraarylporphyrin complexes with bromine in chloroform at −60 °C produces deep red solutions whose ^1H and ^2H NMR spectra indicate that they are the corresponding iron(IV) complexes.[1587] For the low-spin aryl Fe^{III} porphyrins the electron configuration is $(d_{xy})^2(d_{xz},d_{yz})^3$, with one π-symmetry unpaired electron, and for the low-spin aryl Fe^{IV} porphyrins the electron configuration is $(d_{xy})^2(d_{xz},d_{yz})^2$, with two π-symmetry unpaired electrons.[1587] The aryl Fe^{IV} porphyrins are thermally unstable, and upon warming convert cleanly to *N*-phenylporphyrin complexes of Fe^{II} by reductive elimination.[1244] This process has been investigated by electrochemical techniques,[1646,1647] by which it was shown that the reversible (at fast scan rates) one-electron oxidation of σ-aryl complexes of PFe^{III} was followed by an irreversible chemical reaction that yielded the Fe^{II} complex of the *N*-phenylporphyrin, which could then be oxidized reversibly by one electron to yield the Fe^{III} complex of the *N*-phenylporphyrin. (If the Fe^{II} complex of the *N*-phenylporphyrin is instead reduced by one electron, the Fe^{I} complex of the *N*-phenylporphyrin is formed reversibly at fast scan rates.[1646] However, it slowly converts back to the σ-phenyl complex of the Fe^{III} porphyrin by phenyl migration from nitrogen to iron. This $PFe^{III}(\sigma\text{-Ph})$ can be reduced reversibly to the corresponding $[PFe^{II}(\sigma\text{-Ph})]^-$ complex,[1646] as mentioned in Section 6.3.14.) Phenyl migration from Fe^{IV} to a porphyrin nitrogen, which produces a green pigment, is known to occur under aerobic conditions in protein systems such as cytochrome P450, catalase, hemoglobin, or myoglobin.[1648,1649] The phenyl heme is also produced by attack of aryl hydrazines in the presence of oxygen,[1650,1651] and probably goes through a phenyl Fe^{IV} intermediate. These *N*-arylporphyrin complexes of iron, and their *N*-alkyl counterparts, are readily demetallated, leading to destruction of function of the heme protein.[1651]

Reactions of high-valent iron porphyrins with a number of other reagents besides aryl hydrazines lead to so-called ‘suicide inactivation’ of the catalyst, and similar reactions are known to inactivate cytochromes P450. One example is the suicide inactivation by terminal alkenes, which can either react with the Compound I-level ferryl species to produce epoxides, or can react with one of the porphyrin nitrogens to produce *N*-alkyl–O–Fe (N–C–C–O–Fe) metallacyclic hemins.[1652,1653] Loss of iron yields *N*-hydroxyethylporphyrins.[1652,1654] *N*-Alkyl metalloporphyrins can be dealkylated by nucleophiles, such as di-*n*-butylamine.[1655] An antibody specific for *N*-methylmesoporphyrin IX binds iron(III) mesoporphyrin IX and the resulting complex has peroxidase activity toward typical HRP substrates (pyrogallol, hydroquinone, *o*-dianisidine and 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid), ABTS) in the presence of H_2O_2.[1656]

8.3 Iron(IV) Carbene Complexes

Porphyrinatoiron(IV) carbenes, including that resulting from the reaction of 1,1-bis(*p*-chlorophenyl)-2,2,2-trichloroethane (DDT),[1588] are produced by reaction of polyhalogenated hydrocarbons with PFe^{II} (equation 57):[1588,1589]

$$PFe^{II} + RR'CX_2 \xrightarrow[-2X^-]{+2e^-} PFe^{II}(CRR') \qquad (57)$$

It has been shown that these carbenes can insert into $Fe–N_{por}$ bonds to form vinylidine (*N*-alkyl–iron porphyrin metallacycle (N–C–C–Fe)) complexes,[1590–1593] which can then go on to form *cis*-bridged vinylidines of the porphyrin,[1594] with loss of iron. Carbene equivalents of iodosylbenzene can also react with iron porphyrins to give five-membered Fe–O–C–C–N metallocycles.[661] Iron porphyrin carbenes can also react with amines to produce the isocyanide complexes (equation 58):[1595]

$$PFeCCl_2 + 2RNH_2 \longrightarrow PFe(CNR)(RNH_2) + 2HCl \qquad (58)$$

As mentioned above, $TPPFe^{II}$ complexes have been reported to be active catalysts for the cyclopropanation

of alkenes with ethyldiazoacetate. The active species in such carbon transfer reactions are assumed to be iron porphyrin carbene complexes of the general formula TPPFe=CHR.[593–596] Species such as TPPFe($CHCO_2Et$) have been proposed, but thus far have not been observed directly because of their high reactivity. However, remarkably stable arylcarbene or (alkoxycarbonyl)carbene porphyrin complexes are formed when the electron-deficient iron complex of *meso*-tetrakis(pentafluoro)porphyrinato dianion [Fe(TPFPP)C(Ph)R] is reacted with diazo compounds N≡N–C(Ph)R with R = Ph, CO_2Et, and $CO_2CH_2CH=CH_2$.[596] In contrast to the carbene complex [TPPFe(CCl_2)],[1588] only one of these complexes, namely the [Fe(TPFPP)(CPh_2)] porphyrin, reacted with N-methylimidazole to form the six-coordinate diamagnetic complex [Fe(TPFPP)(CPh_2)(N-MeIm)], which is unstable in moist air, suggesting that the addition of the imidazole ligand destabilizes the Fe=CPh_2 bond. The other two complexes did not add N-MeIm or pyridine. Pyridine could also not be added to the [Fe(TPFPP)(CPh_2)] compound. Prolonged reaction with pyridine led to the formation of the [TPFPPFe$(Py)_2$] complex reported originally by Therien.[621] The crystal structures for [Fe(TPFPP)(CPh_2)] and the N-methylimidazole complex were obtained and reveal Fe=CPh_2 bond lengths of 1.767 and 1.827 Å, respectively and Fe–N_{por} bond lengths ranging from 1.96 to 1.98 Å with very large ruffling of the porphyrin core.[596] Of the four carbene complexes synthesized two, [Fe(TPFPP)(CPh_2)CO_2Et] and [Fe(TPFPP)(CPh_2)(N-MeIm)], reacted with styrenes to form cyclopropanes, and with cyclohexene and cumene to form benzylic C-H insertion products. Kano *et al.*[1657] have also shown that reduction of alkenes and alkynes by the BH_4^- anion are mediated by iron porphyrins. It was assumed that as intermediates in these reactions (σ-alkyl) iron^{II} and iron^{III} porphyrins were formed. It was also shown that the addition of thiophenol or other thiols to styrenes or other alkenes was catalyzed by iron(II) porphyrins, for example the complex of protoporphyrin IX dianion. The reaction mechanisms were proposed to proceed via (σ-alkyl)iron(II) porphyrins, which may act as nucleophiles.[1657]

8.4 Iron(IV) Hydrazine Complexes

Hydrazines, such as 1-amino-2,2,6,6-tetramethylpiperidine or phenylhydrazine, in the presence of either dioxygen or one equivalent of iodosylbenzene react with PFe^{III} to give the corresponding nitrene complexes, PFe(NNR_2),[1658,1659] which, in the presence of limited amounts of O_2, react to give σ-alkyl or σ-aryl Fe^{III} complexes.[1659] Similarly, activated nitrogen atoms, such as the imide analogs of iodosylbenzene, PhI=NNR_2, react to form the corresponding nitrenes,[1660] which can insert into a Fe–N_{por} bond to give a Fe−porphyrin−N-aziridine.[1661] Likewise, a side reaction of m-chloroperbenzoic acid with TMPFe^{III} is to insert oxygen into a Fe−N_{por} bond, producing an iron(III) porphyrin N-oxide.[1662]

8.5 Six-coordinate, Bis-methoxide Iron(IV) Porphyrins

As mentioned in Section 7 above, Groves and coworkers[209] have reported the valence isomerization of the Fe^{III} porphyrin π-cation radical in the presence of methoxide (equation 59):

$$\underset{(P^-\bullet)Fe^{III}}{[TMPFe(ClO_4)_2]} + 2OMe^- \longrightarrow \underset{(P^{2-})Fe^{IV}}{[TMPFe(OMe)_2]} + 2ClO_4^- \qquad (59)$$

8.6 Comparison of Iron(IV) Porphyrins and Iron(III) Porphyrin π-Cation Radicals

As concluded by Balch and Renner,[1587] axial ligands play a major role in determining the electronic distribution within highly oxidized iron porphyrins. It has been found that an oxo ligand, a phenyl ligand, or two methoxy ligands favor the Fe^{IV} porphyrin dianion structure, while halide ions, imidazole, or perchlorate ligands produce the Fe^{III} porphyrin π-cation radical monoanion electronic structure. The ability of the iron π electron to interact with the axial ligand(s) appears to make a major contribution to these differences. Density function calculation studies of one-electron oxidized mono- and difluoroiron(III) porphyrins have corroborated this conclusion by showing that for the six-coordinate difluoro complex, the Fe^{IV} ($S = 1$) state is stabilized relative to the Fe^{III} a_{2u} π-cation radical ($S = 3$) state, while for the monofluoro complex this ordering of states is reversed.[1663] A possible relationship between Fe^{III} spin state and the site of one-electron oxidation in iron(III) porphyrins is rationalized in terms of exchange energy stabilization and the σ- and π-donor properties of the axial ligand(s),[1663] in agreement with conclusions reached from experimental investigations.[1587]

9 IRON(IV) PORPHYRIN π-CATION RADICALS AND THEIR REACTIONS

As mentioned in Section 8, the green Compound I species observed in peroxidase enzymes, which contains a heme that is two oxidation levels above PFe^{III}, is believed to consist of a ferryl porphyrin radical, $[(P^-\cdot)\ (Fe^{IV}{=}O)]^+$; the Mössbauer spectrum of this species is consistent with a $S = 1$ ferryl center bound antiferromatically to the porphyrin radical,[1664] although in some cases (notably the cytochrome *c* peroxidases) it has been shown that the radical is located on a tryptophan residue near the heme center (W191), which gives rise to an intense axial[1665] radical signal at g = 2[1666] that is unlike the broadened radical signal reported for the porphyrin π-cation radical form of HRP Compound I (*see* ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***).[1664] The crystal structures of the resting state and Compound I forms of CCP have recently been reported,[1666] and although W191 is π-stacked with the

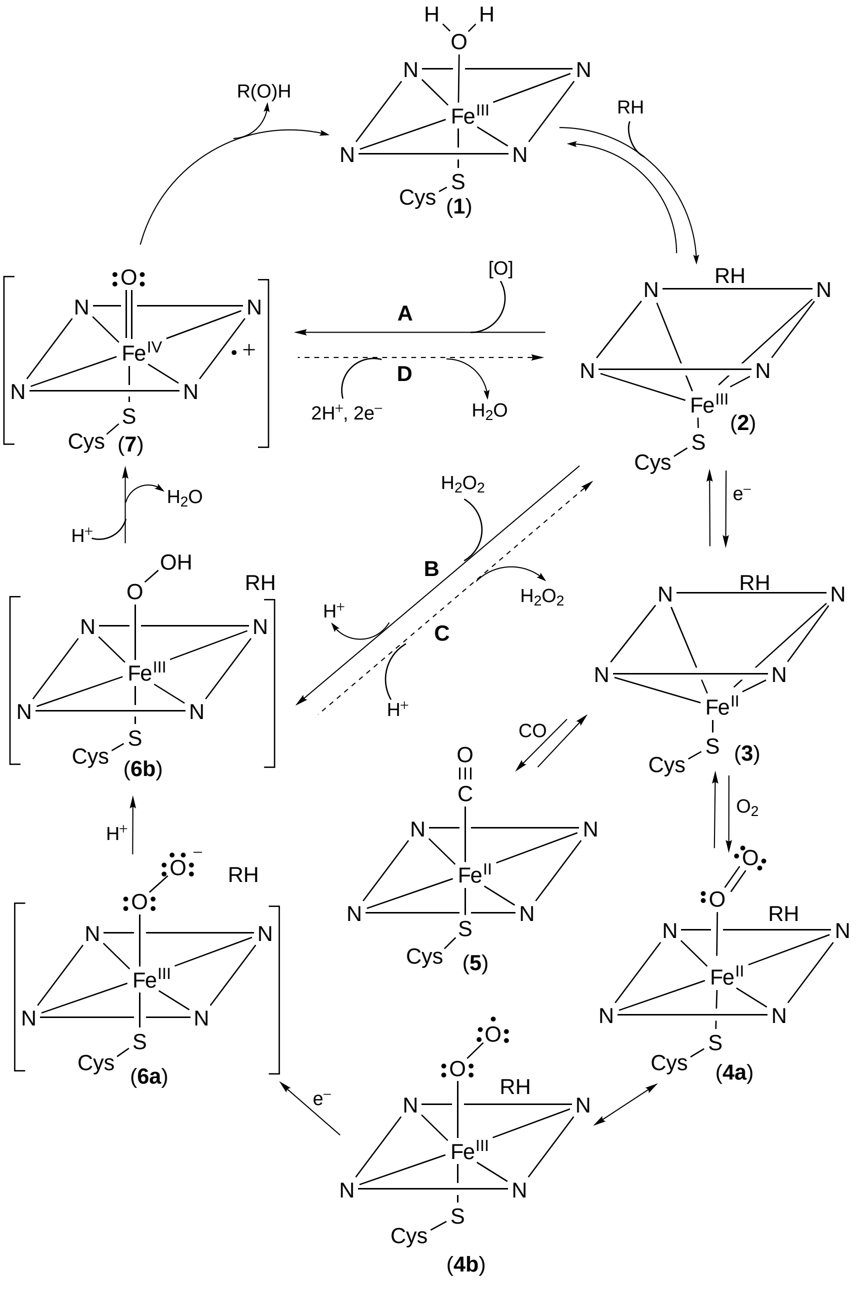

Figure 16 Intermediates involved in alkane oxidation by cytochrome P450.[27] Catalytic cycles involving either O_2 and electrons (from NADPH), or a single oxygen atom donor (AO) are shown. Model reactions often use single oxygen atom donors AO such as iodosylbenzene, amine *N*-oxides and organic or inorganic hydroperoxides or peroxy acids[32]

proximal histidine, H175,[1666] there is much less magnetic coupling between the tryptophan radical and the Fe(IV) center in CCP.[1665]

The same ferryl porphyrin radical, $[(P^{-}\cdot)\ (Fe^{IV}{=}O)]^{+}$, electronic structure is believed to exist for the activated oxygen-inserting species of cytochromes P450, although attempts to trap this species by freeze-quench experiments utilizing peroxyacetic acid on the timescale of 8 ms have invariably led to the observation of a tyrosyl radical of a nearby tyrosine side chain rather than the porphyrin radical.[1667,1668] Thus, the porphyrin π radical part of the ferryl porphyrin radical state of cytochromes P450, is a transient and very reactive species (either in the enzymes or in model hemes) and can readily insert the ferryl oxygen atom into many C–H bonds, epoxidize olefins, and carry out many other monooxygenase, epoxidase and dehalogenase reactions.[24–32,1596] The mechanism proposed for cytochrome P450 hydroxylations is shown in Figure 16. The same general

mechanism is believed to be involved in the reactions of peroxidases, except that H_2O_2 reacts with PFe^{III}, rather than one-electron reduction of PFe^{III}, followed by O_2 binding, followed by one more one-electron reduction.

A number of theoretical calculations related to Compound I and II states and stereoselectivity of oxo-transfer reactions have been reported,[225,1669–1678] and the role of the heme active site and protein environment in structure, spectra, and function of the cytochromes P450 from a theoretical point of view has been reviewed more recently.[1679] Theoretical calculations of the electron configuration of the compound I state have suggested that instead of being porphyrin-based, the radical is thiolate-based,[1680–1684] and possible roles for a higher-spin state ($S = 3/2$)[1680,1682–1684] and either a saddle[1685] or ruffle[1686] distortion of the porphyrin ring have been proposed, especially with regard to the oxygen rebound mechanism of Groves and coworkers,[1687–1693] but not in the case of benzene hydroxylation.[1694] Alternatively, other recent work suggests the possibility of two different electrophilic pathways.[1695–1697] The role of protonation of the peroxide species in producing Compound I of both P450s and peroxidases has also been studied theoretically; it has been shown that for P450s, single protonation of the distal (terminal) oxygen of the bent Fe^{III}–O–O^- unit results in significant weakening of the O–O bond, and that addition of a second proton to the same oxygen leads directly to Compound I and water as products,[1698,1699] while a series of events involving deprotonation of the proximal oxygen of hydrogen peroxide and then donation of the proton back to the other (distal) oxygen atom, then leading to the same products as for P450s are involved for peroxidases.[1700–1702] The multiplicity of reaction pathways of the Fe^{III}-hydroperoxo species is shown by DFT calculations that indicate there are four low-energy epoxidation pathways for the Fe^{III}-hydroperoxo complex, in which the species transfers oxygen to olefins either from the proximal or the distal oxygen atoms, in both concerted and stepwise manners.[1703] However, the barriers of these four pathways, 37−53 kcal mol^{-1}, are too high in comparison with the 14 kcal mol^{-1} observed for epoxidation by Compound I. Therefore, Fe^{III}-hydroperoxo, as such, cannot be the second oxidant in epoxidation reactions, in line with its significant basicity and poor electron-accepting capability.[1703] Further work on this system has resulted in the conclusion that ‘Compound I is a chameleon oxidant that tunes its reactivity and selectivity patterns in response to the protein environment in which it is accommodated’.[1704,1705] This appears to be true for both cytochromes P450 and horseradish peroxidase.[1706] Calculations have also suggested that the radical of catalase Compound I is not located on the proximal tyrosine.[1707] Experimental evidence of alternative pathways of reactivity of these Compound I species has been reported.[1708–1711]

A number of research groups have investigated the NMR, EPR, Mössbauer, and resonance Raman spectra of model complexes of this reactive species.[212,214–217,1618–1656,1588–1595,1657–1713] Resonance Raman spectra have diagnostic bands for Fe=O (828 cm−1) in the Compound I species.[1714,1715] Weiss, Gold, and coworkers[218,219,1716] have also generated oxoferrylporphyrin radicals by m-chloroperoxybenzoic acid oxidation of the chloro- and trifluoromethanesulfonato complexes of [$TMPFe^{III}$] and the trifluoromethanesulfonato complex of tetrakis(2,6-dichlorophenyl)porphinatoiron(III), [$(2,6\text{-}Cl_2)_4TPPFe^{III}$] or [$DCPFe^{III}$], and tetrakis(2,4,6-trimethoxyphenyl)porphinatoiron(III), [$TTMPPFe^{III}$], and have characterized them by EPR, Mössbauer, resonance Raman, and UV−visible spectroscopy. In all but three cases,[213,1717] ‘hindered’ or ‘protected’ porphyrins, such as those mentioned above plus 2,7,12,17-tetramethyl-3,8,13,18-tetramesityl-porphyrin (TMTMP)[216] and tetrakis(2,6-difluorophenyl)porphyrin ($(2,6\text{-}F_2)_4TPP$),[210] were used to elucidate the spectroscopic properties of the π-cation radicals of PFe^{IV}=O. In the case of the TMP complexes it was found that the porphyrin radical is of the $3a_{2u}(\pi)$ type (Figure 4), since large π spin delocalization is detected at the *meso*-phenyl-H and –CH_3 positions, as well as a smaller amount of π spin delocalization at the β-pyrrole positions.[214,228] However, the TMTMP complex has an unpaired $a_{1u}(\pi)$ electron, since the very large pyrrole CH_3 isotropic shift indicates large spin delocalization to the pyrrole positions in this case.[216,228] In comparison, pyrrole-CH_3 and *meso*-H shifts for the ferryl complex of protohemin are 4 and 16 ppm, respectively.[213] The [$TMPFe^{IV}$=O]$^+$ complex has been characterized by MCD spectroscopy.[1718] Horseradish peroxidase Compound I has been assigned as an $a_{2u}(\pi)$ radical, while catalase Compound I is believed to be an $a_{1u}(\pi)$ radical,[1719,1720] and cytochrome c peroxidase Compound I is believed to have a tryptophan rather than a porphyrin π-cation radical,[1665] as mentioned above. Compound I and II analogs have also been created from iron(III) porpholactones.[1721]

The most important property of the model hemes of Compound I oxidation level is their ability to act as catalysts for the hydroxylation of unactivated hydrocarbons,[1630,1631,1722–1726,1717,1727–1733] epoxidation of alkenes,[212,1631,1734–1760] and aromatization of partially unsaturated rings.[1761] Not only iron porphyrins, but also cobalt, manganese, and chromium porphyrins will carry out these reactions.[26,1596,1729,1759,1760,1762,1763] Porphyrin substituents play a role in determining the reactivities of these high-valent species, and it has been shown that oxo-iron porphyrins having electron-withdrawing substituents rapidly epoxidize olefins, that high-valent iron oxo complexes of electron-deficient porphyrin ligands are more powerful oxidizing species than are those of electron-rich porphyrin ligands in alkane hydroxylation reactions, and the presence of electron-donating substituents on a porphyrin ligand gives a relatively high ^{18}O incorporation from labeled $H_2\,^{18}O$ into an oxygenated product when a mixture of olefin and $H_2\,^{18}O$ is added to a reaction solution containing a high-valent iron oxo intermediate, whereas only a small amount of ^{18}O incorporation is observed with iron porphyrin complexes

containing electron-withdrawing substituents.[1764] Structure-reactivity studies of olefin epoxidation indicate that the oxene is formed exclusively via a heterolytic mechanism, and provide evidence for continual changes in transition-state structure rather than a change of mechanism from heterolysis with peracids to homolysis with hydroperoxides, as had previously been proposed.[1765] A highly electron-deficient iron porphyrinate, having four CF_3 groups on two opposite pyrrole rings, was found to be unstable with respect to decomposition, and hence not suitable for use as an oxidation catalyst.[501] Highly halogenated porphyrins[405–409,1766,1767] produce quite robust catalysts that allow many catalytic turnovers before degradation. High degrees of regio- and enantioselectivity can be obtained,[1762,1766] and the adsorption,[1759] intercalation,[1759] or covalent attachment[1760] of these catalysts to various mineral supports offers the possibility of yet more robust and selective catalysts.

A study of isobutane oxidation using O_2 as the sole oxidant by three highly halogenated porphyrin complexes, $(C_6F_5)_4$PFe, $Br_8(C_6F_5)_4$PFe, and $(C_3F_7)_4$PFe, has produced interesting findings that relate to the mechanism of this reaction.[1768,1769] It was found that the nature and distribution of hydrocarbon oxidation products show that an autoxidation reaction pathway dominates the reaction kinetics, consistent with a radical chain process. For each catalytic system examined, PFe^{II} species were shown not to be stable under moderate O_2 pressure at 80 °C; in every case, the PFe^{II} catalyst precursor was converted quantitatively to high-spin PFe^{III} complexes prior to the observation of any hydrocarbon oxidation products.[1769] Once catalytic isobutane oxidation is initiated, all reactions are marked by concomitant decomposition of the porphyrin-based catalyst, even including $Br_8(C_6F_5)_4$PFe-based catalysts, which lack macrocycle C-H bonds, do not exhibit augmented stability with respect to analogous catalysts based on $(C_6F_5)_4$PFe and $(C_3F_7)_4$PFe species.[1769] The data presented are consistent with a hydrocarbon oxidation process in which PFe complexes play dual roles of radical chain initiator and the species responsible for the catalytic decomposition of organic peroxides. This modified Haber-Weiss reaction scheme provides for the decomposition of *tert*-butyl hydroperoxide intermediates via reaction with PFe-OH complexes: the PFe^{III} species responsible for hydroperoxide decomposition are regenerated by reaction of PFe^{II} with dioxygen under these experimental conditions.[1769]

Photoactivation of polyhalogenated porphyriniron(III)–hydroxo complexes with light of wavelengths between 350 and 450 nm has been shown to allow oxidation by O_2 without consumption of a reducing agent.[1770] MP8 can also generate ferryl and π-cation radical species upon photoinduced oxidation.[1771]

Other related reactions of these high-valent species include cyclopropanation of alkenes,[1772–1776] oxidation of benzyltrialkylstannanes,[1777] dehydration of aldoximes,[1778] and olefination of aldehydes and ketones.[1779–1781] Mechanisms of reaction of the $[PM{=}O]^+$ species are believed to involve the intermediates proposed in Figure 16.[32,1679] The manganese complexes are the most active catalysts.[1782,1783]

Usually, Lewis bases that might act as sixth ligands for the $(P^{-}\bullet)$ $Fe^{IV}{=}O$ active species have not been explicitly provided in these catalytic reactions. However, the nature and possible role of the sixth ligand is finally becoming recognized as being important in the activity of the oxotransferase model catalysts, as it has been for some time for the proteins.[36,1784,1785] As suggested in Figure 17 the thiolate ligand of cytochromes P450 is believed to aid in cleavage of the O–O bond by ‘pushing’ electron density on to the metal, while the histidine ligand of horseradish peroxidase is believed to need assistance from a distal hydrogen-bonding framework to cleave the O–O bond by ‘pulling’ on the terminal oxygen.[36] In view of these considerations, catalysis of hydroxylation and epoxidation reactions of model hemes by peroxide-containing oxidants might be expected to have enhanced rates of reaction in the presence of suitable Lewis bases. Anionic axial ligands of $TMPFe^{III}$ have a marked influence on the formation of oxoiron(IV) porphyrin intermediates in their reactions with PhIO and *m*-CPBA; anions of good electron-donating ability (Cl^-, F^-, $CH_3CO_2^-$ and OH^-) increased the tendency to form the high-valent oxoiron(IV) porphyrin intermediates over those of poor electron-donating ability ($CF_3SO_3^-$, ClO_4^-, and NO_3^-).[1786,1787]

In line with the above hypothesis, Momenteau and coworkers[1788] showed that with a proximal imidazole ligand, Fe and Mn hanging-base porphyrins, in the presence of H_2O_2, will carry out both epoxidation and dismutation (of H_2O_2) reactions, while with a phenolate proximal ligand, dismutation of H_2O_2 is favored by the Mn porphyrin, and is the exclusive reaction of the Fe porphyrin. Furthermore, Bruice and coworkers have shown that addition of small concentrations of NH_3 or $CF_3CH_2NH_2$ enhances

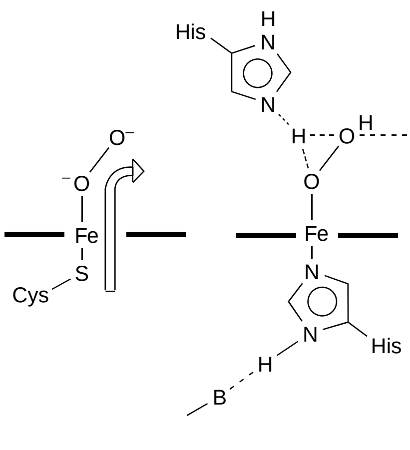

Figure 17 A schematic view of the involvement of axial ligands and distal residues in the ‘push–pull’ mechanism for O–O bond cleavage of an iron-bound peroxide in thiolate-ligated (left) and histidine-ligated (right) systems such as cytochrome P450 and horseradish peroxidase, respectively[36]

the reaction of water-soluble Fe^{III} porphyrins with *t*-BuOOH by a factor of about 100 over that observed in water, while addition of imidazole did not produce a rate enhancement.[1433] (However, reaction of water-soluble Mn^{III} porphyrins with methyl diphenylhydroperoxyacetate showed 100-fold rate inhancements in the presence of imidazole.[1789]) The proposed kinetic scheme for the *t*-BuOOH reactions depends upon the ability to form mono-nitrogen base complexes, $PFe^{III}(H_2O)(L)$ or $PFe^{III}(OH)(L)$, since the bis-ligand complexes, $PFe^{III}(L)_2$, were shown to be unreactive with *t*-BuOOH.[1433] The observed lack of rate enhancement for the reaction in the presence of small concentrations of ImH is thus undoubtedly due to the overwhelming stability of the bis-imidazole complex over the mono-imidazole complex ($K_1 = (1–5) \times 10^3\,M^{-1}$; $\beta_2 = (5–8) \times 10^8\,M^{-2}$) compared to the bis-ammonia complex over the mono-ammonia complex ($K_1 = (0.1–1.5) \times 10^2\,M^{-1}$; $\beta_2 = (4.4–8.4) \times 10^4\,M^{-2}$).[1433] Morishima and coworkers have also shown that addition of one equivalent of imidazole to an acylperoxoiron(III) porphyrin in methylene chloride at $-80\,°C$ produces heterolytic cleavage to the corresponding oxoferryl porphyrin π-cation radical, $(P^{-}\bullet)Fe^{IV}{=}O$, while the same reaction in toluene solution shows little or no heterolysis; however, at higher temperatures (-40 to $-6\,°C$), homolytic cleavage occurs to form the oxoferryl porphyrin ($PFe^{IV}{=}O$) and some iron(III) porphyrin *N*-oxide.[1790] Presumably the apparent change in mechanism is due to the suppression of formation of ionic species (the oxoferryl porphyrin π-cation radical) in toluene, leaving homolytic cleavage as the only (but less favorable) reaction. In the absence of imidazole, both reactions, but especially that in methylene chloride, are slowed.[1790] Dimethyldioxirane is also an effective oxidant.[1791]

10 IRON(V) PORPHYRINS

True high-valent iron porphyrins with the formal iron oxidation state +5 are rare, although complexes have been reported as Compound I intermediates of the heme proteins catalases and peroxidases and their model complexes.[1792] However, as suggested by Dey and Ghosh,[1792] some of these complexes are not true Fe(V) complexes, but are better described as oxoiron(IV) π-cation radical species with the radical either residing on the porphyrin or the axial ligand or being delocalized into porphyrin or ligand orbitals. For example, the perferryl complex $PFe(O)(OCH_3)$ described by Morishima *et al.*[1793,1794] is, according to theoretical calculations, not a true Fe(V) species, but rather contains a ferryl unit coordinated to a methoxy radical.[1795] Spectroscopic studies of heme-peroxidases agree with this finding and show that the catalytically relevant species is not an (oxo)iron(V) complex, but that both the metal and the porphyrin ligand are oxidized, resulting in an (oxo)iron(IV) and a porphyrin π-cation radical. Among the true Fe(V) porphyrins with a $S = 3/2$ ground state and an assumed electron configuration of $(d_{xy})^1(d_{yz})^1(d_{xz})^1$ are the nitrido iron species reported by Wagner and Nakamoto[1796,1797] and the complex described by Nanthakumar and Goff.[1717] The Fe(V) nitrido complexes, which were synthesized at 30 K by laser irradiation of the azide coordinated TPPFe(III) or OEPFe(III) compounds, are very unstable, exhibit a Resonance Raman band at $876\,cm^{-1}$ for the Fe–N stretching frequency, and according to DFT calculations[1792] have a Fe–N bond length of 1.722 Å that is slightly longer than the $Fe^{IV}{=}O$ ferryl bond in oxo porphyrin π-cation radical species. The Fe^{V} porphyrin described by Nanthakumar and Goff[1717] bears electronegative fluorine substituents on the phenyl rings and was obtained by using strong oxidizing agent *m*-chloroperbenzoic acid. A red complex was produced with a Soret band at 430 nm and visible band at 550 nm, similar to those of $PFe^{IV}O$ complexes,[97,218] but with different NMR and EPR spectra. The pyrrole-^{2}H signal was observed at +1.3 ppm at 210 K. The EPR spectrum at moderate temperatures ($g = 4.38$, 3.11, and 2.70, plus a $g = 2$ radical signal from decomposition products) is described to be indicative of a $S = 3/2$ species, rather than a $S = 1$ $Fe^{IV}/S = 1/2$ porphyrin radical species, which is expected to be EPR silent above $\approx$5 K.[1717]

Acknowledgments

The support of NIH grant DK 31038 during the writing of the original and revised article and of F. Ann Walker's research on iron porphyrins over the past 22 years is gratefully acknowledged. Professor Dennis Evans H. Evans provided very helpful comments on the electrochemistry and thermodynamics sections. This revised article was prepared while both authors were on Sabbatical, Professor Simonis at the University of California, San Francisco, and Professor Walker at the University of Lübeck, Physics Institute, with support from an Alexander von Humboldt Senior Research Award.

This article is dedicated to the memory of Dr. Teddy G. Traylor (1925–1993), who was Distinguished Professor of Chemistry at the University of California, San Diego, and an active contributor to our understanding of iron porphyrin chemistry, as detailed in the sections on Fe^{II}, Fe^{III}, and Fe^{IV}

porphyrins and Fe^{IV} porphyrin π -cation radicals. Teddy's iron porphyrin research spanned the design of models for the active sites of hemoglobin and myoglobin and the investigation of their reactions with O_2 and CO, the design of low-spin Fe^{III} model hemes, the design and detailed investigation of the reactions of high-valent iron porphyrin models of the cytochromes P450 with organic substrates, and the utilization of these high-valent iron porphyrins for the development of useful catalytic systems. His scientific creativity, insight, and enthusiasm for discussing and solving chemical problems are sorely missed, as is his vitality, wonderful sense of humor, fun, and adventure, and his great success at enjoying life to the fullest.

1 INTRODUCTION

1.1 Scope and Brief History

The class of proteins referred to in the title includes only those containing nonheme, non-sulfur diiron sites. Several reviews of various members of this class of proteins are available,[1–4] although none are simultaneously comprehensive and completely up-to-date. This state of affairs signals neither neglect nor lack of interest, but rather the rapid expansion and development of knowledge in this area. Though still dwarfed by the numbers of heme or iron–sulfur proteins, the list of proteins known to contain nonheme, non-sulfur diiron sites has steadily expanded over the past thirty years. Until 1973, the O_2-carrying protein, hemerythrin (Hr), was the only known member of this class, whereas at least a dozen proteins with distinct activities containing nonheme, non-sulfur diiron sites have been characterized as of 2003. While Hr for many years served as the prototype, its structure and function have turned out to be distinct from those of the O_2-activating proteins, which now form the largest subclass: at least seven distinct types of such O_2-activating enzymes containing nonheme, non-sulfur diiron sites have been identified.

Some respiratory nitric oxide (NO) reductases, which contain a mixed dinuclear heme, nonheme iron site (*see* ***Cytochrome Oxidase***), and [2Fe-2S] ferredoxins (*see* ***Iron–Sulfur Proteins***), are covered in separate chapters of this encyclopedia. Ferritins and bacterioferritins, which contain a metastable nonheme diiron site are also covered elsewhere in this Encyclopedia (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***). Another chapter in this encyclopedia, ***Iron: Models of Proteins with Dinuclear Active Sites***, provides a synthetic perspective on the properties of nonheme, non-sulfur diiron sites in proteins. Recent reports of synthetic polypeptides that contain nonheme, non-sulfur diiron sites[5] should also be noted.

1.2 General Similarities and Differences

Nonheme, non-sulfur diiron active sites in proteins share the following properties: (1) two iron atoms separated by 4 Å or less; (2) stable high spin ferrous and ferric oxidation states; (3) terminal histidinyl imidazole, carboxylate, and solvent ligands; (4) at least one ligand that bridges the two irons; and (5) magnetic superexchange coupling of the unpaired spins on the two irons mediated by the bridging ligand atom(s). With one possible exception, the bridging ligands are either known or are strongly suspected to include one or two carboxylates, and for this reason these proteins have also been aptly referred to as 'diiron-carboxylate proteins'.[6] The observed superexchange coupling at these sites, however, occurs predominantly via a bridging, solvent-exchangeable oxo or hydroxo ligand. This coupling is typically antiferromagnetic in the diferric and mixed-valent Fe^{II}, Fe^{III} oxidation levels, resulting in ground $S = 0$ and $S = 1/2$ spin states, respectively. The latter mixed-valent ground spin state gives rise to a characteristic axial or rhombic EPR signal with $g_{ave} < 2$, which is observable only below about 30 K. This characteristic signal has proven useful for initial verification of the presence of these nonheme diiron sites in newly isolated proteins. For those diiron proteins where the mixed-valent form is not sufficiently stable, the presence of an antiferromagnetically coupled diferric site can be verified by ^{57}Fe Mössbauer spectroscopy in strong applied magnetic fields. X-ray crystallography, however, has become increasingly important in verifying the diiron nature as well as the structural details of these proteins. The diferrous oxidation

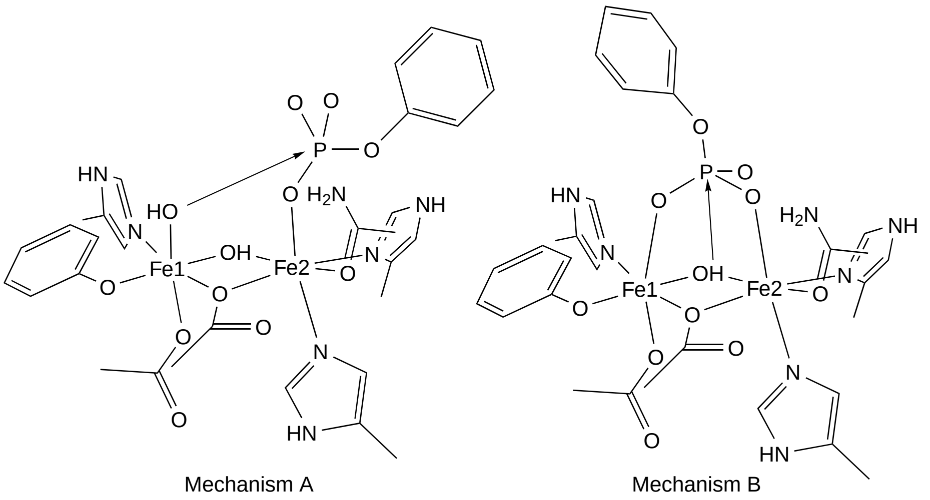

Figure 1 Active site structure of PAPs and proposed mechanisms for their catalytic hydrolysis of a phosphate monoester, involving either a terminal (Mechanism A) or bridging (Mechanism B) hydroxide. The Fe1, containing the tyrosine ligand, is in the Fe(III) oxidation state. (Reprinted with permission from Ref. 9. © 2002 American Chemical Society)

level of these proteins is typically stable under anaerobic conditions, but spontaneously oxidizes (albeit with varying rates) to the diferric level upon exposure to dioxygen.

The active site similarities listed above belie a remarkable functional diversity, which includes phosphate ester hydrolysis, dioxygen and NO reduction, reversible O_2 binding, and O_2 activation, the last of which includes enzymes involved in ribonucleotide reduction, hydrocarbon monooxygenation, and fatty acyl desaturation. At the overall protein level, the purple acid phosphatases (PAPs) seem to be completely unrelated, both structurally and functionally, to any of the others in this class. Similarly, the flavo-diiron enzymes form a structurally and probably functionally distinct family of proteins, catalyzing both dioxygen and NO reduction. These last two examples illustrate that attempts to 'shoehorn' all of these enzymes into a single class can sometimes provide a simplistic and misleading view of their chemistry and biochemistry.

2 PURPLE ACID PHOSPHATASES

PAPs are glycoenzymes of M_r 35–40 kDa characterized by their intense purple color due to a tyrosine ligand-to-iron(III) charge transfer transition near 600 nm.[7] The best studied PAPs are those from bovine spleen, porcine uterine fluids, and rat bone, which have been proposed to be involved in iron transport, the immune response, and bone resorption respectively. However, the biological relevance of the phosphatase activity of PAPs has not been unequivocally established. Recently, a bacterial phospholipase with active site properties resembling those of PAPs has also been reported.[8] All PAPs contain a conserved dimetal binding amino acid sequence motif in which an iron(III) is ligated to tyrosine, histidine, and aspartate side chains and a divalent metal ion (Fe, Zn, or Mn) is ligated by an asparagine and two histidine side chains. The two metal ions are bridged by a hydroxide and an aspartate side chain. The generic active site structure of PAPs, which has been confirmed by X-ray crystallography, is shown in Figure 1. The identification of the solvent bridge as hydroxo, rather than oxo or aqua, has been inferred from the magnitude of the magnetic coupling between the irons.[9] PAPS are enzymatically active only at low pH (pH optimum ∼5), hence their classification as acid phosphatases. Most proposed mechanisms for the phosphatase activity invoke an attack of a coordinated hydroxide, either bridging the metal ions[9] or terminally coordinating to iron(III),[10] on the coordinated phosphate ester substrate (cf. Figure 1). For those PAPS containing a diiron site, only the mixed-valent Fe^{II},Fe^{III} oxidation level, which is air stable, is enzymatically active.

3 FLAVO-DIIRON ENZYMES

Flavo-diiron enzymes, also referred to as flavoproteins A (FprAs) or A-type flavoproteins, are the most recently recognized of the nonheme diiron proteins. FprA homologues are widely distributed among anaerobic bacteria and archaea,[11–13] as well as some facultative anaerobes, including *Escherichia coli*. The discovery that at least some FprAs contain a diiron site came from a 2.5-Å resolution X-ray crystal structure of an enzyme dubbed rubredoxin:oxygen oxidoreductase (ROO), an FprA homologue that had been isolated from an anaerobic sulfate-reducing bacteria.[14] The diiron site in ROO was completely unanticipated because the amino acid sequence

showed no homology to other known diiron proteins. The protein domain surrounding the diiron site also exhibited a folding motif that was completely unrelated to the four-helix bundle motif found in Hr or in the O_2-activating diiron enzymes (discussed below). Each subunit of the ROO homodimer is folded into two distinct domains, one containing flavin mononucleotide (FMN) and the other containing the diiron site, the structure of which is shown in Figure 2. The folding motif of the diiron domain in ROO resembles that of metallo-β-lactamases (*see* ***Zinc Enzymes***).[12] The two subunits of the homodimer are associated in a head-to-tail fashion, which brings the FMN moiety of one subunit into close proximity of the diiron site in the other subunit. This close juxtaposition to a flavin cofactor and the β-lactamase-like diiron domain constitute the unique and defining structural feature of this subclass of nonheme diiron proteins. Since the ROO was crystallized and maintained under aerobic conditions, it was assumed that the diiron site and FMN in the ROO crystal structure are fully oxidized. As with all other known nonheme diiron proteins, the ligands are provided by a combination of histidine, glutamate, and aspartate. The two irons are 3.4 Å apart and bridged by a bidentate aspartate and a solvent ligand, suggested to be either oxo or hydroxo. The carboxylate oxygen of the Glu81 terminal ligand is ~3.5 Å from the C8-methyl group of the FMN across the subunit interface, and this Glu presumably participates in an electron-transfer pathway between FMN and the diiron site. A region of electron density positioned in a pocket just above the diiron site (OXY in Figure 2) was interpreted as a dioxygen molecule. Given the relatively low resolution of the crystal structure, this assignment must be considered inconclusive. The distance from this putative dioxygen molecule and the nearest iron is longer than would be expected for direct coordination, but the proximity is consistent with an O_2-binding pocket near the diiron site of ROO. One reason for assigning a dioxygen molecule to the electron density above the diiron site was the previous report that in vitro, ROO, when combined with a reductase and the small electron-transfer protein, rubredoxin (*see* ***Iron–Sulfur Proteins***), could catalyze the NADH oxidase reaction: $2NADH + 2H^+ + O_2 \rightarrow 2H_2O + 2NAD^+$, in which it was proposed that the diiron site binds dioxygen during its four-electron reduction by the fully reduced ROO.[14] Two of the four electrons would be donated by the two ferrous irons of the diiron site and two more by the fully reduced proximal FMN. A function for this 'dioxygen reductase' activity in anaerobic microorganisms is not obvious; energy conservation and oxidative stress protection during periods of exposure to air have been suggested.[14] More recently, however, evidence has accumulated that, at least in some bacteria, FprA homologues function not as dioxygen reductases but rather as NO reductases, catalyzing the two-electron reduction: $2NO + 2H^+ + 2e^- \rightarrow N_2O + H_2O$.[15,16] This latter catalysis apparently serves a protective function against exposure to NO, micromolar levels of which are toxic to bacteria even under anaerobic growth conditions. A mechanism for catalysis of NO

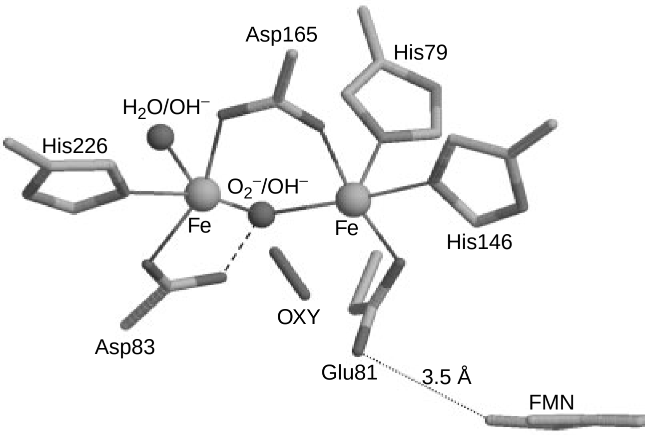

Figure 2 Structure of the diiron site in the flavo-diiron enzyme, ROO from *Desulfovibrio gigas*.[14] Drawing was generated using RASMOL[17] and coordinates from 1ESD in the Protein Data Bank. Iron atoms and solvent ligands are shown as larger and smaller spheres respectively, and protein side chains providing ligands are shown in wireframe representation. The dashed line indicates hydrogen bonding between an aspartate carboxylate and bridging solvent ligands. A portion of the FMN ring is shown approximately edge-on at the lower right. The dotted line indicates the shortest distance between the Glu81 carboxylate ligand and an FMN carbon

reduction by FprAs involving a diferrous dinitrosyl intermediate can be readily envisioned, but observation of such a species has not been reported. Whether all flavo-diiron enzymes function as NO reductases in vivo also remains to be established.

4 HEMERYTHRIN

4.1 Background

Hemerythrin (Hr) is an O_2-carrying protein found in a few phyla of marine invertebrates where it is thought to function as an O_2 storage reservoir.[18,19] The diiron active site reversibly binds the O_2. Several reviews that discuss various aspects of Hr structure and function are available.[2,4,20–22] Hr most often occurs as an octamer of essentially identical O_2-binding subunits, although tetrameric, trimeric, and dimeric Hrs are also known.[21] A monomeric counterpart, myoHr, is confined to muscle tissues of the same marine invertebrates. The structure of the myoHr subunit and active site are both very similar to those of Hr.[21] The following discussion, therefore, applies, with very few exceptions, equally well to both Hr and myoHr.

4.2 Structure and Spectroscopy

The characteristic structure of the Hr polypeptide consists of a 'four-helix bundle' surrounding the diiron site, as shown in Figure 3(a).[21,23]

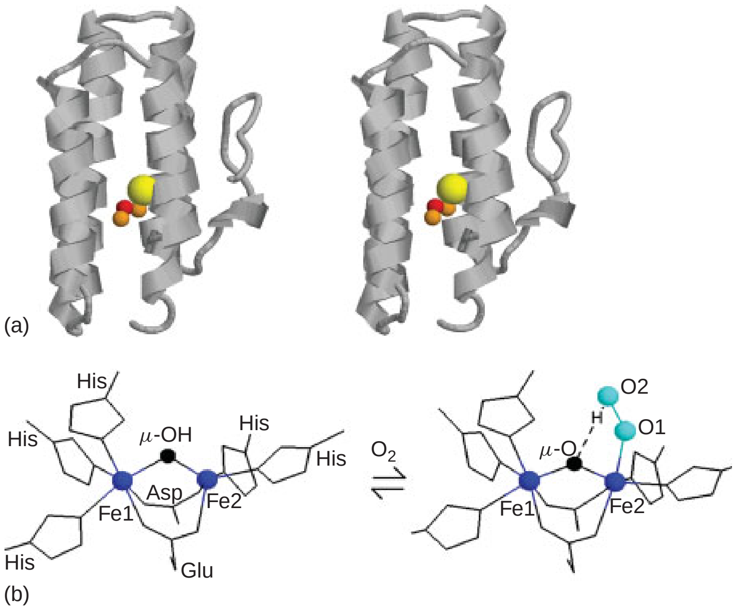

Figure 3 (a) Stereo view of the tertiary structure of a metchloroHr subunit. Protein backbone is traced in ribbon representation, iron atoms (orange), oxo bridge (red), and Cl^- (yellow) are shown as spheres. Drawing was generated using RASMOL[17] and coordinates from 1I4Y in the Protein Data Bank;[23] (b) The diiron site structures of deoxy- (left) and oxy- (right) Hrs. O_2 (cyan) and iron (dark blue) are shown as spheres, and iron ligands are shown in wireframe representation. The hydrogen bond between the oxo bridge and bound O_2 is indicated as a dashed line. Drawing was generated using coordinates from 1HMO[21] in the Protein Data bank

As shown in Figure 3(b), the two iron atoms at the active site are bound directly to protein side chains: five histidines, one aspartate, and one glutamate. The carboxylate side chains of the latter two residues bridge the two irons in a bidentate fashion in both the oxy and deoxy forms. The diiron site structures shown in Figure 3(b) were derived from X-ray crystal structures of both oxy- and deoxyHr.[21] The Hr oxygenation reaction has the well-established formulation: $[Fe^{II}(\mu\text{-OH})Fe^{II}](deoxy) + O_2 \rightleftharpoons [Fe^{III}(\mu\text{-O})Fe^{III}O_2H^-](oxy)$, in which O_2 binds to the five-coordinate iron in deoxyHr, and the hydroxo-bridged diferrous site is converted to an oxo-bridged diferric-hydroperoxo site in oxyHr. It is apparent from the crystal structures that the binding of O_2 to Hr occurs with little structural change or movement of the iron atoms and protein ligands. The only significant structural change upon oxygenation (other than addition of dioxygen) is a shortening of the Fe–O distances of the solvent-derived bridging ligand by ~0.2 Å, consistent with the formal oxidation of the iron atoms and proton transfer from the hydroxo bridge to the dioxygen.

From a bioinorganic perspective, the most celebrated structural feature of Hr has traditionally been the diferric oxo-bridged unit. The spectroscopic feature most readily identified with the diferric oxo-bridged unit having a bent geometry is the presence of two electronic absorptions between 300 and 400 nm with $\varepsilon \sim 6000\,M^{-1}\,cm^{-1}$ per diiron site. While initially controversial, the assignment of these transitions as oxo → Fe^{III} charge transfer in oxyHr has withstood the scrutiny of single-crystal electronic absorption, magnetic circular dichroism (MCD), and resonance Raman spectroscopies.[2] The met form, which results from autoxidation of oxyHr, also shows these characteristic oxo-bridged diferric charge transfer absorptions. ^{57}Fe Mössbauer spectroscopy clearly established that the best description of the irons in both oxy- and metHrs is high-spin Fe^{III}, but with ground-state diamagnetism, due to antiferromagnetic coupling of the two high-spin ($S = 5/2$) Fe^{III}.[24] From the temperature dependence of the magnetic susceptibility, the strength of this coupling, J, (expressed in the $-2J\mathbf{S}_1\cdot\mathbf{S}_2$ Heisenberg–Dirac–Van Vleck formalism) was reported as $-77\,cm^{-1}$ for oxyHr and $-134\,cm^{-1}$ for metHr. Couplings of the latter magnitude are characteristic of the diferric-oxo bridged unit.[24] The hydrogen bonding interaction between the hydroperoxo ligand and the oxo bridge of oxyHr (cf. Figure 3(b)) could be responsible for the lower $-J$ reported for oxyHr. On the basis of paramagnetic NMR shifts of the His ligand Nδ protons, however, the ΔJ between oxy- and metHrs was judged to be smaller than the magnetic susceptibility measurements had indicated, and to support the oxo-bridged formulation for oxyHr.

The assignment of a less intense electronic absorption of oxyHr near 500 nm ($\varepsilon \sim 2000\,M^{-1}\,cm^{-1}$ per diiron site) as a peroxo $\pi^* \rightarrow Fe^{III}$ charge transfer transition has also withstood rigorous scrutiny.[2] Resonance Raman excitation within this absorption band led to the discovery of an O–O stretching frequency at $844\,cm^{-1}$.[25] Isotope labeling studies showed unequivocally that this frequency was due to the bound O_2 and also identified the corresponding Fe–O_2 stretching

frequency near 500 cm^{-1}. Comparison to the O–O stretching frequencies of synthetic complexes clearly classifies the bound O_2 in Hr as a peroxo ligand rather than dioxygen or superoxo. Finally, resonance Raman excitation into the μ-oxo → Fe^{III} charge transfer band of oxyHr enhanced a vibrational mode at 486 cm^{-1}, which shifted downward in $H_2{}^{18}O$ but not with $^{18}O_2$.[26] This frequency was assigned to the symmetric Fe–O–Fe stretch of the oxo bridge, and is close to (but distinct from) the corresponding $H_2{}^{18}O$-sensitive Fe–O–Fe stretch of metHr at 510 cm^{-1}, which can be unambiguously assigned to the oxo bridge.[27] That is, oxyHr contains an oxo bridge similar to that of the met form.

Temperature and field-dependent MCD and paramagnetic ^1H NMR measurements showed that the ground state of deoxyHr is also diamagnetic due to antiferromagnetic coupling between the two high spin (S = 2) Fe^{II}.[20] The magnitude of this coupling, $J = -15\,cm^{-1}$,[28] closely matches that of a synthetic (μ-hydroxo)bis(μ-carboxylato)diiron(II) complex, but is significantly stronger than that of a corresponding μ-aqua bridged core (in which the irons may actually be weakly ferromagnetically coupled).[2] The X-ray crystal structure of the deoxyHr active site was, therefore, interpreted as containing a hydroxo rather than an aqua bridge (oxo-bridged diferrous complexes being unknown). The energies and intensities of the near-infrared (near-IR) d-d electronic transitions of deoxyHr support the crystallographically determined result of one six- and one five-coordinate ferrous iron.[2]

4.3 Mechanism of Dioxygen Binding

A striking feature of the oxygenation reaction of Hr is that, although both iron atoms formally undergo oxidation, O_2 appears to have direct, inner-sphere access to only the five-coordinate iron atom of deoxyHr. The relatively small structural changes and open coordination site on Fe2 in deoxyHr (cf. Figure 3b) seem designed for a facile O_2 association reaction, and this impression is borne out by the rapid rates of oxygenation, 10^7–$10^8\,M^{-1}s^{-1}$, and low activation enthalpies (a few kcal/mole or less) for O_2 association.[20,27,29] On the basis of computational studies, a concerted proton/electron transfer mechanism following the initial contact of O_2 with the diiron site has been proposed.[2] Since no solvent deuterium isotope effect was detected for O_2 association, this concerted proton/electron transfer would have to occur after the rate-determining step, which may be diffusion of O_2 through the protein matrix.[20] A more recent computational study has suggested that the stability of the O_2 adduct is due to van der Waal's interactions of the bound O_2 with protein side chains and an increase in the hydrogen bond strength between one of the histidine ligand side chains and a second coordination sphere glutamate carboxylate.[30] The O_2 binding pocket of Hr is lined with hydrophobic amino acid residues.[20] These hydrophobic side chains and accompanying steric restrictions favor the localized hydrogen bonding interaction of the bound O_2 with the oxo bridge. The hydrophobic, sterically restricted O_2-binding pocket also kinetically inhibits autoxidation, in which oxyHr spontaneously converts to the met form with release of hydrogen peroxide.[20,27,29] Finally, the very stable oxo bridge in oxyHr, together with the lack of simultaneously accessible coordination positions on both irons probably inhibits further activation of the peroxo ligand,[2] in contrast to its behavior in the monooxygenases and desaturases (discussed below). Such subtle protein design features may be the reason that this deceptively simple reversible binding of O_2 in an end-on fashion to one iron of the diiron site depicted in Figure 3(b) has yet to be duplicated by any synthetic nonheme diiron complex.

4.4 Bacterial and Archaeal Hr-like Proteins

Perhaps the most interesting recent development in the area of Hrs is the discovery that Hr-like proteins are present in bacteria and archaea, where they may function as O_2 sensors.[31] This discovery potentially opens an entire new chapter in Hr biochemistry.

5 O_2-ACTIVATING ENZYMES

5.1 General Properties

In 1993, when a similar article was written for the previous version of this encyclopedia, only three O_2-activating diiron enzymes were known: ribonucleotide reductase (RNR), methane monooxygenase (MMO), and stearoyl-acyl carrier protein Δ^9 desaturase (Δ^9D), and these three remain the best characterized within this subclass. As of 2003, however, at least seven additional types of O_2-activating diiron enzymes have been discovered. The majority of these enzymes are monooxygenases, catalyzing insertion of one atom of dioxygen into an alkyl or aryl C–H bond. Other reactions catalyzed by this subclass include formation of a protein tyrosyl radical by RNR, desaturation of a fatty acyl C–C bond by the desaturases, and reduction of dioxygen to water by so-called alternative oxidases. Another feature of some members of this subclass to emerge in recent years is their tight, sometimes integral association with cell membranes, in contrast to the first three enzymes listed above, which are categorized as 'soluble'. As a subclass, the O_2-activating enzymes are in general larger per diiron site than Hr, perhaps reflecting their more complicated functions and the need for regulation of their activities. Nevertheless, as for Hr, the available X-ray crystal structures show four-helix bundle protein folds surrounding the diiron sites in the O_2-activating enzymes. In all of the known O_2-activating enzymes, dioxygen activation occurs upon reaction of the

diferrous site with dioxygen. These apparent similarities to Hr, however, belie some key structural differences. A distinct amino acid sequence motif, consisting of a pair of (D)$EX_{29-37}EX_2H$ sequences (where D = aspartate, E = glutamate, H = histidine and X = an intervening residue), provides protein ligands to the diiron sites in nearly all of the known O_2-activating enzymes. This sequence motif makes the diiron coordination spheres much more carboxylate rich and histidine poor than that of Hr (cf. Figure 3). An exception to this pattern may be the membrane alkane monooxygenases, which appear to have a much more histidine-rich diiron coordination sphere.[22] The coordination spheres of both irons of the diferrous sites in the O_2-activating enzymes contain open or labile (i.e. solvent occupied) coordination sites, which would seem to promote a bridging coordination geometry for dioxygen unlike the diiron site of Hr, where only terminal coordination of dioxygen has been observed. Finally, redox-dependent coordinative flexibility, particularly for the carboxylate ligands, seems to be a characteristic feature of the diiron sites in O_2-activating enzymes.[22]

An organizing reaction scheme for all of the O_2-activating diiron enzymes is shown in Figure 4. A key mechanistic feature of this scheme is hydrogen abstraction from the substrate by a highly oxidizing, formally diiron(IV) species created upon reaction of the diferrous site with dioxygen. The extent to which every O_2-activating diiron enzyme follows this reaction scheme is currently unclear. In fact, with the exception of RNR, the participation of organic radicals in the catalytic mechanisms of these enzymes is controversial. Nevertheless, this scheme or its variants have provided a useful mechanistic framework for investigation of these enzymes.[22] From a bioinorganic perspective, these mechanistic investigations, particularly the trapping and identification of the intermediates along the vertical pathway shown in Figure 4, have been a focal point of study for all of these enzymes.

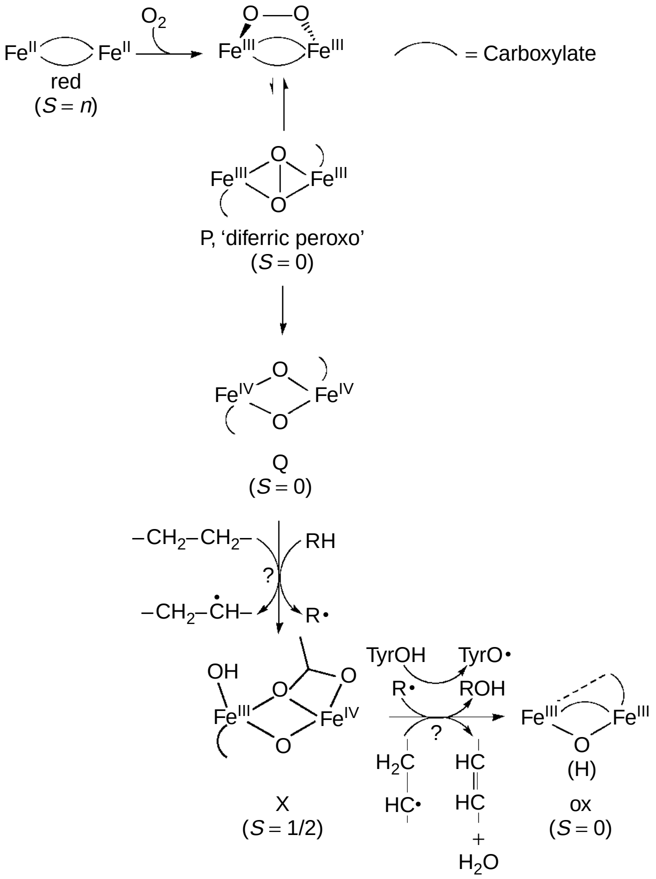

Figure 4 A possible scheme for the catalytic reactions of diiron sites in the O_2-activating enzymes. Formal oxidation states, ground spin states, and shorthand letter designations are listed below each diiron species. Except for tyrosyl (in RNR), the depiction of organic radicals is hypothetical (Ref. 22, © 1997 Springer Verlag)

5.2 Ribonucleotide Reductase

RNRs catalyze the reduction of ribonucleotides to deoxyribonucleotides, which represents the first committed step in DNA biosynthesis and repair.[32] These enzymes are therefore required for all known life forms. Three classes of RNRs have been identified, all of which turn out to be metalloenzymes. The so-called class I RNRs contain a diiron site (*see* ***Cobalt: B_{12} Enzymes & Coenzymes*** and ***Iron–Sulfur Proteins*** for the other two types of RNRs). As diagrammed in Figure 5, these enzymes generate first a tyrosyl radical proximal to the diiron site in the protein subunit labeled R2, and then a thiyl radical in an adjacent subunit (R1) that ultimately abstracts a hydrogen atom from the ribonucleotide substrate. This controlled tyrosine/thiol radical transfer must occur over an estimated distance of ~35 Å, and a highly choreographed proton-coupled electron transfer (PCET) mechanism across intervening aromatic residues has been proposed.[33] Perhaps, even more remarkably, evidence has been presented suggesting that the tyrosyl radical is regenerated by reverse PCET during every turnover cycle.[34]

The most thoroughly studied class I RNR is that from *E. coli*, and the remaining discussion focuses on the diiron site in the R2 homodimer of that enzyme, hereafter referred to simply as R2. R2 can be isolated separately from the R1 subunit. The crystal structures of R2 in both the diferrous and diferric (nonradical) forms revealed the diiron site structures shown in Figure 6.[32] The phenol hydroxyl of tyrosine 122 that forms the radical is hydrogen bonded to an aspartate carboxylate ligand of the diferrous site.

An unusual feature that has been recognized earlier is that the as-isolated R2 contained a stable tyrosyl radical along with an oxo-bridged diferric site. The latter oxo-bridged diferric structure was apparent even before X-ray crystal structures were available from the strong absorption features between 300 and 400 nm, reminiscent of oxy- and metHrs.[2] Superimposed on this diferric site absorption is a sharp absorption feature at 410 nm due to the tyrosyl radical.

Stopped-flow UV-vis absorption and rapid freeze-quench (RFQ) EPR and Mössbauer studies have shown that the reaction pathway diagrammed in Figure 4 for formation of the tyrosyl radical is essentially accurate except that the diiron(IV) species labeled Q in Figure 4 has never been detected in R2. Instead, an intermediate labeled U (not shown in Figure 4), occurring prior to X, has properties consistent with a protonated tryptophan cation radical. This radical may shuttle an electron from an external donor to the diiron site in order to reach intermediate X.[2,3,32] In any case, these rapid kinetic studies have established that intermediate X is kinetically competent to oxidize Tyr122, and that X is an antiferromagnetically coupled ($S = 1/2$) $Fe^{III}Fe^{IV}$ species (cf. Figure 4).[2] The diferric-peroxo species, P (cf. Figure 4) has been detected only in an engineered variant of R2 in which Asp84 (cf. Figure 6) was replaced with a glutamate residue.[35] The bridging ligands in X have been a matter of some controversy. Current evidence favors a mono-oxo-bridged structure, as shown in Figure 4, in which the other atom of the reduced dioxygen is a terminal solvent ligand to the Fe^{III} rather than a second bridging ligand.[2,36]

5.3 Methane Monooxygenase

Methanotrophic bacteria can grow on methane as their sole carbon and energy source, which they achieve via its oxidation to carbon dioxide. The first catalytic step in this pathway is the oxidation of methane to methanol catalyzed by methane monooxygenase (MMO). From an energetic point of view, this room temperature oxidation of methane is arguably the most impressive catalytic reaction in all of biology. MMO catalyzes the insertion of one atom of O_2 into the very inert C–H bond of methane upon its conversion to methanol. Two types of MMO have been identified, namely, soluble and membrane-bound. The hydroxylase component of the soluble MMO (MMOH) is an ~250 kDa protein with an $(\alpha\beta\gamma)_2$ subunit composition. The membrane-bound MMOH contains copper at its active site (*see* ***Copper Proteins: Oxidases***). Hereafter, the MMOH from the soluble MMO is simply referred to as MMOH. Beginning in 1986, EPR, Mössbauer, and other spectroscopic evidence began to accumulate for a nonheme, non-sulfur diiron active site in MMOH.[3] Subsequent X-ray crystal structures of the soluble MMOH confirmed and extended these earlier observations.[2,37] The diferrous and diferric site structures of MMOH revealed by X-ray crystallography are shown in Figure 7. Even before these structures became available, it was clear from the UV-vis absorption spectrum, particularly the lack of any intense absorption features between 300 and 400 nm, that, unlike hemerythrin and RNR-R2, the diferric MMOH site does not contain an oxo bridge. Rather the solvent bridges in Figure 7 are either hydroxo or aqua.

Analogously to the RNR studies discussed above, the key question occupying bio-inorganic investigations on MMOH has been: how does the diferrous site activate dioxygen for insertion into methane, or more specifically, to what extent is the generic reaction pathway in Figure 4 followed? Single turnover experiments established that MMOH could effect hydroxylation of hydrocarbons starting from the diferrous form, $MMOH_{red}$, and adding dioxygen. Starting in 1993, a series of elegant stopped-flow UV-vis absorption, RFQ EPR, and Mössbauer experiments provided evidence for at least two consecutive intermediates, labeled P and Q, which formed upon reaction of $MMOH_{red}$ with dioxygen.[3] (The intermediate analogous to X in RNR has not been unequivocally detected in MMOH.[38]) In the presence of hydrocarbon substrates, the lifetime of P was unaffected, whereas the decay (but not buildup) of Q was substantially accelerated with methane showing the largest such effect. The decay rate of Q also showed a large deuterium isotope for perdeuterated methane:

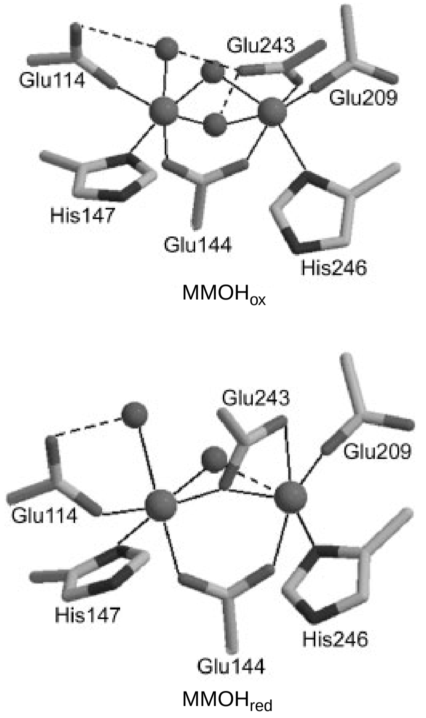

Figure 7 Diferric ($MMOH_{ox}$) and diferrous ($MMOH_{red}$) site structures in MMOH. Iron atoms and solvent ligands are shown as larger and smaller spheres respectively, and amino acid side chains are shown in wireframe representation (with β-carbons of glutamate residues omitted for clarity). Dashed lines indicate hydrogen bonds. Structures were drawn using RASMOL[17] coordinates from 1MTY and 1FYZ in the Protein Data Bank[37]

$k(CH_4)/k(CD_4)$ of 20–50.[37] All of these results pointed to Q as the intermediate that reacts directly with methane in the committed step leading to its hydroxylation. Q was found to be EPR silent; ^{57}Fe Mössbauer spectra of Q were most consistent with a $Fe^{IV}Fe^{IV}$ oxidation level and a diamagnetic ground state due to antiferromagnetic coupling between the two high- or intermediate-spin d^4 Fe^{IV} centers.[3,39] Extended X-ray absorption fine structure (EXAFS) studies of the diiron center obtained from RFQ experiments led to two unusually short interatomic distances in Q: Fe–O = 1.77 Å and Fe–Fe = 2.46 Å.[40] This Fe–Fe distance for Q is much shorter than those determined by X-ray crystallography for either the diferrous (3.28 Å) or diferric (3.1 Å) oxidation levels of MMOH (cf. Figure 7). Analysis of the EXAFS and pre-edge spectra also indicated a coordination number no greater than five for the irons in Q. These structural parameters together with the previous spectroscopic results led to the proposed ‘diamond core’ structure for Q shown in Figure 4.

The hydrogen abstraction mechanism for methane hydroxylation by intermediate Q originated by analogy to the ‘oxygen-rebound’ mechanism proposed for hydrocarbon hydroxylation catalyzed by cytochrome P450, which invokes a high-valent heme iron-oxo intermediate (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***). The question of whether or not a discrete hydrocarbon radical species actually forms upon reaction of methane with Q in MMOH has been the subject of lively experimental investigations and debates. Some experiments, particularly the elegant ‘chiral ethane’ experiments first carried out by Lipscomb and coworkers,[3] seem to indicate at least some degree of hydrocarbon radical formation, whereas, experiments with so-called ‘radical clock’ substrates seem to argue against this possibility.[2,39] Unfortunately, experiments addressing this issue with methane itself are difficult to design. The results of computational studies on the mechanism by several groups, while tending to agree on hydrogen abstraction from methane by a bis(μ-oxo)diiron(IV) species, have generally not favored discrete hydrocarbon radical formation. On the other hand, these various studies have not converged on any single alternative mechanism. In-depth discussions of various alternative mechanisms for methane hydroxylation by Q based on these computational studies are available.[2,39,41,42]

5.4 Butane Monooxygenase

A soluble butane monooxygenase has been isolated from an aerobic bacteria capable of growing on butane as carbon and an energy source.[43] The first step in the degradation of butane is its hydroxylation to 1-butanol catalyzed by a butane monooxygenase. The hydroxylase component of this enzyme shows very high amino acid sequence and subunit homology to the diiron MMOH discussed above. The strain does not grow on methane, however, suggesting that the butane monooxygenase cannot function as an MMO. No studies of the putative diiron site in the butane monooxygenase have been reported as of mid-2003.

5.5 Toluene and Phenol Monooxygenases

Following the discovery of a diiron site in MMOH, the same iron-ligating amino acid sequence motif (i.e. a pair of $EX_{29-37}EX_2H$ sequences) was recognized in the toluene and phenol monooxygenases (TMO and PMO respectively).[3,22,44,45] The hydroxylase components of these enzymes also have the $(\alpha\beta\gamma)_2$ subunit composition homologous to that of MMOH. Thus, although no X-ray crystal structures are yet available for any TMO or PMO, their diiron site structures are expected to closely resemble those of MMOH shown in Figure 7. Mössbauer and EPR studies have confirmed the presence of a diiron site in PMO and in at least one TMO.[3,22,44,46] Three distinct TMOs, T2MO, T3MO, and T4MO catalyze conversion of toluene to *o*-, *m*-, and *p*-cresol respectively. Surprisingly, none of the TMOs catalyze significant oxygenation of the toluyl methyl group, as might be expected by analogy to MMO. PMO catalyzes the oxygenation of phenol and substituted phenols to the corresponding catechols, but shows little or no activity toward toluene. Conversely, TMOs show little activity toward phenol. Finally, while MMOH shows some reactivity toward a variety of aromatic substrates, TMOs and PMOs show no catalysis of methane hydroxylation. The fact that this apparently similar set of monooxygenases can catalyze such substrate specific and regiospecific reactions implies that the surrounding protein environments subtly tune the reactivity of the diiron site in ways that are largely unclear at present. The most systematic mechanistic studies among enzymes in this subclass have been carried out on T4MO. On the basis of product analyses of various specifically deuterated toluenes and xylenes, a mechanism for toluene hydroxylation by TMOs was proposed that invoked formation of an epoxide intermediate (cf. Figure 8) rather than H-atom abstraction upon reaction with the high-valent diiron site.[47] Steric restrictions within the toluene binding pocket of the TMOs may position the substrate for predominant 2-, 3-, or 4-hydroxlation.

5.6 Alkene Monooxygenases

A few species of aerobic bacteria are able to metabolize small alkenes, such as ethylene and vinyl chloride as

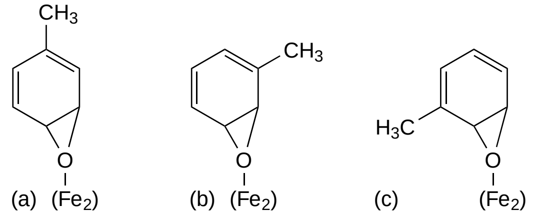

Figure 8 Proposed epoxide intermediates at the diiron sites of TMOs leading to predominantly 4- (a), 3- (b), or 2- (c) hydroxylation of toluene (Ref. 47, © 2003 National Academy of Sciences, USA)

their sole carbon and energy source.[48,49] The first step in the metabolism of these alkenes is oxidation to the corresponding epoxides. These epoxidations are catalyzed by alkene monooxygenases, which have amino acid sequence and subunit structural homologies to the MMOH-diiron type of monooxygenases.[44] Only limited structural and spectroscopic characterizations of these enzymes have been reported up to now. One alkene monooxygenase has been reported to exhibit EPR spectra consistent with antiferromagnetically coupled mixed-valent and diferrous diiron sites.[50]

5.7 Fatty Acyl–Acyl Carrier Protein Desaturases

Fatty acyl−acyl carrier protein desaturases are soluble plant enzymes that catalyze insertion of cis double bonds into specific methylene positions of fatty acids.[44] A distinct group of membrane fatty acyl desaturases are discussed in Section 5.10. The substrate for the soluble plant enzymes is a fatty acyl chain covalently linked to a phoshopantetheine group of an acyl carrier protein (ACP). These desaturases contain the diiron-binding amino acid sequence motif common to the other O_2-activating enzymes discussed above. The best characterized of these enzymes is the ACP Δ^9 desaturase (ACP Δ^9D) from castor bean. Spectroscopic studies established that the diferric site in the castor bean ACP Δ^9D contains an oxo bridge, although a minor proportion of a hydroxo-bridged diferric site may also be present.[2,44] An X-ray crystal structure of this ACP Δ^9D was obtained on an X-ray photoreduced enzyme, that is, containing a diferrous site. The diiron site structure (cf. Figure 9) is highly symmetrical with two five-coordinate irons bridged by two carboxylate ligands. The Fe–Fe separation of 4.1 Å is too long for a single atom solvent bridge.

A more recent X-ray crystal structure[52] of the same enzyme has shown that the open coordination sites on the ferrous irons can be occupied by a 1,3-bridging azide, perhaps mimicking an initial 1,2-bridging mode of dioxygen. A deep hydrophobic channel leading from the surface of the protein likely binds and orients the fatty acyl substrate for a specific reaction of the 9,10-carbons with the diiron site. Spectroscopic studies indicate that one of the ferrous centers switches to four-coordinate upon substrate binding, perhaps triggering its reaction with dioxygen. A diferric-peroxo intermediate was trapped upon rapid mixing of the artificially reduced enzyme-substrate complex with dioxygen, but this intermediate did not break down to form the desaturated product.[53,54] A ferredoxin (*see* ***Iron–Sulfur Proteins***) is apparently required as the catalytically competent electron donor to the desaturase-substrate complex.[53,55] Events in addition to the fatty acyl C–H bond breakage may contribute to the rate-limiting step, which has likely hindered trapping of catalytically competent diiron intermediates.[55,56] Deuterium labeling of the substrate has shown that the desaturation is both regio- and stereospecific and is consistent with hydrogen abstraction from a diiron(IV) intermediate, as shown in Figure 10.

5.8 Rubrerythrin

Rubrerythrin (Rbr) appears to be an 'oddball' among the O_2-activating diiron proteins. The name, rubrerythrin, is a contraction of rubredoxin (*see* ***Iron–Sulfur Proteins***) and hemerythrin, which reflects its two types of iron sites as well as the fact that Rbr was isolated before a function was described for it.[57] Rbr containing these two distinct types of iron sites has been reported so far only in anaerobic bacteria and archaea. Pyrophosphatase,[58] ferroxidase[59] and, most recently, peroxidase[60–62] activities have all been ascribed to this protein. In vivo studies suggest a role for Rbr in oxidative stress protection during periods when these anaerobic microorganisms are transiently exposed to air.[63,64] Amino acid sequence homologies to the MMOH diiron-ligating motif initially suggested an O_2-activation function for Rbr.[22] In fact, sequence analyses have tended to group Rbrs together on one branch of the same phylogenetic dendrogram that contains all the known diiron proteins

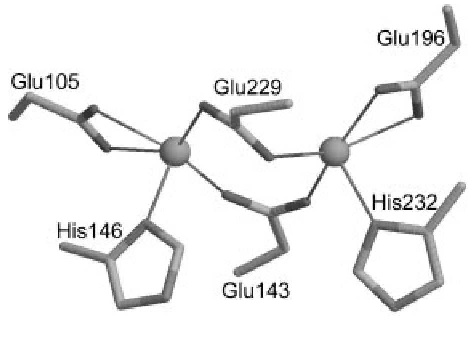

Figure 9 Diferrous site structure of castor bean ACP Δ^9D. Iron atoms are shown as spheres; iron ligands are shown in wireframe representation. Structure was drawn using RASMOL[17] and coordinates from 1AFR in the Protein Data Bank[51]

(b) Schematic structures of the diiron sites and subunit interfaces from the all-ferric and all-ferrous Rbr X-ray crystal structures.[68] (Reprinted with permission from Refs. 68 & 69. © 2002 & 2003 American Chemical Society)

having the characteristic pair of (D)$EX_{29-37}EX_2H$ sequence motifs.[65] Genome sequence analyses have indicated that some microorganisms contain multiple Rbrs.[60] The best characterized Rbr is that from the sulfate-reducing bacteria, *Desulfovibrio vulgaris*, and the remaining discussion focuses on that Rbr. *D. vulgaris* also contains a second Rbr-like protein called nigerythrin.[66] The X-ray crystal structure of *D. vulgaris* Rbr showed that the functional unit in solution is the 'head-to-tail' homodimer, in which the rubredoxin-type $Fe(SCys)_4$ site is ∼12 Å from the diiron site across the subunit interface, as shown schematically in Figure 11.

No monooxygenation chemistry catalyzed by Rbr has been reported, nor does Rbr associate with other nonidentical subunits, as do the soluble diiron monooxygenases. While the ferroxidase activity of *D. vulgaris* Rbr is consistent with the close structural resemblance of both its subunit structure and diiron site to those of bacterioferritin (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***),[67,68] there is no evidence that Rbr forms a large aggregate of subunits that could store the resulting oxidized exogenous iron, as does bacterioferritin. The physiological relevance of the ferroxidase activity of *D. vulgaris* Rbr, if any, is thus unclear. Two independent laboratories have been unable to reproduce the reported pyrophosphatase activity.[57] Hydrogen peroxide oxidizes the diferrous site of Rbr rapidly compared to dioxygen,[60–62] which is the opposite trend to that shown by diferrous sites in the O_2-activating enzymes. The diferric Rbr site shows little or no reactivity with hydrogen peroxide, a behavior that is also in contrast to the O_2-activating diiron enzymes.[44] One possible source of these differences in reactivity may lie in some unique structural features of the Rbr diiron site, which are illustrated in Figure 11. The X-ray crystal structure of the oxidized (all-ferric) Rbr showed the expected oxo-bridged diferric site with two bridging carboxylates, but also revealed an extra terminal carboxylate ligand, Glu97 in Figure 11, to one of the irons. This extra glutamate carboxylate, which has no counterpart in the O_2-activating diiron proteins, is conserved in all known Rbrs.[60,67] This extra carboxylate ligand appeared to displace an expected histidine ligand (His56 in Figure 11) located in an approximately trans coordination position. However, in the X-ray crystal structure of the all-ferrous Rbr, the iron atom ligated to this extra glutamate in the diferric site had moved approximately 1.8 Å such that it was now ligated to the histidine and not to the extra glutamate.[68] The Fe–Fe distance also increased from 3.3 Å in the oxo-bridged diferric site to 4.0 Å in the diferrous site, and the oxo bridge was replaced by two terminal solvent ligands. This redox-dependent Glu ↔ His ligand switching and the extensive movement of one iron are unique among the diiron proteins and presumably contribute to the facile hydrogen peroxide reductase activity of Rbr. Another contributing factor may be

the relatively greater solvent exposure of the Rbr diiron site compared to those in the O_2-activating enzymes.[68] Kinetics studies on engineered site-directed Rbr variants are consistent with a mechanism, in which the diferrous site of Rbr rapidly reduces hydrogen peroxide to water and the $Fe(SCys)_4$ site funnels electrons from exogenous donors to the diiron site.[60] The His56 side chain that exchanges with the Glu97 ligand is hydrogen-bonded to a carbonyl of one of the cysteine residues that provides a ligand to the $Fe(SCys)_4$ site across the subunit interface (C161′; cf. Figure 11). This hydrogen bond is presumably part of the inter-iron site electron-transfer pathway. An X-ray crystal structure of a μ-1,3-azide adduct of the diferrous Rbr site[68] suggests a μ-1,2-H_2O_2 intermediate, as shown in Figure 12. The mixed-valent diiron site structure shown in the lower left corner of Figure 12 is based on recent ENDOR studies.[69]

A mixed-metal Zn,Fe site rather than a diiron site has been reported in Rbr 'as-isolated' from *D. vulgaris*,[70,71] despite the fact that earlier spectroscopic characterizations of the same Rbr isolated directly from the same organism by the same lab,[72] and also by a second independent lab,[66] clearly demonstrated the presence of antiferromagnetically coupled diiron sites and no magnetically isolated iron other than the $Fe(SCys)_4$ site. The Rbr-like protein, nigerythrin, 'as-isolated' from *D. vulgaris* also clearly contained a diiron site,[66] as did an Rbr from another sulfate-reducing bacteria.[65,73,74] The Zn,Fe site in the 'as-isolated' *D. vulgaris* Rbr could be an artifact of either the isolation or crystallization procedure.[70] More recently, the structure of an Rbr homologue, called sulerythrin, which lacks the $Fe(SCys)_4$ domain, was reported.[75] The sulerythrin structure was also reported to contain Zn,Fe sites. The electronic absorption spectrum of sulerythrin, however, clearly showed the intense features between 300 and 400 nm characteristic of an oxo-bridged diferric site,[76] suggesting that the crystallized protein may not reflect the metal occupancy of the as-isolated protein in solution. The crystal structure also

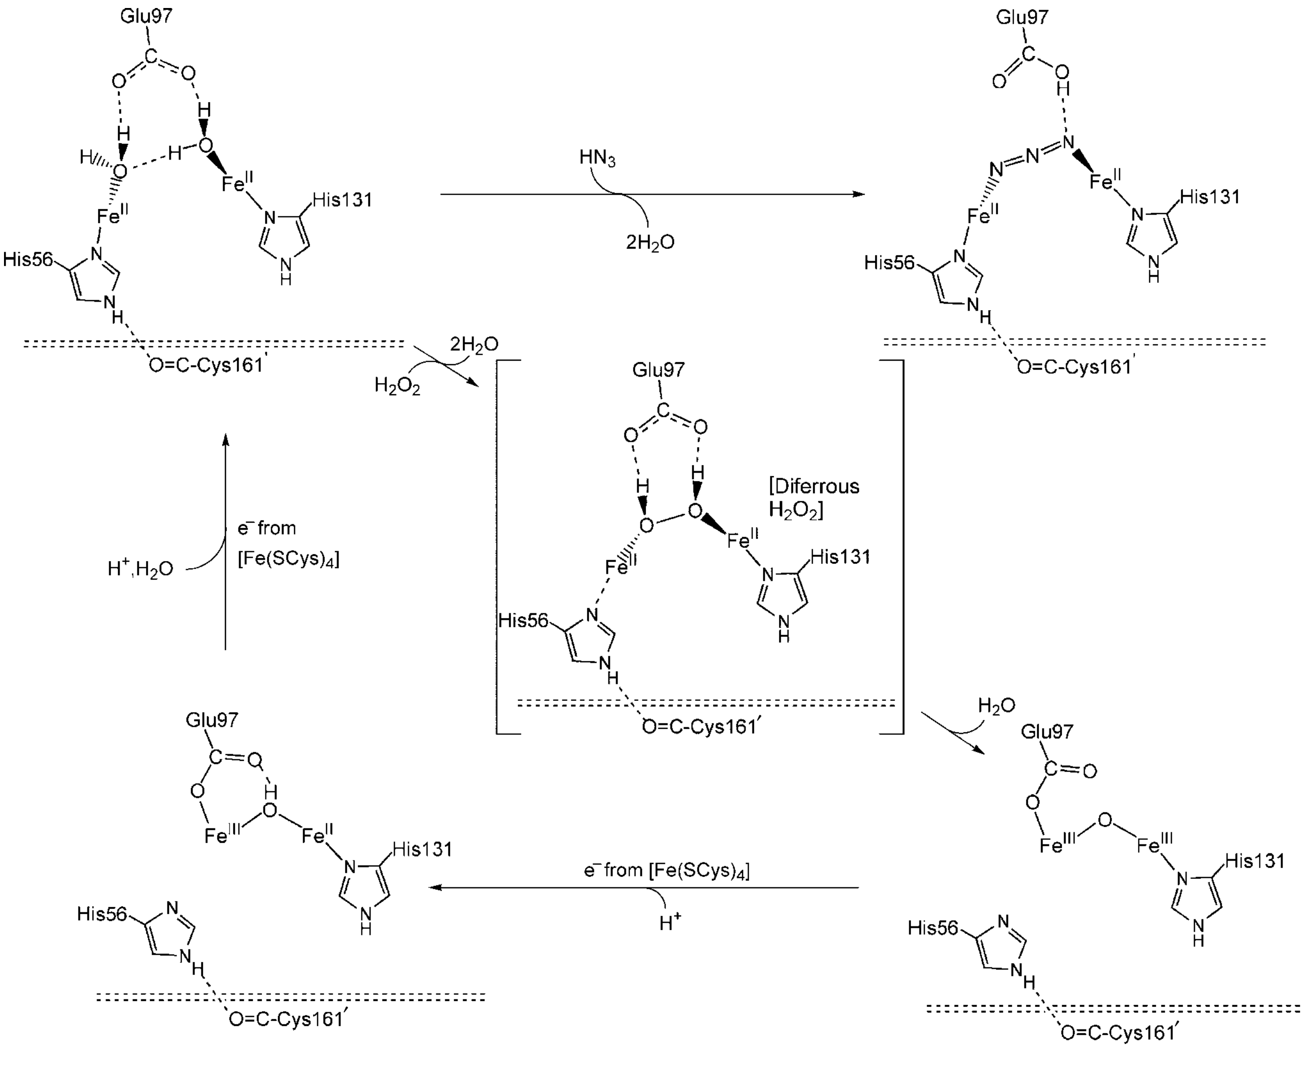

Figure 12 Proposed mechanism for hydrogen peroxide reduction catalyzed by *D. vulgaris* Rbr. (Reprinted with permission from Ref. 68. © 2003 American Chemical Society)

showed that sulerythrin was 'domain swapped' compared to that of *D. vulgaris* Rbr, such that the metal ligands to each of the two Zn,Fe sites were contributed by both subunits of the homodimer. The function of sulerythrin, which is found in an aerobic archaeon, is unknown.

5.9 Membrane Oxidases/Hydroxylases

Membrane oxidases/hydroxylases were first recognized as belonging to the nonheme diiron protein class via their amino acid sequence homologies to the soluble O_2-activating diiron enzymes discussed above.[77] On the basis of these sequence homologies and several site-directed mutagenesis studies, the diiron sites are likely to contain the same mixture of histidine and carboxylate ligands as do those of the O_2-activating diiron enzymes of the soluble MMO type. The sequence homologies and molecular modeling studies also indicate that the diiron sites in these enzymes are surrounded by four-helix protein bundles, once again reminiscent of the soluble O_2-activating diiron enzymes.[1,78] However, the membrane oxidases/hydroxylases contain additional protein domains, which are tightly associated with and possibly embedded within cell or organelle membranes, hence their designation as membrane oxidases/hydroxylases. While reports of homology modeled structures are available,[1,78] no X-ray crystal structure is yet available for any enzyme in this subclass.

Four functionally distinct enzymes in this subclass have so far been identified: alternative oxidase (AOX), plastid terminal oxidase (PTOX), Mg-protoporphyrin IX monomethyl ester hydroxylase (MME hydroxylase), and 5-demethoxyquinone hydroxylase (DMQ hydroxylase).[1] AOX, PTOX, and MME hydroxylases have been found in green plants, algae, fungi, and protists, and recently a bacterial AOX homologue has been reported.[79] AOX is a quinol oxidase, apparently functioning as a nonenergy conserving 'alternative' oxidase under conditions where the normal respiratory membrane oxidases are nonfunctional (*see **Cytochrome Oxidase***). PTOX is a plastoquinol oxidase, which is functional during chloroplast development. However, the exact physiological roles of AOX and PTOX are matters of some contention.[1,80,81] DMQ hydroxylase and its homologues have been found in organisms ranging from bacteria to humans, where it functions as a quinol hydroxylase required for ubiquinone biosynthesis. MME hydroxylase catalyzes one or more steps, including an alkyl carbon hydroxylation, in the formation of the exocyclic ring of chlorophyll.

The plant AOX was the first of this class to be recognized and is the most thoroughly studied to date. The most direct evidence for a diiron site in this subclass is a mixed-valent Fe^{II}, $Fe^{III} = 1/2$ EPR signal that was observed from a plant AOX.[82] This signal is reminiscent of that arising from the mixed-valent diiron sites in Hr and the O_2-activating enzymes discussed above. The relatively weak magnetic coupling between the irons in this mixed-valent site and lack of strong electronic absorption between 300 and 400 nm in the diferric form argue for a hydroxo rather than an oxo solvent bridge between the irons at these oxidation levels. Little or no mechanistic information is available for the enzymes in this subclass. Dioxygen is presumably a substrate in all cases.

5.10 Membrane Eight-His Desaturases/Monooxygenases

The membrane 'eight-His' enzymes constitute a structurally distinct subclass from the other O_2-activating enzymes: they have been recognized to contain a conserved eight-histidine amino acid sequence motif, $HX_{3-4}HX_{20-50}HX_{2-3}HHX_{100-200}HX_{2-3}HH$, that putatively binds a nonheme, non-sulfur diiron site.[2,44] Conserved residues that could conceivably supply carboxylate ligands have not been unequivocally identified in the eight-His enzymes,[83] which may, therefore, represent an exception to the 'diiron-carboxylate proteins'.[6] These eight-His motif enzymes are found in plants, animals, and bacteria where they perform a diverse range of functions that include not only fatty acyl desaturation, long-chain alkane omega hydroxylation, and xylene methyl monooxygenation but also decarbonylation, epoxidation, and acetylenation. Because they are all integral membrane proteins, these eight-His enzymes have proven difficult to isolate and characterize. Only one member of this subclass, a bacterial octane 1-monooxygenase called AlkB, has been proven by Mössbauer spectroscopy to contain a diiron site; the magnitude of the antiferromagnetic coupling between the irons in AlkB implies a bridging solvent ligand, at least at the diferric oxidation level.[84] Although site-directed mutagenesis studies have shown that all eight residues of the histidine motif are required for activity of at least one fatty acyl desaturase and for AlkB,[83] it is unclear whether all eight histidines actually supply iron ligands. Both molecular biological and molecular modeling evidence[44,83,85] indicate that the portions of the polypeptide chain that contain the eight conserved histidine residues and, therefore, the diiron site, protrude from the membrane surface towards the inside of the cell. A speculative model for the xylene monooxygenase (XylM) diiron

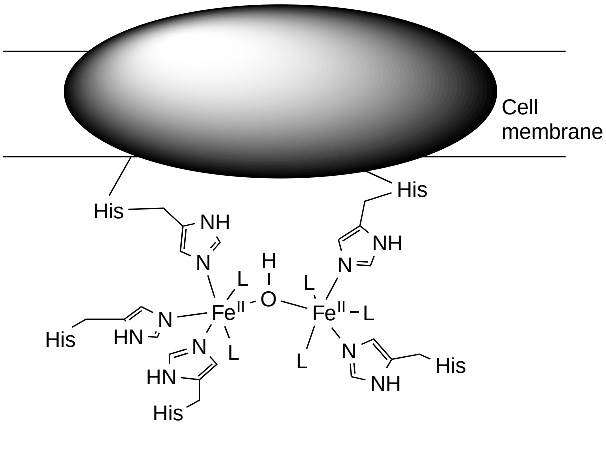

Figure 13 Speculative model for the diferrous site in XylM (Ref. 87, © 2003 Springer Verlag)

site is shown in Figure 13. XylM catalyzes the methyl group monooxygenation of toluene and xylene.[86] Experiments with alternative substrates have suggested a radical mechanism for XylM.[87] These membrane eight-His enzymes are among the most mysterious and intriguing of the nonheme, non-sulfur diiron class.

1 INTRODUCTION

In the 10 years since the first edition of this Encyclopedia was published,[1] there has been an explosion of information on the coordination chemistry of mononuclear nonheme iron centers in metalloenzymes. Almost all of these enzymes are involved in some aspect of dioxygen metabolism. While superoxide dismutase and superoxide reductase are involved in superoxide processing, the rest activate dioxygen to carry out substrate transformations. Electron sources for the latter reactions include NADH (delivered via a reductase), cofactors such as tetrahydrobiopterin and α-keto acids, and the substrates themselves. In this section, we focus on the present state of knowledge regarding their active site structures and the role of the metal center in the catalytic mechanisms. Absent from this section are the metalloproteins rubredoxin and transferrin. Rubredoxin is the simplest iron-sulfur protein, having an iron center tetrahedrally coordinated by four cysteine residues; it is discussed in (*see* ***Iron–Sulfur Proteins***) together with other proteins in its class. Transferrin, an iron transport protein, is discussed in (*see* ***Iron Proteins for Storage & Transport & their Synthetic Analogs***) together with ferritin, the iron storage protein. Transferrin has an iron center that is coordinated to two tyrosines, an aspartate, a histidine, and an exogenous bicarbonate.

2 IRON SUPEROXIDE DISMUTASE AND SUPEROXIDE REDUCTASE

Superoxide dismutases (SODs) catalyze the disproportionation of superoxide into O_2 and H_2O_2 and are proposed to defend the cell against the deleterious effects of exposure to dioxygen (*see* ***Dioxygen & Related Ligands***).[2] In general, SODs react with superoxide at nearly diffusion-controlled rate constants, $\sim 3 \times 10^8$ to $1 \times 10^9\ M^{-1}\ sec^{-1}$. SODs are available in four varieties, a CuZn form found primarily in eukaryotes (*see* ***Copper Proteins with Type 2 Sites***), manganese (*see* ***Manganese Proteins with Mono- & Dinuclear Sites***) and iron forms found in certain fungi, prokaryotes, mitochondria, and some blue-green algae, and most recently a nickel form originally found in several *Streptomyces* species (*see* ***Nickel Enzymes & Cofactors***). All four have been structurally characterized revealing rather distinct active sites. The diversity of metal active sites that nature has evolved to carry out this function is fascinating. The metal centers must all

have a redox potential that allows them in their oxidized states to accept an electron from superoxide forming O_2 and in their reduced states to donate an electron to superoxide forming H_2O_2. In practical terms, this requirement constrains the reduction (or redox) potential values to $+200\,mV \pm 100\,mV$ versus NHE. The iron enzyme is in a sense the prototype of mononuclear nonheme iron enzymes involved in oxygen metabolism as it was the first of this group to have a crystal structure solved.[3] The active site consists of four endogenous ligands arranged in a trigonal pyramid (Figure 1a), with an axial His perpendicular to a trigonal plane defined by two His and an Asp. The iron is 0.5 Å below this plane and displaced towards the axial His. A solvent molecule bound to the available coordination site trans to the axial histidine could be displaced by superoxide allowing an inner-sphere reaction. There is a conserved tyrosine (Tyr34) about 5 Å away from the iron center and bordering the open coordination site. It is proposed that the tyrosine may serve as an acid/base center in the catalytic mechanism. The redox potential of the metal center is $+260\,mV$ versus NHE,[4] a value that permits it to shuttle readily between Fe^{III} and Fe^{II} oxidation states to facilitate the disproportionation of superoxide under physiological conditions.

Interestingly, there is substantial structural homology between the Fe and Mn enzymes; the two metal coordination sites are nearly congruent.[5] However these two metal ions have distinct redox properties; Mn tends to have potentials half a volt higher than Fe in the same ligand environment. The best explanation to date derives from the efforts of A.-F. Miller and coworkers, who have proposed that the second sphere residues tune the redox potentials of the metal centers by controlling the ionization state of the bound water.[6] Thus the Fe and Mn potentials are brought into the same range by having a water ligand on the Fe and a hydroxide ion coordinated to the Mn. This simple yet elegant hypothesis has been supported by experimental evidence that shows the

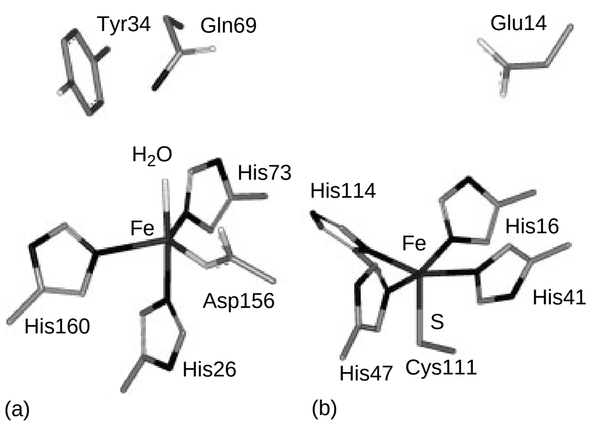

Figure 1 Active sites of (a) iron superoxide dismutase from *Pseudomonas ovalis* (1DTO.pdb) and (b) superoxide reductase from *Pyrococcus furiosus* (1DQK.pdb)

Mn potential to be too high in the Mn-substituted Fe enzyme, and the Fe potential to be too low in the Fe-substituted Mn enzyme.[6]

More recently, several iron proteins characterized to have superoxide reductase activity have been identified in several microaerophilic and anaerobic bacteria and archaea.[7–10] In these systems, transient exposure to dioxygen produces reactive (reduced) dioxygen species, one of which is superoxide. These enzymes are proposed to serve a protective function by lowering the overall steady-state concentration of superoxide in *vivo*, similar to the role of superoxide dismutases in aerotolerant organisms. However, these superoxide reductases (SORs) directly reduce superoxide to hydrogen peroxide, without producing dioxygen. Interestingly, X-ray crystal structures of SORs show a very different iron active site representative for this new class of enzymes (Figure 1b) consisting of a square pyramidal iron(II) center with four basal histidines and an apical cysteine.[11,12] The open coordination site (trans to the cysteine) allows diffusion-controlled ($\sim 1 \times 10^9\,M^{-1}\,sec^{-1}$) direct ligation of superoxide to the iron(II) center, producing a violet ($\lambda_{max} \sim 600\,nm$, $\varepsilon_{600} \sim 3500\,M^{-1}\,cm^{-1}$) intermediate proposed to be an Fe^{III}–OO(H) species.[13] A nearby glutamate residue (Glu14 in Figure 1b) then displaces this peroxo moiety, leaving a blue ($\lambda_{max} \sim 650\,nm$, $\varepsilon_{650} \sim 1900\,M^{-1}\,cm^{-1}$) pseudo-octahedral iron(III) center.[14] Recently an iron(III)-peroxo intermediate was trapped in the active site of a mutant SOR,[15,16] when the coordinating Glu was mutated to an Ala, and then reacted with H_2O_2. This transient iron(III)-peroxo species has been characterized using EPR, resonance Raman, and Mössbauer spectroscopy.

Similar to their SOD counterparts, the iron centers of SORs have reduction potentials typically ranging between + 200 mV to 300 mV versus NHE.[14,17] In SORs, however, little catalytic disproportionation of superoxide is measurable, even in Glu14-variant SORs. This implies that superoxide is unable to reduce the SOR active center, as it does with SODs, a result which remains quite perplexing.

3 LIPOXYGENASE

Lipoxygenases (LOs) are nonheme, mononuclear iron enzymes that catalyze the regio- and stereoselective conversion of polyunsaturated fatty acids with a *cis,cis*-1,4-diene functionality into products having a 1-hydroperoxy-*trans,cis*-2,4-diene functionality.[18,19] The mammalian LOs typically act on arachidonic acid and produce alkyl hydroperoxides that are converted into leukotrienes and lipoxins, which are involved as messengers in the inflammatory response. Plant enzymes act on linoleic acid, but the role of the product alkyl hydroperoxide is less well understood.

Owing to its relative availability, the soybean LO has been the focus of most efforts to characterize the iron active

site. As isolated, the enzyme is colorless and the iron is in the high-spin Fe^{II} state. This form appears to be inactive, as full enzyme activity is elicited only after an extended lag period. This lag is eliminated when the iron center is oxidized to the high-spin Fe^{III} state, which is yellow in color ($\lambda_{max} \sim 350$ nm, $\varepsilon_{350} \sim 2000\,M^{-1}\,cm^{-1}$) arising from a hydroxo-to-iron(III) charge-transfer transition.[20] The presence of this hydroxide has been unequivocally established by the observation of a short Fe–O distance (1.9 Å) from EXAFS analysis, which is highly consistent with an Fe^{III}–OH bond.[21] This Fe^{III} state has been further characterized as having an $S = 5/2$ EPR signal, which is axial ($g \sim 6$) for the soybean enzyme but rhombic ($g \sim 4.3$) in the rabbit enzyme.[20,22] Interestingly, the only known oxidant to afford active enzyme is the product hydroperoxide.[23] Presumably the inactive iron(II) enzyme is slowly activated by trace amounts of the product hydroperoxide derived from autoxidation of linoleic acid.

The iron active site for soybean LO as determined by several crystal structures of the Fe^{II} form[24–28] has a distorted octahedral geometry. The six coordinating ligands are derived from three histidines, the carbonyl oxygen of an asparagine side chain, a carboxylate of the C-terminal isoleucine, and a solvent molecule (Figure 2a). The X-ray crystal structure of rabbit lipoxygenase has a slightly modified iron center, where the asparagine residue is replaced by a fourth more strongly binding histidine residue.[29]

When the Fe^{III} enzyme is treated with an excess of the product hydroperoxide or a combination of linoleic acid and O_2, a transient purple intermediate having a chromophore at 585 nm ($\varepsilon_{585} \sim 1300\,M^{-1}\,cm^{-1}$) is formed.[18] The structure of this species has been determined by X-ray crystallography

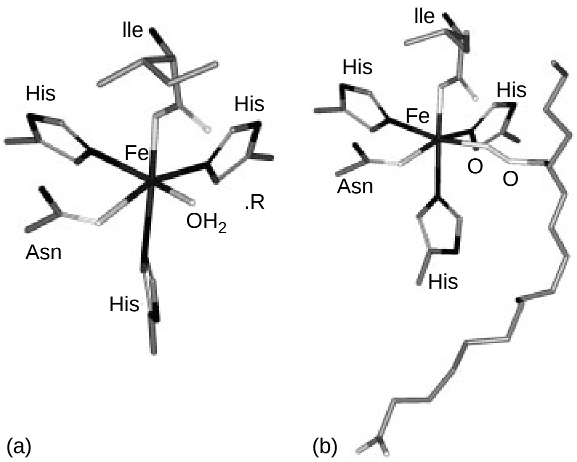

Figure 2 Iron centers of (a) as-isolated soybean Lipoxygenase (1F8N.pdb) and (b) the Fe^{III}–OOR intermediate (1IK3.pdb)

on soybean lipoxygenase-3. This structure shows the known product hydroperoxide bound to the iron center, in place of the solvent molecule (Figure 2b).[30]

The role of the iron(III) center in the catalytic reaction has been the subject of some speculation. A plausible mechanism for lipoxygenase is shown in Figure 3. The Fe^{III}–OH unit is proposed to abstract a hydrogen atom from the fatty acid, producing an organic radical. Kinetic studies of this step have revealed a large kinetic isotope effect of greater than 50, indicating the C–H bond cleavage step is rate determining.[31,32] Dioxygen enters and reacts with the organic radical and then binds the metal center, affording the Fe^{III}-(product

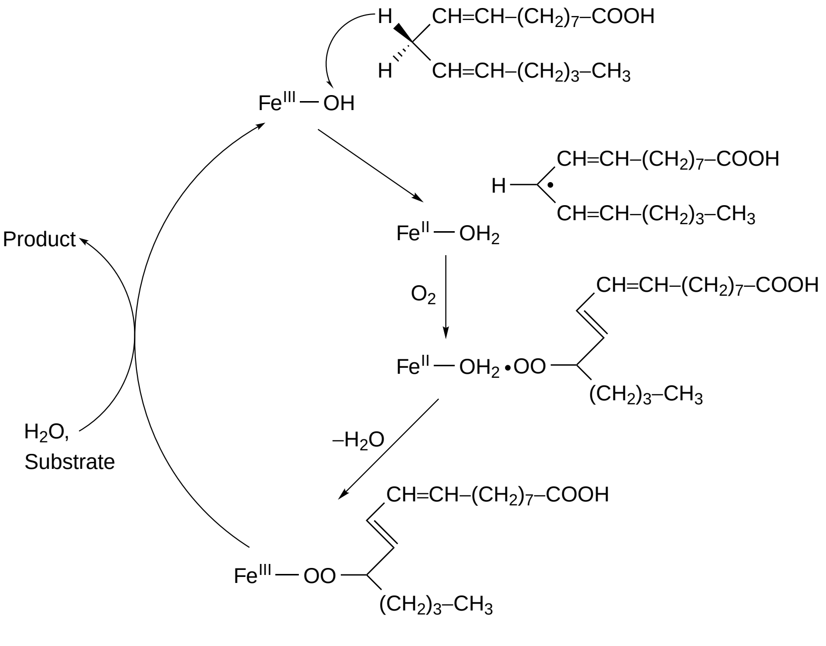

Figure 3 Proposed mechanism for lipoxygenase

alkylperoxo) species. The proposed role of the Fe^{III}–OH center is analogous to that of Fe^{IV}=O centers in other iron enzymes (see below). The relatively high redox potential of the metal center (≥ +600 mV vs. NHE)[33] and the rather weak C–H bond to be cleaved allows this chemistry to proceed without requiring the iron(IV) state. A high potential Fe^{III}–OCH_3 complex described by Stack and coworkers mimics the C–H cleavage step in LO chemistry and has provided further insights into the energetic considerations of this key step in the mechanism.[34]

4 CATECHOL DIOXYGENASES

Nonheme iron enzymes of the catechol dioxygenase family catalyze the last step in Nature's strategy for converting aromatic molecules into aliphatic products.[35] These bacterial enzymes transform dihydroxylated aromatic molecules into acyclic aliphatic products. The catechol substrates can be oxidatively cleaved in two distinct modes: intradiol cleavage breaks the C–C bond between the two hydroxyl functions, while extradiol cleavage breaks the C–C bond adjacent to the enediol function. In the process, the elements of dioxygen are incorporated into the product, therefore the name dioxygenases (*see* ***Iron: Heme Proteins, Mono- & Dioxygenases***).

4.1 Intradiol-cleaving Enzymes

The intradiol-cleaving enzymes represented by catechol 1,2-dioxygenase and protocatechuate 3,4-dioxygenase (PCD) catalyze the reactions shown in Figure 4. Both enzymes have iron(III) active sites and are spectroscopically well characterized.[35,36] The enzymes exhibit a distinct burgundy red color (λ_{max} ∼ 460 nm, ε_{460} ∼ 3500 M^{-1} cm^{-1}) that is associated with ligand-to-metal charge-transfer transitions from two distinct tyrosine ligands as deduced from resonance Raman data. The participation of solvent water is evidenced by the line broadening found in the EPR spectrum of the native enzyme from *Brevibacterium fuscum* dissolved in $H_2{}^{17}O$.[37] Analysis of the first-shell EXAFS data required the solvent water to be bound as hydroxide,[38] thereby providing a charge-neutral active site.

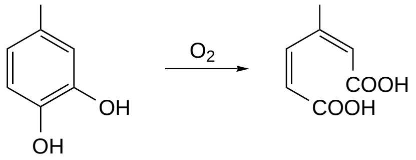

Figure 4 Reaction catalyzed by catechol 1,2-dioxygenase (R = H) and protochatechuate 3,4-dioxygenase (R = COOH)

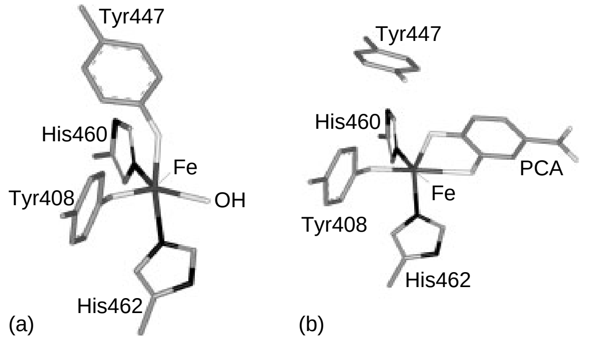

Figure 5 Active sites of (a) *P. putida* 3,4-PCD (2PCA.pdb) and (b) the 3,4-PCD-substrate complex (2PCD.pdb)

In agreement with spectroscopic studies, the crystal structure of as-isolated PCD from *Pseudomonas putida* (formally known as *Pseudomonas aeruginosa*) displays a trigonal bipyramidal geometry about the iron center with four endogenous protein ligands, namely, His460, His462, Tyr408, and Tyr447, as shown in Figure 5(a), and a solvent-derived ligand in the fifth position.[39] Structures of several enzyme-substrate complexes,[40,41] and many enzyme complexes with inhibitors[42] are also available, providing many details on how the PCD active site interacts with exogenous aromatic ligands. In particular, the structure of the PCD-substrate complex shows that the axial Tyr447 residue and the hydroxide ligand are displaced upon substrate binding.[40,41] The catechol donates both enediol protons to the displaced ligands and chelates to the metal center as a dianionic ligand (Figure 5b) trans to His460 and Tyr408. The Fe–$O_{catecholate}$ bonds differ by 0.2 Å in length, presumably due to the distinct trans effects exerted by the histidines and the tyrosinates.

When the structural data of *P. putida* PCD are combined with the wealth of spectroscopic data, a clear picture of the enzyme active center during catalysis emerges,[35,43] validating the substrate activation mechanism proposed ∼ 30 years ago (Figure 6).[44] This novel mechanism has the metal center retaining its iron(III) character throughout the catalytic cycle. The lack of spectroscopic evidence for the participation of the iron(II) oxidation state[45,46] strongly suggested that O_2 does not first bind to the metal center but instead attacks a different site. This notion is supported by the lack of reactivity of the enzyme-substrate complex with the O_2 surrogate NO, unless the metal center was first reduced by added reductant.[47,48]

The first step in the proposed mechanism (Figure 6) is the binding of the catecholate substrate to the iron(III) center, displacing the hydroxide and the axial Tyr447 residue to generate a square pyramidal [$Fe(His)_2$(Tyr)(catecholate)] complex. The covalency of the iron(III)-catecholate interaction introduces semiquinonate radical character to bound substrate and makes it susceptible to O_2 attack, generating a transient alkylperoxoiron(III) intermediate. This alkylperoxo intermediate then undergoes a Criegee-type rearrangement to form muconic anhydride and a Fe^{III}–OH species. The

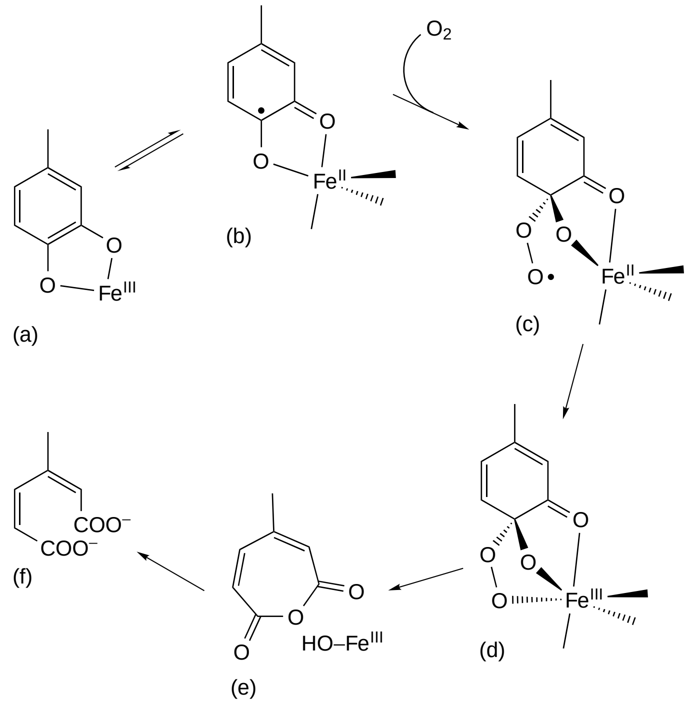

Figure 6 Proposed substrate activation mechanism for intradiol-cleaving catechol dioxygenases. Substrate activation is proposed to occur via an iron(II)-semiquinone prior to O_2 binding

hydroxoiron(III) species then acts as the nucleophile converting the anhydride into the ring-opened product.

Model studies support the mechanism proposed in Figure 6. A large number of [Fe^{III}(L)(catecholate)] complexes (L = tetradentate ligands) have been synthesized by various groups and found to react with O_2 and afford intradiol cleavage products.[49] In a systematic study,[50–53] Que and coworkers found that, as the iron became more Lewis acidic, the yield of intradiol cleavage product increased to approach quantitative conversion and the rate of reaction accelerated significantly. These results are rationalized by the argument that the increased Lewis acidity of the iron center enhances the covalency of the iron-catecholate bond and increases the semiquinone character of the bound catecholate, which renders it more reactive toward O_2.

4.2 Extradiol-cleaving Dioxygenases

Extradiol cleavage of dihydroxybenzenes represents the more common pathway for biodegradation of aromatic molecules in soil.[35] While the intradiol-cleaving enzymes utilize an iron(III) active site, the extradiol-cleaving enzymes typically use iron(II) (or manganese(II) in a few examples). A representative reaction of this subgroup is shown in Figure 7(a). This class of dioxygenases has been shown to cleave a variety of substrates including catechol (2,3), protocatechuate (2,3 or 4,5), and 3,4-dihydroxyphenylacetate (2,3). Also included in this class are the enzymes that cleave gentisate and homogentisate (Figure 7b). Although these substrates are not catechols but substituted benzene-1,4-diols, these enzymes also require Fe^{II} for activity and have similar properties as the catechol-cleaving enzymes.

The extradiol-cleaving enzymes are more challenging to study than their intradiol-cleaving counterparts because of the lability of the Fe^{II} centers and the difficulty of probing such sites by spectroscopy. Sequence comparisons classify the enzymes in this category into three subclasses,[54] but crystallographic data for representative proteins of each subclass show a common active site with the metal center bound to two His residues and an Asp or a Glu residue, which

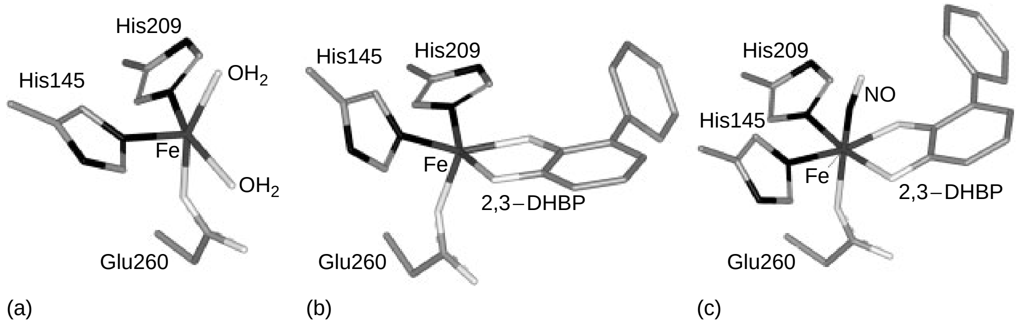

Figure 8 Active sites of BphC in (a) the as-isolated form (1KW3.pdb), (b) the enzyme-substrate complex (1KW6.pdb), and (c) the ternary enzyme-substrate-NO adduct (1 KW8.pdb)

together occupy one face of an octahedron (Figure 8a).[55–59] This metal-binding arrangement has been termed the 2-His-1-carboxylate facial triad[60,61] and is emerging as a recurring motif for dioxygen activating nonheme iron(II) enzymes.

Steady-state kinetic studies have revealed that extradiol-cleaving enzymes utilize an ordered mechanism with substrate binding prior to O_2 activation.[35] The coordination of the substrate appears to serve as a trigger to significantly increase the affinity of the metal center for O_2, as inferred from NO binding studies.[62] Crystallographic studies on 2,3-dihydroxybiphenyl 1,2-dioxygenase (BphC),[55,57] 3,4-dihydroxyphenylacetate 2,3-dioxygenase,[59] and protocatechuate 4,5-dioxygenase[56,58] demonstrate that substrate binding results in the displacement of the water ligands found in the active sites of the as-isolated enzymes to form a square pyramidal metal center poised to bind O_2. In the BphC structure, the site trans to Glu260 is vacant (Figure 8b) and has been shown to bind the O_2 surrogate NO (Figure 8c).

EXAFS studies[63] and the aforementioned high-resolution crystallography[55–59] indicate that the catechol substrate binds in an asymmetric fashion to the iron(II) center with Fe–$O_{catecholate}$ bond lengths that differ by 0.2–0.4 Å. These structural parameters are in excellent agreement with those reported for synthetic iron(II)-monoanionic catecholate complexes,[64,65] and, on the basis of this comparison, it was proposed that the catechol binds to the iron(II) center as a monoanion. This notion was supported by subsequent UV-resonance Raman[66] and UV-vis studies.[67–69] The monoanionic nature of the catechol substrate in extradiol dioxygenases is in sharp contrast with the dianionic catecholate character commonly found in iron(III) complexes.[35,43] This difference can be rationalized by the differing Lewis acidities of the metal centers in their divalent and trivalent oxidation states.

The structural and spectroscopic data accumulated so far have led to the proposed mechanism in Figure 9.[49] The first step of the reaction involves the displacement of water

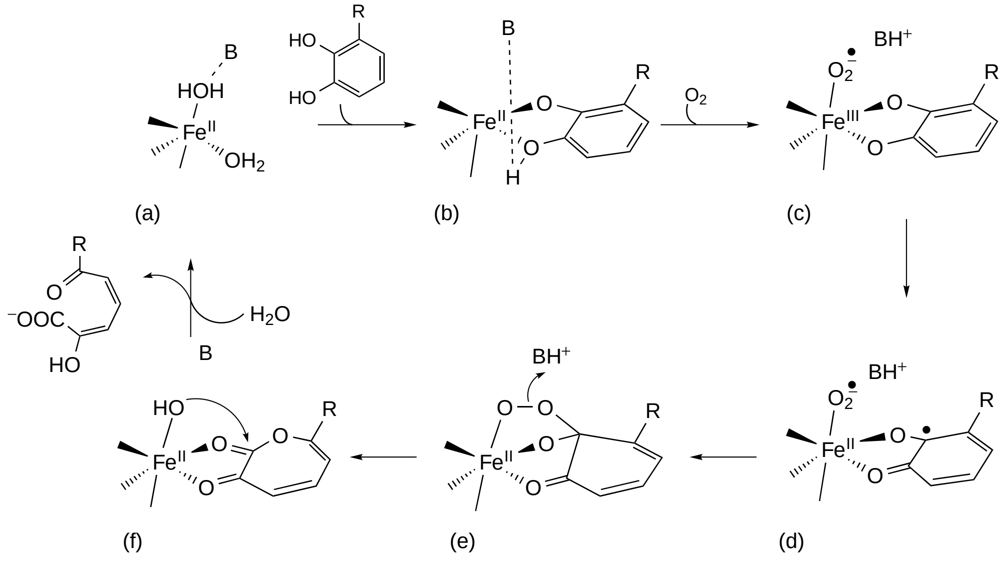

Figure 9 Proposed mechanism for the extradiol-cleaving catechol dioxygenases

molecules from the enzyme resting state (Figure 9a) by substrate to form typically a five-coordinate iron(II) species with a chelated monoanionic catecholate (Figure 9b). This change in ligation would be expected to lower the redox potential of the metal center, readying it to react with O_2. The ternary enzyme·substrate·O_2 complex is formed as O_2 binds to the iron(II) center, resulting in a one-electron transfer from metal to O_2 forming an iron(III)-superoxide complex, analogous to the formation of the Fe–NO adduct, as shown in Figure 9(c). This arrangement poises the two substrate molecules into the proper orientation for reaction.

Another one-electron transfer from substrate to metal gives rise to a semiquinonatoiron(II)-superoxide species (Figure 9d). Evidence for the development of a radical species on the catecholate substrate in the mechanism is provided by experiments on the enzyme 3-(2′,3′-dihydroxyphenyl)propionate 1′,2′-dioxygenase.[70] Bugg and co-workers used a substrate analogue containing a cyclopropyl side chain as a radical probe and found that the substituents on the cyclopropyl group underwent substantial epimerization in the course of enzyme-catalyzed extradiol cleavage. The formation of a semiquinonate radical (Figure 9d) during the catalytic cycle would promote reversible cyclopropyl ring opening that rationalizes the observed epimerization.

The next step of the mechanism is the nucleophilic attack of the aromatic ring by the incipient superoxide generating an alkylperoxo intermediate (Figure 9e) similar to that proposed for the intradiol-cleaving enzymes (Figure 6d). This species undergoes a Criegee rearrangement to generate a seven-membered α-oxolactone ring (Figure 9f) that is hydrolyzed to afford product. The structural similarity between intermediates 9E and 6D raises the question of how the regiospecificity of ring cleavage can be so exquisitely controlled. Bugg has proposed that the regiospecificity of the cleavage may derive from the different orientations of the peroxo group.[71] Rearrangement of the alkylperoxo intermediate (Figure 9e) by acyl migration would afford the intradiol product, while alkenyl migration would give rise to the extradiol product. There are precedents for both alkenyl and acyl migration in organic hydroperoxo species, and the choice of mechanism may be dictated by stereoelectronic factors.[72] An axial orientation for the peroxo group favors alkenyl migration, while an equatorial orientation favors acyl migration. Bugg and coworkers tested this model by preparing a series of substrate analogues where the putative hydroperoxo function was replaced by a CH_2OH, and the 1-hydroxocyclohexadien-2-one moiety was replaced by a 1-hydroxocyclohexan-2-one ring.[73] Only substrate analogues with the proximal hydroxymethyl group placed in an axial orientation relative to the cyclohexanone ring exhibited competitive inhibition of the MhpB enzyme. A recent DFT study provides yet another view of what determines the regiospecifity of cleavage.[74]

To date the few structurally characterized biomimetic extradiol-cleaving systems are all five-coordinate iron(III) complexes.[49] The facts that oxidative cleavage is regiospecific in many cases and quantitative in some strongly suggest that a divalent metal oxidation is not absolutely required for this chemistry. There are also examples of iron(II) complexes that catalyze extradiol cleavage, but these systems are less well characterized.[75–77] The observation that iron(II) centers may be better effectors of extradiol cleavage should serve as a compelling rationale for future work aimed at obtaining structurally characterized functional models with iron(II) centers.

5 α-KETO ACID DEPENDENT ENZYMES

α-Keto acid-dependent enzymes, which are found in microorganisms, plants, and animals, play vital roles in environmental, pharmaceutical, and biological pathways. Enzymes that require an α-keto acid, typically 2-oxoglutarate (2-OG), as a co-substrate constitute the largest and most diverse family of mononuclear nonheme iron enzymes, catalyzing many pivotal metabolic transformations that require dioxygen activation.[78–80] The function of the α-keto acid is to provide the two electrons required to reduce O_2 and generate an oxidant capable of functionalizing a C–H bond on the substrate. For example, the bacterial enzyme TfdA hydroxylates the broadleaf herbicide 2,4-dichlorophenoxyacetate in the first step in its biodegradation;[81,82] AlkB demethylates 1-methyladenine and 3-methylcytosine residues in the repair of single-stranded DNA and RNA;[83–85] clavaminic acid synthase catalyzes three distinct steps in the synthesis of the β-lactamase inhibitor clavulanic acid;[86] deacetoxycephalosporin C synthase (DAOCS) catalyzes the ring expansion of the thiazolidine ring of the penicillin *N* nucleus to afford deacetoxycephalosporin C;[87,88] and carbapenam synthase (CarC) catalyzes the epimerization/desaturation of carbapenam in the formation of carbapenam-related antibiotics.[89] These enzymes also appear in microbes that can utilize alternative nutrient sources such as sulfonates and hypophosphites. For example, taurine dioxygenase (TauD) enables *E. coli* to use the aliphatic sulfonate taurine as a sulfur source during periods of sulfate starvation,[90] and hypophosphite dioxygenase (HtxA) allows microbes to oxidize phosphite and hypophosphite.[91]

α-Keto acid-dependent oxygenases are also found in higher organisms and enzyme mutations are linked to a variety of diseases. Prolyl 3-hydroxylase, prolyl 4-hydroxylase and lysyl hydroxylase are responsible for the post-translational modification of procollagen, which is crucial to the formation of fibrous tissues.[80] Recent reports show prolyl and asparaginyl hydroxylases are linked to oxygen sensing in cells.[92–94] Under conditions of low oxygen tension (hypoxia), hypoxia inducible factor (HIF) promotes increased expression of: erythropoietin, a precursor to red blood cells; vascular endothelial growth factor, a vasodilator and key component in the growth of new blood vessels; certain glycolytic enzymes, leading to the

liberation of energy rich compounds; and tyrosine hydroxylase (vide infra), which catalyzes the rate determining step in the synthesis of adrenaline. At normal oxygen concentrations, proline hydroxylation leads to ubiquitination and degradation of HIF, while asparagine hydroxylation inhibits interaction of HIF with transcriptional co-activators, thereby exerting a second level of control over gene expression. Disruption of the signaling cascade in which prolyl and asparaginyl hydroxylases participate can affect the onset and development of cancerous tumors and ischemia.[95,96] This, coupled with observation of an α-keto acid-dependent enzyme in a virus that initiates DNA replication,[97] has led to a proliferation of interest in the relationship of structure to function in α-keto acid-dependent dioxygenases not only on therapeutic grounds but also for etiological reasons.
